11 **Abstract**

12 To study the feasibility of a fluorescence lidar for aerosol characterization, the fluorescence
13 channel is added to LILAS - multiwavelength Mie-Raman lidar of Lille University, France. A
14 part of fluorescence spectrum is selected by the interference filter of 44 nm bandwidth centered
15 at 466 nm. Such an approach has demonstrated high sensitivity, allowing to detect fluorescence
16 signal from weak aerosol layers (backscattering coefficient at 1064 nm is below 0.02 Mm⁻¹sr⁻¹)
17 up to a height of 5000 m. Simultaneous detection of nitrogen Raman and fluorescence
18 backscatters allows to quantify the fluorescence backscattering coefficient. Observations were
19 performed during November 2019 – February 2020 period. The fluorescence capacity (ratio of
20 fluorescence to elastic backscattering coefficients) varied in a wide range, being the highest for
21 the smoke and the lowest for the dust particles. The fluorescence capacity depends as well
22 strongly on the relative humidity, because the water uptake at the condition of high RH increases
23 the elastic backscattering, without significant modification of the fluorescence. Thus,
24 simultaneous measurements of Mie-Raman and fluorescence lidars open opportunity for the
25 study of the particle hygroscopic growth. The fluorescence technique can be used also for
26 monitoring the aerosol inside the cloud layers. The results presented demonstrate, that aerosol
27 and cloud particles can be mixed both externally and internally. When the cloud is formed at the
28 top or inside the aerosol layer (such scenario can be probably considered as internal mixing) we
29 observed significant (up to factor 5) increase of fluorescence backscattering. Among possible
30 mechanisms of such enhancement we can assume modification of the scattering phase function
31 of the particles embedded in the water microspheres and the lens effect due to the water shell
32 presence.

33

34 **1. Introduction**

35 The aerosol – cloud interaction is one of the key factors influencing the Earth radiation
36 balance and, for its realistic modeling, knowledge of aerosol properties both outside and within
37 the cloud layer are needed. The multiwavelength Mie-Raman and HSRL lidars, measuring
38 aerosol backscattering and extinction coefficients at multiple wavelengths, are widely used for
39 remote characterization of aerosol properties (Burton et al., 2012). However, although useful for
40 studying aerosol, the amount of information contained in these measurements remains limited
41 (Burton et al., 2016; Alexandrov and Mishchenko, 2017). In addition, such lidars are not able to
42 detect and characterize aerosol inside a cloud layer, because aerosol scattering is masked by the
43 strong cloud particles scattering. To improve the lidar capability for aerosol characterization,
44 additional channels, measuring the laser induced fluorescence, can be used. Moreover, the
45 fluorescence provides unique opportunity to detect (and characterize) aerosol particles within
46 cloud layer, at least near the cloud base, thus allowing to investigate the aerosol – cloud
47 coexistence.

48 Fluorescence spectroscopy is a highly sensitive technique, widely used for the in-situ
49 monitoring of atmospheric organic particles (Pan et al., 2007, 2015; Miyakawa et al., 2015;
50 Huffman et al., 2019). The synergy of fluorimetry and lidar technology provides an opportunity
51 to perform such monitoring remotely (Immler et al., 2005; Rao et al., 2018; Saito et al., 2018).
52 Numerous types of atmospheric aerosols, such as biological particles, biomass burning and even
53 dust particles are fluorescent, being excited by UV radiation. When the excitation wavelength is
54 355 nm, the main part of emission spectra is usually contained within the 400–650 nm range
55 (Pan et al., 2015). The fluorescence spectrum varies with the aerosol types/composition, making
56 therefore possible their identification.

57 The recent interest in fluorescence lidars was stimulated also by the progress in the
58 development of the multianode photomultipliers allowing, in combination with spectrometer,
59 simultaneous detection of lidar signal in 32 spectral bins (Sugimoto et al., 2012; Reichardt et al.,
60 2014, 2017; Saito et al., 2018). Such multichannel detection has the obvious advantage to
61 analyze the whole spectrum, allowing the aerosol identification. However, sensitivity of such
62 lidar spectrometers is low when compared to the standard technique based on selection of
63 fluorescence spectrum intervals with interference filters (Immler et al, 2005; Rao et al., 2018; Li
64 et al., 2019). Such an approach, in addition to being more sensitive, allows more affordable
65 modification of a multiwavelength Mie-Raman lidar by adding one or more fluorescence
66 channels.

67 To obtain the highest sensitivity, it is mandatory to acquire the fluorescence in a wide
68 spectral range which, however, makes the data analysis more complicated, because variation of
69 aerosol and molecular transmission within the detection spectral range has to be accounted for.

70 In addition, in Mie-Raman multi-wavelength lidars one should avoid the spectral intervals
71 affected by elastic scattering and corresponding strong Raman lines. In this work, we present the
72 results of a feasibility experiment and evaluate the sensitivity of a single-channel fluorescence
73 lidar to different aerosol types. We focus in this study also on the possibility to monitor the
74 aerosol fluorescence within a cloud layer. However, to obtain quantitative measurements of
75 aerosol content within a cloud layer, several factors should be considered.

76 First of all, external/internal mixtures of aerosol particles with water droplet should be
77 distinguished. In case of external mixture, the fluorescence signal can be used directly for the
78 estimation of the particle concentration, if the particle type and corresponding fluorescence cross
79 section are known. For internal mixture (aerosol particle is inside the water droplet) the
80 fluorescence backscattering can be enhanced due to modification of the scattering phase function
81 of the particles embedded in the water microspheres (Kerker and Druger, 1979; Veselovskii et
82 al., 2002a). For insoluble particle, the presence of the water shell can lead also to an additional
83 increase of the fluorescence, due to the water droplet lens effect. Similar effect is well known for
84 the soot particles covered by non-absorbing shell (Schnaiter, 2005).

85 In our paper we present the results of fluorescence measurements performed at
86 *Laboratoire d'Optique Atmosphérique* (LOA) during November 2019 – February 2020 period.
87 During that period, the aerosol load was very low, so we were not able to determine the particle
88 properties from multiwavelength observations. The objective was then to estimate the efficiency
89 /added value of the fluorescence channel. We therefore mainly focus on analysis of efficiency of
90 fluorescence lidar monitoring of different types of aerosol and on detection of aerosol particles
91 inside low level cloud layer.

92

93 **2. Experimental setup and data analysis**

94 The measurements were performed using the LILAS - multiwavelength Mie-Raman
95 lidar, based on a tripled Nd:YAG laser with a 20 Hz repetition rate and pulse energy of 70 mJ at
96 355 nm. The backscattered light is collected by a 40 cm aperture Newtonian telescope. The
97 system is designed for simultaneous detection of elastic and Raman backscatters, allowing the so
98 called $3\beta+2\alpha+3\delta$ data configuration, including three particle backscattering (β), two extinction
99 (α) coefficients along with three depolarization ratios (δ). Description of the system can be found
100 in recent publication of Hu et al., 2019. The aerosol extinction and backscattering coefficients at
101 355 and 532 nm were calculated from Mie-Raman observations (Ansmann et al., 1992) while
102 β_{1064} was derived by the Klett method (Klett, 1985).

103 For the experiment described, the system was modified: water vapor 408 nm Raman filter
104 was replaced by a fluorescence one. Corresponding optical scheme together with transmission

105 curve of the interference filter in the fluorescence channel are shown in Fig.1. The nitrogen
106 Raman and fluorescence optical signals are separated by a dichroic mirror: more than 98% of
107 387 nm radiation is reflected and more than 95% of fluorescence signal is transmitted. For both
108 nitrogen Raman and fluorescence channels, the R9880U-01 PMTs were used. A part of the
109 wideband fluorescence signal was selected by an Alluxa interference filter centered at 466 nm
110 with 44 nm bandwidth. The filter transmission, at maximum, exceeds 98%. The operational band
111 was chosen outside of the overtones of O₂ and N₂ vibrational Raman lines. In addition, the
112 transmission of the selected fluorescence filter band matches the maxima of fluorescence of
113 many organic molecules (Saito et al., 2018; Reichardt et al., 2017). Filter provides OD6
114 suppression outside the transmission band. To increase the suppression, two identical
115 interference filters were used in tandem. For additional rejection of elastic scattering at 355 nm
116 and 532 nm the two-band notch filter was used. With such design, we estimate that the total
117 suppression of elastic scattering in the fluorescence channel is above OD14. In this paper,
118 observations were carried out during night-time only.

119 In an elastic channel, the backscattered radiative power P_L , at distance z is described by
120 the lidar equation

$$121 \quad P_L = O(z) \frac{1}{z^2} C_L (\beta_L^a + \beta_L^m) \exp \left\{ -2 \int_0^z (\alpha_L^a + \alpha_L^m) dz' \right\} = O(z) \frac{1}{z^2} C_L (\beta_L^a + \beta_L^m) T_L^2 \quad (1)$$

122 Here $O(z)$ is the geometrical overlap factor, which is assumed to be the same for elastic, Raman
123 and fluorescence channels. C_L is the range independent constant, including efficiency of
124 detection channel. T_L is one-way transmission, describing light losses on the way from the lidar
125 to distance z at laser wavelength λ_L . Backscattering and extinction coefficients contain aerosol
126 and molecular contributions: $\beta_L^a + \beta_L^m$ and $\alpha_L^a + \alpha_L^m$, where the superscripts “a” and “m” indicate
127 aerosol and molecular scattering, respectively.

128 In a Raman channel, the backscatter radiative power, P_R , can be rewritten as:

$$129 \quad P_R = O(z) \frac{1}{z^2} C_R \beta_R \exp \left\{ - \int_0^z (\alpha_L^a + \alpha_R^a + \alpha_L^m + \alpha_R^m) dz' \right\} = O(z) \frac{1}{z^2} C_R \beta_R T_L T_R \quad (2)$$

130 Here T_R is the atmospheric transmission at Raman wavelength λ_R . Raman backscattering
131 coefficient is:

$$132 \quad \beta_R = N_R \sigma_R, \quad (3)$$

133 where N_R is the number of Raman scatters (per unit of volume) and σ_R is the Raman differential
134 scattering cross section in the backward direction. To account for spectral dependence of aerosol
135 extinction, the Angstrom exponent γ is used:

$$136 \quad \frac{\alpha_L^a}{\alpha_R^a} = \left(\frac{\lambda_R}{\lambda_L} \right)^\gamma \quad (4)$$

137 The aerosol backscattering and extinction coefficients can be computed from Mie – Raman lidar
 138 observations using equations (1-4), as shown by Ansmann et al. (1992).

139 In the case of the fluorescence, the emitted wavelengths are spread over wide spectral
 140 range, so the spectral dependence of aerosol and molecular extinction coefficients, inside the
 141 fluorescence band, should be considered. Moreover, the spectral differential fluorescence cross
 142 section $\frac{d\sigma_F}{d\lambda}(\lambda, r)$ depends on particle size (Hill, et al., 2015), so the particle number size
 143 distribution $\frac{dN(r)}{dr}$, which is the number of particles with radii between r and $r+dr$ per unit of
 144 volume, has to be considered. The radiative power in the fluorescence channel within the
 145 spectral interval $[\lambda_{\min}, \lambda_{\max}]$ is:

$$146 \quad P_F = O(z) \frac{1}{z^2} T_L \int_{\lambda_{\min}}^{\lambda_{\max}} \int_{r_{\min}}^{r_{\max}} C_F(\lambda) \times \frac{dN(r)}{dr} \times \frac{d\sigma_F}{d\lambda}(\lambda, r) \times \exp \left\{ - \int_0^z [\alpha^a(\lambda, z') + \alpha^m(\lambda, z')] dz' \right\} dr d\lambda \quad (5)$$

147 The spectral dependence of $C_F(\lambda)$ is determined mainly by the transmission of the interference
 148 filter in the fluorescence channel. If the filter spectral width $\lambda_{\max} - \lambda_{\min}$ is not very high, the
 149 procedure of data analysis can be simplified. The atmospheric transmission for fluorescence
 150 signal

$$151 \quad T_F(\lambda) = \exp \left\{ - \int_0^z [\alpha^a(\lambda, z') + \alpha^m(\lambda, z')] dz' \right\} \quad (6)$$

152 can be taken at wavelength λ_F , corresponding to the center of the filter transmission band
 153 $T_F(\lambda) = T_F(\lambda_F) \equiv T_F$. The filter transmission used (Fig.1) is close to rectangular and sensitivity
 154 of the PMT used doesn't vary significantly within $[\lambda_{\min}, \lambda_{\max}]$ interval, which means the
 155 calibration constant C_F can be considered as spectrally independent. Expression (5) can be
 156 rewritten, by introducing the fluorescence backscattering coefficient β_F :

$$157 \quad \int_{\lambda_{\min}}^{\lambda_{\max}} \int_{r_{\min}}^{r_{\max}} \frac{dN(r)}{dr} \times \frac{d\sigma_F}{d\lambda}(\lambda, r) dr d\lambda = \int_{r_{\min}}^{r_{\max}} \frac{dN(r)}{dr} \times \sigma_F(r) dr = \beta_F \quad (7)$$

158 Here $\sigma_F(r) = \int_{\lambda_{\min}}^{\lambda_{\max}} \frac{d\sigma_F}{d\lambda}(\lambda, r) d\lambda$ is the effective fluorescence differential cross section, integrated
 159 over spectral interval $[\lambda_{\min}, \lambda_{\max}]$. The use of β_F allows to rewrite equation (5) for the power of
 160 the fluorescence backscattering similarly to the Raman one.

161
$$P_F = O(z) \frac{1}{z^2} C_F \beta_F T_F T_L \quad (8)$$

162 The fluorescence backscattering coefficient, β_F , can be obtained from the ratio of
163 equations (8) and (2) for fluorescence and Raman backscatters:

164
$$\beta_F = \frac{C_R}{C_F} \frac{P_F}{P_R} N_R \sigma_R \frac{T_R}{T_F} \quad (9)$$

165 The ratio of atmospheric transmissions at λ_R and λ_F wavelengths (T_R/T_F) can be calculated the
166 same way as for water vapor measurements (Ansmann et al., 1992; Whiteman et al., 2006). In
167 our study, for the nitrogen molecule we used Raman scattering cross section at 355 nm
168 $\sigma_R = 2.1 \cdot 10^{-30} \text{ cm}^2$ (Burriss et al., 1992), but, to obtain absolute values of β_F , C_R/C_F ratio must be
169 determined. This ratio can be found from calibration, performed by using a lamp with known
170 spectrum, as it has been done for the Raman water vapor lidars (Venable et al., 2011). At current
171 stage, for β_F estimations, we assume that sensitivities of PMTs in both channels are similar
172 (switching of PMTs between N_2 -Raman and fluorescence channels didn't change results
173 noticeably), thus only difference in transmission of interference filters was considered. In all
174 results presented below $C_R/C_F = 0.7$ value was used for calculations.

175 To characterize the efficiency of the fluorescence respect to elastic scattering, it is
176 convenient to consider also the particle fluorescence capacity, $G_F = \frac{\beta_F}{\beta_L}$, which is the ratio of
177 fluorescence and aerosol elastic backscattering coefficients (Reichardt et al., 2017). Here and
178 below, for simplicity, we will use notation $\beta^a \equiv \beta$. The aerosol loading in the atmosphere during
179 the experiment was very low and, in order to decrease the interference of the Raleigh scattering,
180 the backscatter at 1064 nm was mainly used for aerosol characterization, while for the cloud
181 layers the backscattering coefficients at 355 and 532 nm were used as well.

182 Multiwavelength Mie-Raman lidar measurements allow estimation of the particle number
183 density $N = \int_{r_{\min}}^{r_{\max}} \frac{dN(r)}{dr} dr$ as well as their total volume V (Müller et al., 1999; Veselovskii et
184 al., 2002b), thus a mean fluorescence cross section per a single particle can be estimated as
185 $\sigma_F^N = \frac{\beta_F}{N}$. Assuming, that in the simplest case, a fluorescence backscattering coefficient is
186 proportional to the particle volume, we can estimate the fluorescence cross section per a unit
187 particle volume as $\sigma_F^V = \frac{\beta_F}{V}$. Thus, synergy of Mie-Raman and fluorescence lidar measurements
188 should allow remote characterization of the particle fluorescent properties.

189

190 **3. Observation results.**

191 **3.1. Fluorescence of aerosol layers.**

192 The measurements reported were performed during November 2019 – February 2020
193 period at the Lille Atmospheric Observation Platform ([https://www-loa.univ-](https://www-loa.univ-lille1.fr/observations/plateformes.html?p=apropos)
194 [lille1.fr/observations/plateformes.html?p=apropos](https://www-loa.univ-lille1.fr/observations/plateformes.html?p=apropos)) hosted by Laboratoire d’Optique
195 Atmosphérique, University of Lille, Hauts-de-France region. Two examples of measurement are
196 presented in Fig.2 and are showing height–temporal distributions of the range corrected lidar
197 signal (RCS) at 1064 nm, of volume depolarization ratio, δ_{1064} , and of fluorescence
198 backscattering coefficient, β_F , for the nights 29-30th November 2019 and 6-7th February 2020.

199 During the first night (left column in Fig. 2), aerosol layer is localized mainly below 2000
200 m. Though the aerosol loading is low ($\beta_{1064} < 0.01 \text{ Mm}^{-1} \text{sr}^{-1}$) above 2000 m, it is well revealed by
201 the enhanced depolarization ratio and the enhanced fluorescence backscattering coefficient.
202 During the second night of observation (right column in Fig.2), a detached/isolated layer is
203 observed at approximately 3000 m. This layer is characterized by high depolarization ratio (the
204 particle depolarization ratio at 1064 nm in the center of the layer exceeds 15%), indicating to the
205 presence of dust. An explanation of the observed increase of fluorescence signal could be mixing
206 of mineral dust particles with organic materials (Sugimoto et al., 2012; Miyakawa et al., 2015)
207 and local aerosol during transportation.

208 The time averaged profiles (β_{1064} , β_F , G_F) for these two nights, as well as for 16th January
209 episode are shown in Fig.3. Backscattering coefficient β_{1064} was calculated by Klett method,
210 assuming a lidar ratio $S=50$ sr. Due to low aerosol extinction value, the results are not sensitive
211 to the choice of S . The closest available radiosonde data are from the Herstmonceux (UK) and
212 Essen (Belgium) stations, located 160 km and 120 km away from the observation site
213 respectively. Data from both stations show that on the night 29-30 November 2019 the relative
214 humidity (RH) was about 70% at 1000 m and dropped below 20% above 2000 m. Pure water is
215 not fluorescing, so the water uptake by the particle, in the condition of high relative humidity
216 (RH), is expected to yield an increase of elastic scattering without significant effect on the
217 fluorescence emission. The aerosol backscattering β_{1064} on 29-30th November (Fig.3a) is 0.4
218 $\text{Mm}^{-1} \text{sr}^{-1}$ at 1000 m and decreases by a factor 40 at 1900 m, while β_F within this height range
219 changes less than twice. This is supporting the assumption that the observed variation of aerosol
220 backscattering in the PBL is mainly due to the change of the particle water fraction. The water
221 uptake at low altitudes agrees with low values of the observed particle depolarization ratio δ_{1064}^p ,
222 which is below 0.5% at 1000 m. Within weak aerosol layer at the range 2500 – 4000 m, the
223 particle depolarization δ_{1064}^p is about 5% and we observe the increase of fluorescence capacity G_F ,

224 with respect to the layer below 2000 m, up to $2.5 \cdot 10^{-4}$. This increase of G_F in the 2500 – 4000 m
225 layer can be due to the presence of another particles type, for example, biomass burning. From
226 this episode, one can conclude that fluorescence backscattering, though being almost 4 orders
227 lower than elastic one, can be reliably detected with our current lidar configuration.

228 On January 16th (Fig.3b), atmospheric RH also decreases with height, from about 80% at
229 1000 m to less than 20% above 2000 m, leading to an increase of G_F for more than one order of
230 magnitude. Such variation of G_F within the PBL is probably also related to the particle water
231 uptake, just like in Fig.3a. Aerosol backscattering increases above 3000 m and reaches its
232 maximum value at 5000 m. Within 3000 m – 5500 m range, fluorescence capacity was about
233 $2.5 \cdot 10^{-4}$, which is higher than in the PBL.

234 On February 6-7th the aerosol loading in the PBL is very low ($\beta_{1064} < 0.003 \text{ Mm}^{-1} \text{sr}^{-1}$ at 1000
235 m) and RH from radiosonde at Herstmonceux is below 40% in the height range considered. At
236 3000 m, a dust layer is observed (Fig.3c). In the middle of this layer, fluorescence capacity is
237 about $0.6 \cdot 10^{-4}$ which is about factor 4 lower than in the elevated layers in Fig.3a,b. Still,
238 significant value of G_F can indicate the presence of organic materials in the dust layer (Sugimoto
239 et al., 2012).

240 As discussed in section 2, lidar measurements provide an opportunity to estimate the
241 particle fluorescence cross section. For this, we need to know the particle number N and volume
242 V density in the aerosol layer, which, in principle, can be determined from the multiwavelength
243 lidar observations (Muller et al., 1999; Veselovskii et al., 2002b). In our case, however, due to
244 very low aerosol loading the extinction coefficients could not be determined. Still, the rough
245 estimations of the particle parameters can be done using the predefined aerosol model driven by
246 only a few parameters. In our study we use a simplified approach, modeling aerosol as an
247 external mixture of several aerosol components with predetermined properties. The definition of
248 aerosol components is based on global multiyear AERONET observations (Dubovik et al., 2002)
249 with some modifications. All aerosol types are described by a bimodal particle size distribution
250 (PSD)

$$251 \quad \frac{dV}{d \ln r} = \sum_{i=f,c} \frac{C_{V,i}}{\sqrt{2\pi}\sigma_i} \exp\left[-\frac{(\ln r - \ln r_{V,i})^2}{2\sigma_i^2}\right] \quad (10)$$

252 where $C_{V,i}$ denotes the particle volume concentration, $r_{V,i}$ is the median radius, and σ_i is the
253 standard deviation. Subscripts f and c correspond to the fine and coarse mode respectively. The
254 parameters of the number size distribution $\frac{dN}{d \ln r}$ can be obtained from (10) using the
255 expressions from Horvath et al. (1990). Table 1 shows the model parameters for three aerosol

256 types: biomass burning (BB), urban (UR) and dust (DU). From this model, the aerosol
257 backscattering and extinction coefficients can be calculated at any wavelength. As mentioned
258 above, due to low aerosol loading, we use only backscattering coefficient at 1064 nm, so Table 1

259 presents $\beta_{1064}^N = \frac{\beta_{1064}}{\int_{r_{\min}}^{r_{\max}} \frac{dN(r)}{dr} dr}$ - mean backscattering coefficient for a single particle (N=1),

260 together with corresponding complex refractive index (CRI) used in computations. Calculations
261 were performed in assumptions of spherical particles for BB and UR and for the randomly
262 oriented spheroids for dust (Dubovik, et al., 2006). The volume $V^{N=1}$ in the Table 1 is also given
263 for N=1 (so can be considered as a single particle average volume). Thus, if the aerosol type is
264 known, comparing of computed $\beta_{1064}^{N=1}$ from Table 1 with observed values β_{1064} , yields the
265 number and volume particle densities as $N = \frac{\beta_{1064}}{\beta_{1064}^{N=1}}$ and $V = N \times V^{N=1}$.

266 Table 2 summarizes for the three nights from Fig.3, the fluorescence cross sections per a
267 single particle, $\sigma_F^N = \frac{\beta_F}{N}$, and per unit volume, $\sigma_F^V = \frac{\beta_F}{V}$. Values are provided for the altitudes
268 corresponding to the maximum of fluorescence backscattering β_F in elevated layers, where the
269 relative humidity (RH) should be low and hygroscopic effect reduced. Particles are assumed to
270 be of biomass burning origin for November 30th and January 16th, and from dust origin for
271 February 6-7th. We should remind, however, that our estimations of N (and so σ_F^N) are rough,
272 since they depend on the assumed aerosol type. The particle volume, V, is however a more
273 reliable parameter. For example, if the UR aerosol type is considered, rather than the BB one, the
274 particle number density, N, for November 30th becomes $N=21\text{cm}^{-3}$ (instead 63cm^{-3} for BB)
275 while the total volume remains rather constant ($V=0.34\text{ }\mu\text{m}^3\text{cm}^{-3}$ instead of $0.37\text{ }\mu\text{m}^3\text{cm}^{-3}$).
276 Thus, presentation of cross section per a unit of volume σ_F^V appears more trustable. The
277 fluorescence cross sections σ_F^V for November 30th and January 16th are very close, but for the
278 dust layer (February 6-7th, 2020), the cross section is about a factor 4 lower. From the data
279 presented it is also possible to estimate the spectral differential cross section, $\frac{\sigma_F^V}{\Delta\lambda}$, where $\Delta\lambda$ is
280 the width of the filter transmission band.

281 It is rather difficult to validate our values of the fluorescence differential cross section. We
282 nevertheless compare them to in situ ground-based fluorescence measurements. Such reference
283 data are available mainly for biological particles (e.g. Pan, 2015). For biological particles, the

284 highest $\frac{d\sigma_F}{d\lambda}$ value, for a single particle with diameter 1.2 μm – 3.0 μm varies in the range (1-
285 $100) \cdot 10^{-15} \text{ cm}^2 \text{ sr}^{-1} \text{ nm}^{-1}$ when stimulating radiation at 365 nm is used (Pan, 2015). Thus, our
286 estimated values look reasonable, keeping in mind that the fluorescence cross section of the
287 biological particles is higher than that of smoke.

288

289 *3.2. Fluorescence of aerosol particles within cloud layers*

290 One of the attractive features of the fluorescence technique is the possibility to detect
291 aerosol and derive its content within the cloud layer. However, aerosol and cloud particles can be
292 mixed externally or internally. In the first case, the estimation of the dry particle volume is more
293 or less straightforward, using the fluorescence cross sections obtained from the measurements in
294 the aerosol layers. For the internal mixing, aerosols are located inside the water droplet in solid
295 or dissolved state. It is known, that the fluorescence of microspheres can be increased in the
296 backward direction by factor ~ 2 , comparing to fluorescence of a bulk material, due to
297 modification of the scattering phase function (Kerker et al., 1979; Veselovskii et al., 2002a).
298 Moreover, a fluorescence cross section of solid substance may differ from dissolved one. All this
299 complicates the quantification of the measurements for the case of internal mixing.

300 The results from November 13th and 18th, representing an **external** mixture case of
301 aerosol and clouds particles, are shown in Fig. 4. The backscattering coefficients are given at 532
302 nm, because in the cloud layers the detector in 1064 nm channel was sometimes saturated. On
303 November 13th, we observe a strong oscillation of β_{532} , due to the contribution of the cloud
304 layers within 1000 m – 3000 m. The increase of β_{532} , however, does not lead to significant
305 enhancement of the fluorescence backscattering β_F in the range of 1000–3000 m.

306 On 18th November, the cloud layer within 1500 – 2000 m range exhibit an even stronger
307 elastic backscattering, exceeding $80 \text{ Mm}^{-1} \text{ sr}^{-1}$. However, no significant change of fluorescence
308 backscattering is observed. These results clearly indicate the absence of leaks/contamination of
309 elastic scattering in the fluorescence channel, which in turn allow us monitor fluorescence within
310 cloud layers.

311 The situation, however, can be different, when the cloud droplets are formed on the aerosol
312 particles, thus fluorescent aerosols are inside the water particles. Fig.5 shows the height –
313 temporal distributions of the lidar signal at 1064 nm and the fluorescence backscattering
314 coefficient on the night 19-20th November 2019.

315 After 21:50 UTC a thin cloud layer starts to form at the top of the PBL resulting in
316 simultaneous increase of β_F . To quantify the influence of cloud water droplet on the fluorescence
317 backscattering, Fig.6a provides profiles of aerosol and fluorescence backscattering coefficients

318 for two temporal intervals 20:00 – 21:30 UTC and 21:30 – 00:30 UTC, prior and after the cloud
319 layer formation respectively. Prior to cloud formation the aerosol load is very low, so
320 backscattering is provided only at 1064 nm and to be distinguished at this figure, the value of
321 β_{1064} is multiplied by factor 100. For 20:00 – 21:30 β_{1064} at 1500 m (height where the cloud
322 forms) is about $0.07 \text{ Mm}^{-1}\text{sr}^{-1}$. After the cloud formation the backscattering coefficient is shown
323 at 532 nm, because 1064 nm detector in the cloud layer was overloaded. β_{532} increases up to 500
324 $\text{Mm}^{-1}\text{sr}^{-1}$ (maximum value) and the fluorescence backscattering increases by approximately
325 factor 5.

326 Similar scenario occurred on the night 23-24th November 2019 (Fig.6b). Prior to the cloud
327 formation (21:00 – 23:00 UTC) the backscattering coefficient at 900 m height is $\beta_{1064}=0.02 \text{ Mm}^{-1}\text{sr}^{-1}$
328 and after cloud formation β_{532} increases up to $130 \text{ Mm}^{-1}\text{sr}^{-1}$, while β_F again increases about
329 factor 5. The profiles of β_F in Fig.6 prior and after the cloud formations remain the same, below
330 the cloud. It corroborates the suggestion that the cloud was not transported by the air masses with
331 different properties, but the process of water vapor condensation occur, leading to formation of
332 internal mixture of aerosol and cloud particles.

333 We should recall also, that the enhancement of β_F can not be explained by just insufficient
334 suppression of elastic scattering. The enhancement was observed only inside an aerosol layer,
335 while clouds with similar backscattering coefficients, but outside the aerosol layer, didn't
336 provide the increase of β_{532} . Several possible mechanisms could be responsible for the observed
337 fluorescence backscattering increase. As mentioned above, the fluorescence scattering phase
338 function of microspheres can have a peak in the backward direction (Pan et al., 2002;
339 Veselovskii et al., 2002a). The fluorescence cross section of particles may be subject to
340 hygroscopic effect so impacted by the amount of available water vapor (RH). For example, it is
341 known, that fluorescence cross section of wet bacterial spores is higher than that of dry ones
342 (Kunnil et al., 2004). For insoluble particles, the presence of a water shell can lead also to
343 additional increase of the fluorescence, due to the lens effect produced by the droplet. Similar
344 effect is well known for the soot particles covered by non-absorbing shell (Schnaiter et al.,
345 2005).

346 One of the objectives of this study was to discuss the possibility to derive the aerosol
347 content within cloud layers, from the fluorescence measurements. Fig.7 shows, for November
348 15th 2019, 2:45 – 6:15 UTC, the height – temporal distributions of the range corrected lidar
349 signal at 1064 nm and the fluorescence backscattering β_F . Low cloud layers appear at
350 approximately 2000 m and a signal of aerosol fluorescence is observed within this layer up to
351 3000 m. The vertical profiles of β_{532} and fluorescence backscattering β_F , integrated over this
352 temporal interval, are shown in Fig.8a. Fluorescence backscattering does not change

353 significantly inside 1000 – 3500 m height range, thus aerosol content outside and inside the
354 cloud layer is similar. Strong increase of elastic scattering at 2700 m does not lead to significant
355 increase of β_F , hence the mixture of aerosol and cloud particles can be considered as external.
356 Using the results from the previous section for UR aerosol model, the volume density of the
357 ambient particles within the cloud layer can be estimated as $\sim 2 \mu\text{m}^3\text{cm}^{-3}$.

358 On November 25th 2019 (Fig.8b), a low cloud layer at 850 m leads to increase of β_F by
359 approximately of factor 2, in a similar way as in Fig.6. However, in the cloud above 2000 m, no
360 fluorescence signal, exceeding the noise level, is observed, indicating that the cloud is free of
361 aerosol. Thus, the results in Fig.8 demonstrate, that the fluorescence technique is capable to
362 distinguish between “clean of particles” and “polluted” cloud layers.

363

364 **Conclusion**

365 In our research we analyzed the feasibility of the fluorescence channel, added to the
366 multiwavelength Mie-Raman lidar for aerosol characterization. The results obtained,
367 demonstrate that the use of an interference filter for selection the part of the fluorescence
368 spectrum allows highly efficient lidar operation. In particular, LILAS lidar with the interference
369 filter of 44 nm width in the fluorescence channel, was able to detect fluorescence signal from
370 weak aerosol layers ($\beta_{1064} < 0.02 \text{ Mm}^{-1}\text{sr}^{-1}$) up to 5000 m. During the experiment the fluorescence
371 capacity $G_F = \frac{\beta_F}{\beta_{1064}}$ of aerosol at condition of low RH varied through the $(0.6 - 2.5) \times 10^{-4}$ range,
372 being the highest for the smoke and the lowest for the dust particles. The fluorescence capacity
373 depends as well on the relative humidity, because the water uptake at the condition of high RH
374 increases the elastic backscattering, without significant modification of the fluorescence. Thus
375 simultaneous measurements of Mie-Raman and fluorescence lidar open opportunity for the study
376 of the particle hygroscopic growth.

377 The lidar measurements, in principle, allow to get the quantitative information about the
378 aerosol fluorescence cross section in the elevated aerosol layers. For several atmospheric
379 situations the rough estimations of σ_F were performed in this study and the results obtained look
380 reasonable, comparing with published values for biological particles. Still these results should be
381 taken as preliminary and the next important step in quantification of the fluorescence
382 measurements will be the system calibration, using a lamp with known spectrum. As well, more
383 deep comparison of σ_F obtained from the lidar and laboratory measurements, for different
384 aerosol types, is needed for validation. It should be mentioned, that the fluorescence and
385 multiwavelength Mie-Raman lidar techniques are complimentary. The multiwavelength lidar

386 allows aerosol typing and estimation of the particle number and volume densities, that are later
387 used to derive the fluorescence cross sections from observed β_F . The fluorescence
388 measurements, in turn, help to improve the aerosol classification. The synergy of fluorescence
389 and multi-wavelength lidar techniques was not realized in this study, due to too low aerosol
390 loading in November – February period. However, we plan new experiments during Spring –
391 Summer season, when AOD is larger in Lille.

392 Results presented demonstrate also, that the fluorescence technique can be efficiently
393 used to estimate the particle concentration inside the cloud layer (at least near the cloud base, if
394 penetration depth of the laser radiation is small), which is important in the study of aerosol –
395 cloud interaction. Moreover, our measurements indicate, that aerosol and cloud particles can be
396 mixed both externally and internally. In the clouds formed at the top or inside the aerosol layer
397 (which makes possible internal mixture scenario), significant increase of the fluorescence
398 backscattering coefficient (up to factor 5), was observed. Among possible mechanisms of such
399 enhancement we can assume the increase of fluorescence cross section in solvent state,
400 modification of the scattering phase function of particles embedded in microspheres and the lens
401 effect due to the water shell. At a moment we are not able to specify the mechanism and future
402 studies are needed.

403 In coming studies we plan additional modifications of the lidar. The efficiency of the
404 fluorescence channel is demonstrated to be high, so the filter bandwidth can be decreased to 10-
405 20 nm, which will make more solid our simplified approach to data analysis. We consider also
406 the possibility to add second fluorescence channel near 550 nm, which should improve
407 selectivity of the fluorescence technique to different aerosol types. The water vapor channel will
408 be returned back to the system, which is essential for the study of particle hygroscopic growth.
409 Collocated measurements of the microwave radiometer of the Laboratoire d'optique
410 atmosphérique will be used to derive the RH profiles. When considering, the aerosol
411 characterization inside the cloud, the possible effect of the multiple scattering on the results will
412 be also analyzed.
