Authors’ response to Reviewer Comment 2

Reviewer:

The manuscript presents an interesting use of a network of all-sky-imagers (ASIs) to derive mean cloud-base-height over a wide area. The method presented is interesting and, overall, the proposed system seems robust of probable practical use. The authors offer practical suggestions about the optimal layout of future ASIs installations, thus providing some useful information to the user. Reading the manuscript, it is clear that a lot of interesting work has been done, but unfortunately this has not been distilled enough yet to be clearly presented to the scientific community. The new algorithm is poorly presented, the novel contributions are not clearly identified, and the discussion of the results lacks focus. The authors should drastically revise the manuscript, trying to clearly present the essence and motivation of their work and separate it from implementation details.

To my understanding, there are three technical aspects presented: a) Implementation of three different approaches to calculate CBH from a pair of ASIs b) Evaluation of CBH retrievals from ASI-pairs. c) The use of a network of multiple ASI-pairs to derive a robust CBH estimate for the region.

Each of these aspects should be discussed and evaluated one by one, or references should be given in studies evaluating their performance. Otherwise, the reader cannot properly interpret the results.

Authors’ response:

We really appreciate the reviewer’s time and effort spent on reviewing our manuscript, their insightful comments and suggestions. We have addressed all comments and incorporated the suggestions as good as possible to us and we believe, these changes led to valuable improvements of our manuscript. In particular, we have strongly revised the sections on modelling and validation.

In the following, we will address the reviewer’s comments point-by-point. Changes to the manuscript are extracted from the adapted manuscript within which changes were highlighted using latexdiff. Blue indicates insertions, red indicates deletions. Please note, that the order of Sect. 3.3 and Sect. 3.4 has been reversed as suggested by Reviewer Comment 1, General Comment 5. This change has been excluded from the markup, as it would have obscured all other changes.

Changes in manuscript:

See below.

Major comment 1

Reviewer:

Sections 3.3 and 3.4 should be rewritten. The sections seem like a direct translation of computer code into words, with no effort to describe why each step was implemented, what is essential, and
what is just an implementation detail or even an experiment that happened to work. E.g. why use the three-gaussian filters? Why use the specific $\sigma$ thresholds? Why add an offset of 0.5 in low frequency bins (why not 0.01 or 1)? Implementation details could be even moved into an appendix.

Authors’ response:

Based on the reviewer’s feedback we revised Sect. 3.3 and 3.4 drastically. Especially regarding the modelling of conditional probability distributions, we moved the exact description of the procedure to the appendix and focused more on describing the idea behind the procedure and every filter. We further gave a reason for the value assigned to each of the parameters. However, we also stated that these parameters may still be optimized in a future work and are so far only rough approximations.

Similarly, we reworked Sect. 3.3. In particular, we focused on pointing out for each step of the procedure, what the intention of each equation/calculation step was.

Sections 3.3 and 3.4: pp. 12-20

3.3 Estimating CBH in the ASI network (ORDER OF SECTIONS 3.3 AND 3.4 WAS EXCHANGED).

The estimation procedure presented here is motivated by In this section we present our method to combine the measurements of CBH from a large number ASI-pairs organized as network. Prior works estimated CBH by a small number of two or in some cases four ASIs (Nouri et al., 2019a). However, with a large number of ASI-pairs, we consider a statistical method promising, which analyzes the CBH samples received and, based on the known characteristics of each ASI-pair, determines
Figure 5. Inference procedure — Step 1: For each range \(i\) of camera distance \(\text{CHL}_i\) is computed as mean CBH from the respective ASI pairs. Conditional probability is evaluated that \(\text{CHL}_i\) would be received if true CBH (at the ceilometer) took on a value \((0.9, 0.1, 0.4, 0.2, 0.11.9, 0.12)\) km (red boxes). Step 1 yields a likelihood function for each range of camera distance. Step 2: Cumulative and complementary cumulative likelihood are calculated for each range of camera distance. Step 3: These functions are logarithmized and then summed over all ranges \(i\) of camera distance yielding overall cumulative and complementary cumulative likelihood. Step 4: The intersection of both functions gives the estimated likelihood CBH.
the CBH which is most likely to be present. The characteristics of each ASI-pair are in the following described by conditional probability distributions, which will by retrieved in Sect. 3.4. These distributions provide the probability of receiving a certain CBH reading from an ASI-pair, given that actually a specific reference CBH is present. Our estimation procedure then uses principles from Maximum Likelihood Estimation (MLE). - Figure and modifies them for the specific case. To the best of our knowledge, the usage of a statistical method and in particular one relying on conditional probability distributions is novel to the task of estimating CBH from the observations of a multitude of ASIs.

To give an overview, Fig. 5 shows the inference process used to estimate CBH by the network based on the 42 CBH readings provided by the individual ASI-pairs. For each range i of camera distance, conditional probabilities estimated in Sect. 3.4, conditional probability distributions will be estimated. These conditional probabilities are translated into the likelihood that actually certain values of (reference) CBH are present (step 1) based on the readings of CBH received for-from ASI-pairs in this range i of camera distance. After calculating the cumulative likelihood for each range of camera distance (step 2), these are combined yielding the overall cumulative and complementary cumulative likelihood from all ASI-ASI-pairs (step 3). Finally, the value of CBH which is most likely to be present at the site and at the evaluated time, given the readings from all involved ASI-pairs, is estimated (step 4). These steps are explained in more detail in the following.

Step 1: For each ASI-pair, the median value of all valid CBH readings of the previous 10 min is calculated. If an ASI-pair does not provide any valid CBH within this period, it is excluded from the prediction for the instance in time evaluated. The ranges of camera distance 1...2.5 km and 3..4 km are represented by a larger number of ASI-pairs than the remaining distances. Thus, the readings of ASI-pairs in these ranges of camera distance may prevail in the estimation of CBH. As the variety of camera distances is considered to bring a benefit to the procedure, we intend to represent all camera distances as uniformly as possible. For this, we define ranges of camera distance, using the range limits {0.5, 1, 1.5, ..., 6} km and CBH readings of all ASI-pairs with camera distance in range i are averaged to yield $\text{CBH}_i$. Consecutively, the conditional probability $P(\text{CBH}_i | \hat{\theta}) = P(\text{CBH}_i | \hat{\text{h}}_{\text{true}})$ is evaluated that the found CBH, would be received for a given true CBH $\hat{\text{h}}_{\text{true}}$ (red marked box prior to step 1 in Fig. 5). Note that $P(\text{CBH}_i | \hat{\theta}) = P(\text{CBH}_i | \hat{\text{h}}_{\text{true}})$ will be modeled in Sect. 3.4 measuring CBH $\hat{\text{h}}_{\text{true}}$ by a ceilometer which provides $\hat{\text{h}}_{\text{true}}$ with $\hat{\text{h}}_{\text{true}}$. Thus, the likelihood $L_i(\hat{\theta})$ is obtained (Fig. 5, step 1):

$$L_i(\hat{\theta}) = P(\text{CBH}_i | \hat{\theta}) \quad \text{(1)}.$$  

Step 2: likelihood - We define cumulative likelihood $L_i(\hat{\text{h}}_{\text{true}})$ as the likelihood of receiving the present reading CBH, given that $\hat{\text{h}}_{\text{true}}$ is smaller or equal to an estimation of true CBH $\hat{\text{h}}_{\text{true}}$. Accordingly in the implementation, likelihood is summed cumulatively over all bins of reference CBH $\hat{\theta}$ to define cumulative likelihood $L_i(\hat{\text{h}}_{\text{true}})$ (Fig. 5, step 2):

$$L_i(\hat{\text{h}}_{\text{true}}) = \sum_{\hat{\theta} < \hat{\text{h}}_{\text{true}}} L_i(\hat{\theta}) \quad \text{(2)}.$$  

Likewise, a complementary cumulative likelihood is defined

$$L_i(\hat{\theta}) = \sum_{\theta > \hat{\theta}} L_i(\theta) \quad \text{(2')}.$$
as the likelihood of receiving the present reading CBH, given that \( h_{true} \) is greater than an estimation of true CBH \( \hat{h}_{true} \): 

\[
C_0(h_{true}) = \sum_{h_{true} > \hat{h}_{true}} C_0(h_{true}).
\]

(3)

\( C_1(\hat{\theta}) \) and \( C_1(\theta) \) are used here as measures how likely it is that actual CBH \( \theta \) is in the interval \([0 \ km, \hat{\theta}] \) or \([\hat{\theta}, 12 \ km] \) respectively. It is mainly the use of these cumulative functions that and the estimation of likelihood functions from measurement data distinguishes the present approach from a regular Maximum-Likelihood-Estimation (MLE). This modification is used as in MLE typically smooth analytical likelihood functions are assumed as likelihood function. In contrast, likelihood functions here are will be estimated based on empirical conditional probabilities. These approximated likelihood functions, derived from a dataset of finite size, may therefore be less smooth and may not be completely representable. When using cumulative distributions, it is expected that the method still works robustly if the conditional probabilities are not estimated accurately for each grid cell of the discrete distribution if at least the cumulative value over a range of CBH is appropriate. In spite of the modification, the presented approach may adopt beneficial properties of MLE:

The use of appropriate conditional probabilities (described in Sect. 3.4) reduces systematic deviations of estimated CBH compared to the measurement of a single ASI-pair. Moreover, applied conditional probabilities are in general not specific to the studied site and its meteorological conditions, which allows to apply the method at other sites. When using cumulative distributions, it is expected that the method still works robustly if the conditional probabilities are not estimated accurately for each joint frequency grid cell but at least the cumulative value over a range of CBH is appropriate. Both functions \( C_1(\hat{\theta}) \) and \( C_1(\theta) \) both functions \( C_0(h_{true}) \) and \( C_1(h_{true}) \) are shown for three exemplary intervals of camera distance in Fig. 5 as output of step 2.

Step 3: The natural logarithm is then applied to \( C_0(h_{true}) \) and summed over all We aim to determine the likelihood of receiving the combination of readings CBH, from all the intervals \( i \) of camera distance to yield the given that \( h_{true} \leq \hat{h}_{true} \). This can be expressed as product of \( C_0(h_{true}) \) from all intervals \( i \). As this product would often become zero in our numerical treatment, we instead calculate its natural logarithm, which we refer to as an overall logarithmic cumulative likelihood \( \log C_0(h_{true}) \). This operation also allows to replace the product by a sum (Fig. 5, step 3) given the readings CBH, per interval \( i \) of camera distance

\[
\log C_0(h_{true}) = \sum_i \log C_i(h_{true}).
\]

(4)

Analogously, an overall complementary logarithmic cumulative likelihood is computed given all readings CBH, per interval \( i \) of camera distance

\[
\log C_0(h_{true}) = \sum_i \log C_i(h_{true}).
\]

(5)

Both functions are visualized exemplarily as output of step 3 in Fig. 5. In theory, the method could do without the application of a logarithm to \( C_i \) and \( C_0 \) in Eq. and Eq. respectively. In that case, the sum would be replaced by a multiplication in the respective equations. However, this would induce numerical problems regularly as handled products approach zero.
Step 4: The left-hand sides in Eq. 1 and Eq. 2—log \( C_n(h_{true}) \) and log \( C_n(h_{true}) \)—are only known at discrete points. Linear interpolation yields continuous representations of these. An estimation of the likeliest actual CBH \( \hat{h}_{true} \) is selected for which \( \log C_n(\hat{h}) \) and \( \log C_n(\hat{h}) \). Then finally, we aim to select the true CBH \( h_{true}^{\text{most}} \), which makes it likeliest to receive the given combination of CBHs. In our formulation of the problem, this means we intend to find a \( h_{true}^{\text{most}} \) which simultaneously maximizes \( \log C_n(h_{true}) \) and \( \log C_n(h_{true}) \). Consequently, we accept \( h_{true}^{\text{most}} \) for which \( \log C_n(h_{true}) \) and \( \log C_n(h_{true}) \) are equal (Fig. 5, step 4):

\[
\hat{h}_{true}^{\text{most}} = \arg\min_{h_{true}} \left| \log C_n(h_{true}) - \log C_n(h_{true}) \right|
\]

(6)

Besides this estimation of CBH, a version of this procedure will be discussed that includes further refinements (in the following referred to as refined estimation). The refinement is motivated by the finding that some AAs first observation from the generation of conditional probabilities, AA-pairs are already accurate if actually a certain range of CBH is present as we will discuss in Sect. 4. First, the procedure presented above is modified to exclude AA-pairs with camera distance greater than 4.5 km as these AA-pairs cause large deviations for CBH < 4 km and only provide a limited benefit exhibit only a moderate advantage at greater CBH. Results from this procedure are accepted as refined estimation \( \hat{h}_{true}^{\text{refined}} \) if estimated CBH is within 3...12 km. Otherwise, the arithmetic average of CBH measured by These AA-pairs are excluded from the refined estimation of \( h_{true}^{\text{most}} \). On the other hand, AA-pairs with specific camera distance is used. The most appropriate small camera distance are already accurate if only small CBH occur, as we will discuss in Sect. 4. We inspected conditional probabilities of the AA-pairs for an interval of CBH are identified by an inspection of the conditional probabilities (exemplarily viewed as input to step 1 in Fig. 5). This and identified the AA-pairs which are most appropriate for an interval of CBH. Based on this, the refined estimation is restricted to remain within the specific interval of CBH from the unrevised estimation in which it is applied received from the arithmetic average of CBH measured by AA-pairs with corresponding small camera distance, if the first iteration of \( h_{true}^{\text{most}} \) yielded a sufficiently small CBH. In summary, the refinement procedure to receive the final estimation of CBH \( \hat{h}_{true}^{\text{refined}} \) reads:

\[
\hat{h}_{true}^{\text{refined}} \begin{cases} 
\min(3 \text{ km}, \text{mean}(h_{true} < 1.6 \text{ km})), & h_{true}^{\text{refined}} \in [3, 12] \text{ km} \\
\min(1.5 \text{ km}, \text{mean}(h_{true} < 1.2 \text{ km})), & h_{true}^{\text{refined}} \leq 3 \text{ km} \land \text{mean}(h_{true} < 1.6 \text{ km}) > 1.5 \text{ km} \\
\min(1.5 \text{ km}, \text{mean}(h_{true} < 1.2 \text{ km})), & h_{true}^{\text{refined}} \leq 3 \text{ km} \land \text{mean}(h_{true} < 1.6 \text{ km}) \leq 1.5 \text{ km}.
\end{cases}
\]

(7)

3.4 Estimation of conditional probabilities of CBH (ORDER OF SECTIONS 3.3 AND 3.4 WAS EXCHANGED)

The procedure to combine CBH-measurements from independent AA-pairs, which are organized as a network, requires knowledge of the conditional probability to receive a certain reading of CBH from an AA-pair given the true CBH takes on some specific value. The method itself will be presented in Sect. 3.3. Here we discuss the probability distributions used. The required distribution aims to answer the following question: If true CBH ranges in between 1.8...1.9 km, how large will be the probability that an AA-pair with camera distance 2.2 km delivers a certain CBH e.g. within 0...0.1 km or 1.8...1.9 km or 11.9...12 km? In the following, these conditional probabilities are estimated not only for the range of true CBH between 1.8...1.9 km but
for each range \{0...0.1, 0.1...0.2, 0.2...0.3, ..., 11.9...12\} km of true CBH. **Conditional probability distributions of this kind are not available so far for ASI-pairs. Therefore, we aim to approximate them from the measurement data of a modelling period.**

Estimations of CBH from the available ASI-pairs and measurements from the ceilometer during the period 01 April 2019 to 29 June 2019 are used. CBH measured by the ceilometer serves as reference CBH. It is considered not to be essential that the training period is representative of the period to which the method is applied. However, we expect that the method works best if the included ASI-pairs exhibit a similar distribution of measurement deviations given the same reference CBH in both periods. For solar applications and the latitude of our study, we consider the used dataset and its split reasonable. The summer and shoulder months provide the main share of the annual solar yield at the site and are therefore in focus of the nowcasting system under development. In that sense, the training dataset is considered to be for the large part representative of conditions relevant to solar applications at similar latitudes.

The seven ASIs available in the urban area are arranged into 42 ASI-pairs. Each tuple of two ASIs, that is, is selected from the set of seven ASIs, yields 2 independent ASI-pairs by swapping the ASI used as main camera (see Sect. 3.1).

The procedure is developed based on periods in which valid measurements from ceilometer and the respective ASI-pair are available and in which the variability of CBH is moderate: For each time stamp a window of 30 min centered at this time stamp is defined. A time stamp is only included if standard deviation of reference CBH within the window is less than 30\% of the mean value of reference CBH within the same window. As discussed before, ASI-pairs and ceilometer measure CBH as spatial median and point-wise respectively. Therefore, this filter intends to assure that ceilometer and ASI-pair measure CBH of the same layer. CBH from the respective ASI-pair and from the ceilometer are processed by a moving-median filter with a window of 10 min. The frequency distribution of CBH measured by ceilometer \( h_{\text{CEI}} \) and the respective ASI-pair \( h_{\text{ASI}} \) is computed from these simultaneously acquired time series. That means the domain of reasonable values \([0,12 \text{ km}] \times [0,12 \text{ km}]\) which the pair \( (h_{\text{CEI}}, h_{\text{ASI}}) \) can take on, is discretized into a mesh of square grid cells with side lengths \( \Delta h \). Then the frequency is calculated with which \( (h_{\text{CEI}}, h_{\text{ASI}}) \) is observed in a discrete grid cell defined by the interval \([j \Delta h, (j+1) \Delta h]\) for \( h_{\text{CEI}} \) and the interval \([k \Delta h, (k+1) \Delta h]\) for \( h_{\text{ASI}} \), where \( j, k \in \{0, 1, 2, ..., N-1\} \) each of the discrete grid cells. A bin size \( \Delta h = 100 \text{ m} \) is chosen in a trade-off between sources of error. Finer bins will allow to represent the distributions at higher resolution and will thus allow for higher resolved measurements of CBH in the network. However, the size of the used data set is limited which makes it difficult to model these distributions at highest resolution. The bin size chosen here is expected to limit the achievable uncertainty of the measurement to a minimum level of 100 m. **Joint frequency distributions modeled here are restricted to a maximum CBH of 12 km. This yields \( N = 120 \).**

Joint frequency distributions were inspected and found to be well reproduced among the studied independent ASI-pairs, if only the corresponding camera distances are similar. This meets the expectation from literature discussed in Sect. 3.1. Moreover, we conclude that the distributions modeled here will be transferable to other setups that use camera distances in the studied range. Local climate is expected to influence the transferability to a minor extent as will be discussed later. To further support this transferability to...

The limited size and representativeness of the data set used in model development are expected to cause random features in the joint frequency distributions which are not useful to the estimation procedure, when it is applied to other setups, sites and
times, we aim to suppress (such as represented by the validation data set). To suppress such random features of received joint frequency distributions. For this, the original joint frequency distribution $F_i$ of ASI-pair $i$ is transformed by a first filter into $F_{i,filter}^{\text{first}}$, and by a second, consecutively applied filter into $F_{i,filter}^{\text{second}}$. We introduce a filtering procedure with two consecutive steps described here and in more detail in Appendix A. The parameter values set in the filtering procedure are approximate to this point and are based on a visual comparison of unfiltered and filtered distributions, evaluating the degree to which noise and also reasonable features were suppressed. The parameters values may be optimized in a future study.

First, a weighted mean filter is applied between the original joint frequency distributions $F_i$ received for all received for ASI-pairs with arbitrary camera distances.

$$F_{i,filter}^{\text{first}} = \frac{\sum_{m} w_{i,m} F_{i,m}}{\sum_{m} w_{i,m}}.$$

For the joint frequency distribution $F_i$ of each respective ASI-pair $i$, weights $w_{i,m}$ are used that include similar camera distances. As discussed above, ASI-pairs with similar camera distance $d_{i,m}$ are weighted with a triangular window, based on the difference of camera distance $\Delta d_{i,m}$ of ASI-pair $m$ compared to ASI-pair $i$, is used that is defined by:

$$w_{i,m} = \max(0, 1 - \Delta d_{i,m}/0.5 \text{ km}).$$

Then are expected to perform similarly in the measurement of CBH and should consequently also exhibit similar joint frequency distributions of CBH. Thus, the filter aims to suppress differences between the joint frequency distributions of ASI-pairs which may result from disturbances in the estimation rather than from a difference in the systems' characteristics.

To each filtered distribution resulting from the prior step, a composite of three Gaussian filters is applied to $F_{i,filter}^{\text{first}}$ of each ASI-pair $i$. We first decompose each distribution $F_{i,filter}^{\text{first}}$ into three separate modes. In the second step, which correspond to parts of the joint frequency distributions which are estimated with descending precision. Thereafter, we apply to each mode a Gaussian filter with distinct standard deviation $\sigma_{\text{mode}}$ to each mode. The standard deviation of the Gaussian kernel. The subscript mode indicates the specific mode for which $\sigma_{\text{mode}}$ is applied. Filter applied to each mode corresponds qualitatively to the uncertainty with which the prior joint frequency distribution is estimated within grid cells of that mode. Consequently, the three filtered modes are summed to receive the smoothed joint frequency distribution.

The first mode is constituted by all outlier observations. Outliers are defined here as grid cells $(h_{\text{Ref}}, h_{\text{ASI}})$ for which grid cells for which the ASI-pair based measurement of CBH $h_{\text{ASI}}$ deviates by more than $1.5 \text{ km}$ from the ceilometer reading $h_{\text{Ref}}$.

$$F_{i,filter}^{\text{second}}(h_{\text{Ref}}, h_{\text{ASI}}) = \begin{cases} F_{i,filter}^{\text{first}}(h_{\text{Ref}}, h_{\text{ASI}}), & |h_{\text{ASI}} - h_{\text{Ref}}| > 1.5 \text{ km} \\ 0, & \text{else}. \end{cases}$$

Such outliers will contain a large random component. We expect that in a reproduction of the experiment, a similar number of outliers will be received, while the large deviations represented by this mode occur less frequently, which is why the joint frequency distribution will be estimated less precisely for the respective grid cells. On the other hand, apart from such
scattering effects, the joint frequency found for a single grid cell \((h_{\text{Ref}}, h_{\text{ASR}})\) may vary significantly. Therefore, the strongest filter distributions are found to be comparably smooth in the grid cells of this mode. A Gaussian filter with a large standard deviation of 1 km is applied to this mode using \(\sigma_{\text{filter}} = 1\) km, which is considered to be apt to preserve the expected distribution while suppressing random features.

The second mode is constituted by grid cells that are not part of the first mode and for which the ASR-pair based measurement of CBH deviates by less than 1.5 km from the ceilometer reading and which feature a joint frequency less than the average over the average of all grid cells of the joint frequency distribution:

\[
F_{\text{inconfident}}(h_{\text{Ref}}, h_{\text{ASR}}) = \begin{cases} 
F_{\text{filter}1}(h_{\text{Ref}}, h_{\text{ASR}}); & |h_{\text{ASR}} - h_{\text{Ref}}| \leq 1.5 \text{ km} \\
\land F_{\text{filter}1}(h_{\text{Ref}}, h_{\text{ASR}}) < \text{mean}(F_{\text{filter}1}) & 
0, \quad \text{else.}
\end{cases}
\]

The grid cells of this mode typically exhibit a larger joint frequency, i.e., more observations, than grid cells in the first mode. Still, the comparably small number of observations in these grid cells is expected to cause an increased uncertainty of the estimated joint frequencies. For this mode, \(\sigma_{\text{inconfident}} = 0.5\) km. Consequently, in a trade-off between suppressing random scattering and preserving meaningful variations a Gaussian filter with standard deviation 0.5 km is applied.

The third mode \(F_{\text{confident}}(h_{\text{Ref}}, h_{\text{ASR}})\) makes up the complementary of the first and second mode. It contains grid cells that are observed with at least average joint frequency and which are not classified as outliers:

\[
F_{\text{confident}}(h_{\text{Ref}}, h_{\text{ASR}}) = \begin{cases} 
F_{\text{filter}1}(h_{\text{Ref}}, h_{\text{ASR}}); & |h_{\text{ASR}} - h_{\text{Ref}}| \leq 1.5 \text{ km} \\
\land F_{\text{filter}1}(h_{\text{Ref}}, h_{\text{ASR}}) \geq \text{mean}(F_{\text{filter}1}) & 
0, \quad \text{else.}
\end{cases}
\]

Joint frequencies in these grid cells are considered to have been estimated with a comparably high accuracy. To avoid a loss of precision and ultimately a loss of accuracy in the estimation of CBH, a small value of \(\sigma_{\text{confident}} = 0.1\) km Gaussian filter with a standard deviation of 0.1 km is used. The three filtered modes \(F_{\text{filter}}\) are summed to receive the smoothened joint frequency distribution:

\[
F_{\text{filter}2} = g_{\text{outlier}}(F_{\text{outlier}}) + g_{\text{inconfident}}(F_{\text{inconfident}}) + g_{\text{confident}}(F_{\text{confident}})
\]

Hence, only neighboring grid cells have a significant influence on this filter.

In many joint frequency distributions, there are grid cells with joint frequency close to zero. Especially for these grid cells, a greater dataset would be required to receive more representative values. For all grid cells, joint frequency is increased to a minimum value of 0.5 to avoid underestimations of joint frequency. This value corresponds to half of the joint frequency associated with a single actual observation in a grid cell. For the estimation procedure of CBH, this such a minimum value leads to slightly reduced precision for most readings but increased robustness in the case that these grid cells \((h_{\text{Ref}}, h_{\text{ASR}})\) are indeed observed in the measurement.
Finally, from each joint frequency distribution is normalized with the sum of all joint frequency grid cells. In this way, a probability mass function (also known as discrete density function) to measure a certain CBH with the respective ASI-pair and to coincidentally measure a certain CBH with the ceilometer is yielded. The conditional probability \( P(h_{ASI} | h_{REF}) \) to receive a certain CBH reading from an ASI-pair, given that the ceilometer measures some certain CBH, is calculated by dividing the respective probability mass function by the marginal distribution of CBH measured by the ceilometer. The latter distribution gives the probability to receive CBH from the ceilometer within a certain bin \( h_{REF} \) regardless of which CBH reading is simultaneously received from an ASI-pair. The distribution can be derived from any of the probability mass functions by summing all grid cells of the probability mass function which correspond to the respective bin \( h_{REF} \) of CBH measured by the ceilometer. Derived (see Appendix A for a more detailed description).

Inference procedure — Step 1: For each range \( i \) of camera distance CBH is computed as mean CBH from the respective ASI-pairs. Conditional probability is evaluated that CBH would be received if true CBH (at the ceilometer) took on a value \( \{0, 0.01, 0.1, 0.2, \ldots, 11.9, 12\} \) (red boxes). Step 1 yields a likelihood function for each range of camera distance. Step 2: Cumulative and complementary cumulative likelihood are calculated for each range of camera distances. Step 3: These functions are logarithmized and then summed over all ranges \( i \) of camera distance yielding overall cumulative and complementary cumulative likelihood. Step 4: The intersection of both functions gives the estimated likeliest CBH.

The inference procedure, which was introduced in Sect. 3.3, represents each range \( i \) of camera distance bounded by the limits \( \{0.5, 1, 1.5, \ldots, 6\} \) km by a single distribution of conditional probability. For each range of camera distance, the distribution of conditional probability, which corresponds to the camera distance closest to the center of this range, is selected. For example, for the range \( i = 2 \) representing camera distances 1.1-1.5 km, the center of the range would be 1.3 km. For the camera distances 1.083, 1.247 and 1.352 km, conditional probabilities have been modeled. Consequently, for this range of camera distance, the distribution of conditional probability corresponding to the camera distance 1.247 km is used. (example provided in Appendix A). Figure 5 (above Step 1) shows exemplary conditional probabilities for three ASI-pairs with camera distances 0.8, 2.2, 5.7 km representing the ranges of camera distance \( i = 1, 4, 11 \) respectively. The further content of Fig. 5 is explained in the next section BIAS and precision, with which ASI pairs of distinct camera distances measure CBH, given a certain reference CBH, are visible in those conditional probabilities. Such characteristics will be evaluated in more detail in the following, based on a separate validation data set.

Appendix A, pp. 35-37:

Appendix A: Details on the retrieval of conditional probabilities

A1 Retrieval of raw joint frequency distributions

CBH from the respective ASI-pair and from the ceilometer are processed by a moving median filter with a window of 10 min. The joint frequency distribution of CBH measured by ceilometer \( h_{REF} \) and the respective ASI-pair \( h_{ASI} \) is computed from these simultaneously acquired time series. That means, the frequency is calculated with which \( (h_{ASI}, h_{REF}) \) is observed in a discrete grid cell defined by the interval \( j \Delta h, (j + 1) \Delta h \) for \( h_{REF} \) and the interval \( k \Delta h, (k + 1) \Delta h \) for \( h_{ASI} \), where \( j, k \in \{0, 1, 2, \ldots, N - 1\} \), where \( N \) is the number of bins used for CBH in the analysis. A bin size \( \Delta h = 100 \) m is chosen in a trade-off between sources of error. Finer bins will allow to represent the distributions at higher resolution and will thus allow for higher resolved measurements of CBH in the network. However, the size of the used data set is limited which makes it difficult to model these distributions at highest resolution. The bin size shown here is expected to limit the achievable uncertainty of the measurement to a minimum level of 100 m. Joint frequency distributions modeled here are restricted to a maximum CBH of 12 km. This yields \( N = 120 \).
Filtering operations applied

First, a weighted mean filter is applied between original joint frequency distributions \( F_l \) received from all ASI-pairs with camera distance \( d \), this yields \( F_{\text{filter} \cdot 1} \):

\[
F_{\text{filter} \cdot 1} = \sum_{m} \frac{w_{l,m} F_m}{\sum_{m} w_{l,m}}.
\] (A1)

For the joint frequency distribution \( F_l \) of each respective ASI-pair \( l \), weights \( w_{l,m} \) are used that include ASI-pairs with similar camera distance. More precisely, a triangular window, based on the difference of camera distance \( \Delta d_{l,m} \) of ASI-pair \( m \) compared to ASI-pair \( l \), is used that is defined by:

\[
w_{l,m} = \max(0, 1 - \Delta d_{l,m}/0.5 \text{ km}).
\] (A2)

We decompose each distribution \( F_{\text{filter} \cdot 1} \) by conditional filters into three separate modes. In the second step, we apply to each mode a Gaussian filter \( g_{\sigma} \) with distinct standard deviation \( \sigma_{\text{mode}} \) of the Gaussian kernel. The subscript \( \text{mode} \) indicates the specific mode for which \( g_{\sigma_{\text{mode}}} \) is applied. The first mode is constituted by all outlier observations. Outliers are defined here as grid cells \((h_{\text{Ref}}, h_{\text{ASI}})\) for which ASI-pair measurement of CBH \( h_{\text{ASI}} \) deviates by more than 1.5 km from the ceilometer reading \( h_{\text{Ref}} \):

\[
F_{\text{outliers}}(h_{\text{Ref}}, h_{\text{ASI}}) = \begin{cases} F_{\text{filter} \cdot 1}(h_{\text{Ref}}, h_{\text{ASI}}), & |h_{\text{ASI}} - h_{\text{Ref}}| > 1.5 \text{ km} \\ 0, & \text{else}. \end{cases}
\] (A3)

Such outliers will contain a large random component. We expect that in a reproduction of the experiment, a similar number of outliers will be received, while the joint frequency found for a single grid cell \((h_{\text{Ref}}, h_{\text{ASI}})\) may vary significantly. Therefore, the strongest filter is applied to this mode using \( \sigma_{\text{mode}} = 1 \text{ km} \).

The second mode is constituted by grid cells that are not part of the first mode and feature a joint frequency less than the average over all grid cells of the joint frequency distribution:

\[
F_{\text{inconsistencies}}(h_{\text{Ref}}, h_{\text{ASI}}) = \begin{cases} F_{\text{filter} \cdot 1}(h_{\text{Ref}}, h_{\text{ASI}}), & |h_{\text{ASI}} - h_{\text{Ref}}| \leq 1.5 \text{ km} \\ \land F_{\text{filter} \cdot 1}(h_{\text{Ref}}, h_{\text{ASI}}) < \text{mean}(F_{\text{filter} \cdot 1}) \\ 0, & \text{else}. \end{cases}
\] (A4)

The comparably small number of observations in these grid cells is expected to cause an increased uncertainty of the estimated joint frequencies. For this mode, \( \sigma_{\text{inconsistencies}} = 0.5 \text{ km} \) is applied.
The third mode $F_{\text{confident}}(h_{\text{ref}}, h_{\text{ASI}})$ makes up the complementary of the first and second mode. It contains grid cells that are observed with an at least average joint frequency and which are not classified as outliers:

$$F_{\text{confident}}(h_{\text{ref}}, h_{\text{ASI}}) = \begin{cases} 
F_{\text{filter}1}(h_{\text{ref}}, h_{\text{ASI}}) & \text{if } |h_{\text{ASI}} - h_{\text{ref}}| \leq 1.5 \text{ km} \\
F_{\text{filter}1}(h_{\text{ref}}, h_{\text{ASI}}) \geq \text{mean}(F_{\text{filter}1}) & \text{else.}
\end{cases}$$

Joint frequencies in these grid cells are considered to have a comparably high accuracy. To avoid a loss of precision and ultimately a loss of accuracy in the estimation of CBH, a small value of $\sigma_{\text{confident}} = 0.1$ km is used. The three filtered modes $g_k$ are summed to receive the smoothed joint frequency distribution:

$$F_{\text{filter}2} = g_{\text{median}}(F_{\text{median}}) + g_{\text{mean}}(F_{\text{mean}}) + g_{\text{confident}}(F_{\text{confident}}).$$

For all grid cells, joint frequency is increased to a minimum of 0.5 to avoid underestimations of joint frequency. This value is chosen to be half of the joint frequency associated with a single actual observation in a grid-cell.

Each joint frequency distribution is normalized with the sum of all joint frequency grid cells. In this way, a probability mass function $P(h_{\text{ref}}, h_{\text{ASI}})$ (also known as discrete density function) to measure a certain CBH with the respective ASI-pair and to coincidentally measure a certain CBH with the ceilometer is yielded. The conditional probability $P(h_{\text{ASI}} | h_{\text{ref}})$ to receive a certain CBH reading from an ASI-pair, given that the ceilometer measures some certain CBH, is calculated by dividing the respective probability mass function by the marginal distribution of CBH measured by the ceilometer. The latter distribution gives the probability to receive CBH from the ceilometer within a certain bin $h_{\text{ref}}$, regardless of which CBH reading is simultaneously received from an ASI-pair. The distribution can be derived from any of the probability mass functions by summing all grid cells of the probability mass function which correspond to the respective bin $h_{\text{ref}}$ of CBH measured by the ceilometer.

The inference procedure represents each range $i$ of camera distance bounded by the limits $\{0.5, 1.15, ..., 6\}$ km by a single distribution of conditional probability. For each range of camera distance, the distribution of conditional probability, which corresponds to the camera distance closest to the center of this range, is selected. For example, for the range $i = 2$ representing camera distances $1 ... 1.5$ km, the center of the range would be $1.25$ km. For the camera distances 1.081, 1.247 and 1.352 km, conditional probabilities have been modeled. Consequently, for this range of camera distance, the distribution of conditional probability corresponding to the camera distance $1.247$ km is used.

Major comment 2
Reviewer:

A similar comment goes also for the discussion part: It should be made much more concise, focusing on key results. Moreover, the stated aim of the proposed method is to assist nowcasting, and thus the authors should add an evaluation of the single measurement accuracy of the network. I.e. if the network outputs a CBH value of $h$, what is the uncertainty of this estimate? It is good that the network shows small overall biases in a three month period, but it wouldn’t be of much use if the correct CBHs were measured at the wrong times.

Authors’ response:
We reworked the validation part strongly, intending most of all to focus on the key results. Still, we also needed to add passages at some points as further discussions or clarifications were suggested by the reviewers.

As suggested, we included an additional subsection which evaluates the accuracy of an ASI-pair and of the ASI network for the nowcasting application as suggested above. We agree with the reviewer that this is an interesting aspect, which attests a certain advantage of the ASI network for this application.

In particular, we made the following larger changes to the discussion part (Sect. 4):

- The behavior of the ASI network during mostly clear periods has been detailed and described more precisely.
- The discussion of exemplary time series of CBH has been limited to a single day. Descriptions and visualizations of 06 August 2019 have been moved to Appendix B.
- To give the reader a faster overview of the results (and also based on Reviewer Comment 1, Minor Comment 7) scatter-density plots have been enhanced to include performance metrics and quantiles
- Discussion of minimum CBH has been condensed and has been placed in Sect. 4.2.1 also relating it to the expectation from geometry.
- Sect 4.3, evaluating accuracy in a nowcasting context, was added
- Based on Reviewer Comment 1, General comment 3, we described which portion of the validation data set was filtered out
- Based on Reviewer Comment 1, General comment 7, we discussed the relationship between the accuracy of CBH and the resolution of irradiance maps created by a nowcasting procedure.
- We merged the prior “Sect. 4.4” with the present Sect. 4.4, intending to shorten discussions as far as possible.

We hope to have found a reasonable trade-off regarding the length of this section. As another measure to shorten the discussion part, Sect. 4.1, which analyzes time series of CBH from the different sources, could still be moved to the Appendix. This section is majorly intended to give the reader concrete examples of the effects discussed thereafter by statistical tools.

Changes in manuscript:

pp. 20-34
Validation of CBH measurement by the ASI network and comparison to CBH measurements by the ASI-pairs

In this section, the accuracy of CBH measurement by the ASI network and by 42 independent ASI-pairs set up at a wide variety of camera distances and alignments is compared. This section is based on a validation data set including the days from 30 June 2019 to 27 September 2019. This dataset was excluded from the model development described in Sect. 3. The analyzed quantity is 10 min-median CBH. The evaluations are restricted to times in which the variability of CBH is small. More precisely, the standard deviation of CBH within a window 10 min before and after the analyzed time is required to be less than 30% of mean CBH within the same window. As discussed above, the ASI-pairs and the ASI network are expected to measure a spatial median CBH whereas the ceilometer measures CBH at the point of its installation. This restriction aims to assure comparability of both measurements.

First, characteristics of CBH measurements from the ASI network and from individual ASI-pairs are compared to the CBH measurement of the reference ceilometer based on insightful days. Then, the coincidence of CBH measured by ASI network and ASI-pairs with CBH measured by the ceilometer is analyzed and compared to the one of the ceilometer by scatter-density plots. Subsequently, CBH derived by the network and by all individual ASI-pairs are validated against the ceilometer by RMSE and BIAS. Finally, these deviation metrics received validation metrics of CBH received from the network and from all individual ASI-pairs per interval of CBH are discussed.

![Diagram](image)

**Figure 6.** Time series of cloud base height for two exemplary days/day (02 September 2019) measured by 42 ASI-pairs (grey filled), by two exemplary ASI-pairs DON-MAR and CLO-FLE with respective camera distances 0.8 and 4.2 km, by the ASI network with refinements and by a ceilometer in the urban area of Oldenburg.

4.1 Comparison of CBH measurements for two exemplary days/day

**Figure 6 bottom:** We first analyze the properties of the different procedures to measure CBH based on exemplary situations. Fig. 6 visualizes time series of CBH for a variable day (02 September 2019) measured by ceilometer, by all available ASI-pairs and by the ASI network. The time series of two exemplary ASI-pairs DON-MAR and CLO-FLE with respective camera distances 0.8 and 4.2 km are plotted. The range of CBH readings covered by all available ASI-pairs is shaded grey in the figure. The day features a high cirrus cloud layer which is later obscured by a low cumulus cloud layer. Occasionally, the low layer opens and the high layer is observed. Towards the evening, the sky becomes mostly clear.
In the morning (06:00), both ceilometer and the ASI network recognize adequately a high cloud layer. The ASI-pairs with valid measurements deliver similar estimations of CBH. Around (07:00), the ceilometer still recognizes the high layer whereas many ASI-pairs as well as the ASI network recognize the approaching cumulus clouds. These already cover a significant fraction of the sky in the urban area (compare Fig. 7, center left). The CBH estimation approach tends to react stronger to clouds in this area of the sky in which contrasts are typically pronounced. Around 10:20 a multilayer situation is present. In the whole sky dome cumulus clouds are visible but a large fraction of the cloud cover is made up by the cirrus layer. Around this time the measurements of ceilometer and ASI network coincide well. All ASI-pairs recognize a rather low cloud layer while there are periods in which the ceilometer recognizes the cirrus layer. All of the ASI-based CBH estimations react stronger to the low layer and miss the high layer clouds. These two situations impress well why the ASI-based estimations of CBH are less accurate for higher clouds and tend to be negatively biased. On the other hand, for low clouds a high accuracy of the combined CBH estimation is demonstrated.

Meanwhile, it is visible that, for low clouds, many ASI-pairs such as ASI pair CLO-FLG, tend to overestimate CBH. In these conditions, the ASI network manages well to follow appropriate estimations.

Around 17:00, a nearly clear sky is visible (compare Fig. 7, right). Consequently, the ceilometer does not provide any valid CBH. The ASI-pairs provide a CBH that scatters over a wide range, while the ASI network provides a CBH that is assumed to be reasonable. The an intermediate CBH, A similar reading of CBH is also recognized by a fraction of the ASI-pairs. From around 17:05, the ASI network detects a CBH of 3 km. With 3.1 km, the following CBH measurements of the ceilometer around 17:50 confirm the suggested CBH of the approaching cloud layer (see Fig. B1 for a detail view of the CBH measurements during this almost clear sky period). This situation reflects the expected behavior of the ASI network under mostly clear conditions. However, for a completely clear sky, the ASI network partly produces invalid readings (NaN) and partly it detects a large CBH of around 10 km. In this case, a consecutive image processing step detects the absence of clouds. This step is not part of the present study.
Figure 6 top shows CBH on 06 August 2019 again measured by ceilometer, by all available ASI-pairs and by the ASI network. This day, similar to 02 September 2019, discussed previously, includes multi-layer conditions with high layers overlaid by low layers, resulting in similar observations. In the morning and evening high cloud layers are dominant. The CBH of these varies in the range of 7...11 km according to the ceilometer. The range of CBH from ASI-pairs reflects this spread. Still, it is not obvious which of the ASI-pair based observations would be the most appropriate. From the ASI network a rather steady CBH estimation results which most of the time reflects the dominant CBH layer as recognized by the ceilometer. The combined estimation misses physically meaningful variations of CBH typically towards higher values recognized by the ceilometer. Also for this day time series of CBH and corresponding ASI images were compared. Again large underestimations of CBH by the ASI network (at 05:30, 08:15, 10:00, 12:30, 16:00) were traced back to the ASI-based estimations responding stronger to lower optically denser low cloud layers which pass the vicinity of the urban area (compare Fig. 7, left).

The time series of CBH from DON-MAR and CLO-FLE demonstrate the properties of ASI-pairs with respectively small and large camera distance. DON-MAR is typically close to the reference CBH if it actually takes on a value below 4 km (e.g. 02 September 2019 9:00...13:00) while this ASI-pair tends to take on large deviations and a negative BIAS for larger CBH (e.g. 02 September 2019 6:00...9:00). ASI-pair CLO-FLE typically misses the CBH of low clouds and provides a significantly underestimated CBH (e.g. 02 September 2019 9:00...13:00). For high clouds, however, CBH measured by CLO-FLE often coincides well with the reference. However, for CLO-FLE as in general for the ASI-pairs, high layer clouds are missed if low layer clouds are present (e.g. 02 September 2019 6:00...9:00). To give further insight, in Appendix B2, timeseries of CBH from the different sources are compared for another exemplary day.

4.2 Comparison of CBH measurements by relative frequencies

In the following deviations found for two Deviations found for the exemplary ASI-pairs DON-MAR and UOL-HOL with camera distances of 0.8 km and 5.7 km as well as for the ASI network, with and without without and with the refinements described in Sect. 3.3, are now analyzed with the help of scatter-density plots provided in Fig. 8. The plots visualize the relative frequency of CBH measured by the respective ASI-based systems given a CBH measured by ceilometer. Thus, relative frequencies in each of the columns add to one. The plots also include the median (red dotted), limits to the interquartile range (IQR, red dashed) and 5...95... percentiles (red solid line) based on floating 1000 m-bins of CBH from the ceilometer. Each of the subplots further indicates performance metrics of the individual systems: Root mean squared deviation (RMSD), BIAS and coefficient of correlation (\( \rho \)).

4.2.1 ASI-pairs

The readings of ASI-pair DON-MAR, (Fig. 8 upper row, left) with camera distance 0.8 km exhibit significant scattering of the CBH readings. Additionally, CBH from the are well aligned with the main diagonal up to a reference CBH of around 4 km. As reference CBH increases further, the ASI-pair increasingly underestimates CBH, indicated e.g. by the median. On the contrary, ASI-pair UOL-HOL, (Fig. 8 upper row, right), overestimates CBH massively if reference CBH decreases below 3 km. Whereas based on the median value, its readings are well aligned with the reference at larger CBH.

23
Both ASI-pairs exhibit a strong scattering of the measurements, clearly visible from the wide spread of the quartiles as well as of the 5-95 percentiles. In agreement with the prior finding, DON-MAR is rather precise at low CBH (< 3 km), whereas UOL-HOL is notably more precise at greater CBH. CBH from the ASI-pairs often deviates towards very low CBH. This
feature is in part also seen for the ASI-network (Fig. 8 bottom row) low CBH, when the ceilometer measures CBH in the range 3–12 km. In this range, the 5-quantile of ASI-based CBH increases only slightly with reference CBH and comparatively large relative frequencies are found close to the 5-quantile. As discussed before in Sect. 4.1, this can in part result from low cloud layers which are actually present in the ASI-pairs’ field of view but not at the ceilometer’s location. Towards high readings of the reference (> 8 km) DON-MAR underestimates CBH for most readings.

CBH measured by ASI-pair

Qualitatively, the effects seen meet the expectation from the literature (Nouri et al., 2019a; Kuhn et al., 2019; Nguyen and Klets, 2019). ASI-pairs with large camera distance are expected to be more accurate when measuring the CBH of high clouds. On the other hand, ASI-pairs with large camera distance are expected to be less accurate for small CBH values and are expected to exhibit a larger minimum CBH, below which no physically meaningful readings are received. From the geometric considerations in Sect. 3.1, a minimum CBH of about 0.18 \( \times d \) was expected. Where \( d \) is the camera distance. For UOL-HOL, which has a camera distance of 0.7 km, it is visualized in Fig. 8 upper row, right. CBH measured by UOL-HOL scatters a significantly larger minimum CBH of about 2 km is evident. If reference CBH is smaller than 2 km, the ASI-pair yields measurements of CBH which scatter randomly around a median value of 0.5 km for reference CBH < 1.5 km. If reference CBH ranges between 1.5–5 km, this behavior is still observed for a significant part of the readings. For UOL-HOL, nearly no reading of less than 0.5 km is recognized. In general, strong scattering is seen for this ASI-pair. However, towards large values of reference CBH the measurement appears to scatter to a smaller extent and especially for very large CBH (> 8 km) a satisfying agreement of CBH from ASI-pair and ceilometer is seen; median value of 4 km. This behavior can be explained as the matching procedure fails if pattern are matched which are located at a larger zenith angle than a maximum value. Consequently, random features observed under a zenith angle smaller than the maximum value are often matched erroneously which yields a too large estimation of CBH. Similarly for DON-MAR a minimum CBH of around 0.3 km is suggested.

The measurement of CBH by the ASI-network without refinements is shown in Fig. 8. The ASI-pairs are characterized by a minimum CBH in the range of 0.3–2 km. As described above, this suggests that the matching procedure of the ASI-pairs almost always fails if matched windows cover zenith angles larger than 67°. Further, also for reference CBH close to this minimum CBH, the ASI-pairs yield increased deviations, e.g., below 0.5 km and 3 km for DON-MAR and UOL-HOL.

4.2.2 ASI network

Based on Fig. 8 bottom row, left. The mode of the relative frequency distribution is the median values of the ASI network are well aligned with the main diagonal for most-reference CBH. As indicated by the quartiles, the ASI-network’s precision is similar to that of an ASI-pair with small camera distance, such as DON-MAR, for reference CBH < 2 km. For larger CBH, the network’s precision is closer to the one of an ASI-pair with large camera distance, such as UOL-HOL. Additionally, outliers are less frequent and occur with smaller deviations compared to the ASI-pairs discussed before. The ASI-network returns no reading of CBH of more than 10.9 km. Thus, CBH is underestimated if a corresponding reference CBH is present.
In the range of reference CBH > 10 km, the ASI network constantly returns CBH of around 10 km. In the studied climate (see Fig. 4) and accordingly in the dataset used for modeling readings of reference CBH in this range are comparatively rare. Therefore, conditional probabilities used in the estimation are modeled inaccurately. The estimation procedure uses cumulative — compared to the range of likelihood, this avoids frequent strong (see Fig. 4). Therefore, corresponding grid cells of the conditional probability distributions, used by the estimation procedure, were approximated coarsely based on a small number of observations. The ASI network’s combination method using cumulative likelihood is intended to avoid deviations resulting from these inaccuracies and yields, thus, to yield a more conservative but in this case biased estimation of CBH estimation. However, this approach also suppresses the estimation of extreme CBH readings, which causes a bias under these conditions. For the analyzed site, deviations found in this range of CBH are of minor importance. For low values of reference CBH, ASI network and ASI-pair DON-MAR both appear to perform similarly at high accuracy. Only for very low values of reference CBH (especially CBH < 0.5 km) with CBH < 0.3 km), the ASI network a large share of strong deviations is recognized. This deviation is connected to without refinements overestimates CBH drastically. None of the minimum CBH which is indicated as mentioned ASI-pairs used has a sufficiently small minimum CBH for this range. We expect that the ASI network’s accuracy would be enhanced significantly, especially in this range, if ASI-pairs with smaller camera distance than 0.8 km were added.

To improve shortcomings connected to conditions with very low clouds (CBH < 1 km), the refinements introduced in Sect. 4.1 for EOL-FLE but also for any other ASI-pair. Minimum CBH will be further detailed in the following sections. Applied as indicated by Fig. 8 bottom row, right, these refinements significantly improve the ASI network’s performance for reference CBH < 2 km. In this range, the ASI network behaves for the greatest part like ASI-pairs with a very small minimum CBH are underrepresented in the set of available ASI-pairs. The smallest minimum CBH is provided by ASI-pair DON-MAR and MAR-DON ranging at 0.5 km. Thus, the estimation of CBH from the ASI network is dominated by ASI-pairs which are not capable to cover the range of very small CBH. MAR-DON. The refinements do not affect the statistics notably for reference CBH > 2 km. Overall, this evaluation indicates, that the ASI network performs significantly better than an individual ASI-pair, especially if the whole range of studied reference CBH 0...12 km should be covered. This is also indicated by the performance metrics shown in Fig. 8.

To meet these shortcomings, refinements to

4.3 CBH accuracy under nowcasting conditions

The procedure to estimate CBH, developed here, will be used as part of a nowcasting system. In this application, it is of special interest to be aware at any time which accuracy can be expected from a specific reading provided by the procedure have been proposed. ASI-network. For this purpose, Fig. 9 shows the relative frequency of CBH measured by the ceilometer given a specific ASI-based estimation of CBH. In each row, the frequencies add up to one. It should be noted, that the performance indicated by this evaluation is more dependent on the local cloud conditions than the one in Sect. 4.3. With these adoptions the CBH measurements shown in Fig. 8 bottom row, right are received. The adoptions noticeably affect measurements if reference CBH is smaller than 0.5 km and most pronouncedly if reference CBH is smaller than 0.75 km. In the latter range 4.2, we analyze
the systems which are best in class: ASI-pair DON-MAR (Fig. 9, left) and the ASI network with refinements (Fig. 9, right). As in the previous section, the plots also include the median (red dotted), limits to the interquartile range (IQR, red dashed) and 5-95 percentiles (red solid line) based on floating 1000 m-hits of ASI-based CBH.

Under most conditions included in Fig. 9, median and interquartile range indicate a good alignment of the CBH estimation from the ASI-network and of CBH from the ceilometer. For ASI-pair DON-MAR, a notable negative BIAS is indicated if the ASI-pair returns a CBH of 9 km or more. Also, if a CBH of more than 4 km is detected, the interquartile range indicates a notably increased precision of the ASI network, as does for the greatest part like ASI-pairs DON-MAR and MAR-DON. Conversely, the ASI network keeps its advantages over these ASI-pairs for larger CBH as described above.

Based on Fig. 9, both systems are considered suited for an application in nowcasting at the studied site, while a considerable uncertainty is present. The ASI-network provides a notably improved accuracy in particular in cases when clouds at a CBH > 4 km are detected.

Figure 10. RMSE (left) and BIAS (right) for five ranges of CBH received for all individual ASI-pairs (dots), for the ASI network without (circles), with refinements (diamonds) and for a basic average of CBH measured by all ASI-pairs (horizontal line).

The statistical evaluations are now restricted to times in which the variability of CBH is small. More precisely, the standard deviation of CBH within a window 15 min before and after the analyzed time is required to be less than 30% of mean CBH.
within the same window. As discussed above, the ASI-pairs and the ASI network are expected to measure a spatial median CBH whereas the ceilometer measures CBH at the point of its installation. This restriction aims to assure a good comparability of both measurements. Further, this way our results are more comparable to a prior study by Kuhn et al. (2019).

Accuracies of CBH measurement by ASI-pairs and ASI network are analyzed separately for five ranges of reference CBH defined by the bounds \(0, 1, 2, 4, 8, 12\) km. The number of CBH measurements included in this evaluation is given in Table 1 for each of these ranges. The interval bounds are spaced irregularly to correspond better to the distribution of CBH at the site (see also Fig. 4). Table 1 also shows the number of observations excluded from the validation as significant temporal variability of CBH was detected for these observations. While a significant fraction of the readings is sorted out, the representation of the CBH range remains widely comparable to the original data set (see Fig. 2, left). Only the range of lowest CBH \(< 1000\) m is represented by a notably smaller share of the validation data set.

### 4.4.1 Accuracy of the ASI network and ASI-pairs

Figure 10 compares RMSD (left) and BIAS (right) for CBH estimated by the ASI network, with (diamonds) and without refinements (circles) described in Sect. 3.3, to the one estimated by all ASI-pairs (dots). As implied by the findings from Sect. 4.2, the final results from the ASI network provide the ASI network with refinements provides measurements of CBH that are the most accurate or at least among the most accurate ones for all conditions. In terms of RMSD the estimation from the ASI network is the most accurate for the range of CBH \(\in [1, 8]\) km (see Fig. 10 left). For CBH \(< 1\) km it is slightly outperformed by two ASI-pairs (DON-MAR, MAR-DON) as well as for CBH \(> 8\) km by two other ASI-pairs (UOL-CLO, CLO-UOL). ASI network-based measurement of CBH provides among the smallest BIAS for CBH \(< 8\) km (see Fig. 10 right). The magnitude of BIAS ranges constantly below 100 m. Only for CBH \(> 8\) km the ASI network independently from applied corrections yields a BIAS of roughly \(-1050\) m that corresponds to the average BIAS of all used ASI-pairs for these conditions. This deviation was traced back to situations in which the ASI-based measurements of CBH missing high layer clouds in the presence of low layer clouds in Sect. 4.1 estimation of CBH recognizes a low cloud layer whereas the ceilometer also recognizes a high layer when gaps in the low layer appear. Therefore, this deviation is rather related to the different nature of the measurements (spatial-median compared to point-wise).

RMSD (top) and BIAS (bottom) received by 42 ASI-pairs utilizing camera distances in the range of 0.8...5.7 km and by the ASI network with refinements (no camera distance applicable) for the period 30 June 2019 to 27 September 2019. Figure 11 also provides deviation metrics received from the ASI network and the distance between the cameras used by an ASI-pair and the reference ceilometer were considered as an influence on the accuracy of an ASI-pair. However, for the ASI-pairs but distinguishes the latter by camera distance. Metrics of studied, this distance to the validation site is not confirmed as a significant influence on received accuracy. This was expected in part from the ASI network, with refinements, are given by horizontal lines. For small CBH (CBH \(< 4\) km) camera distance clearly influences accuracy measured by RMSD and BIAS causing those metrics to increase steadily with camera distance. Apart from this influence metrics of the studied assumption that the ASI-pairs are very similar in this range of CBH measure the median CBH of the most dominant cloud layer in terms of features, driven by area and optical thickness.

29
For intermediate and large CBH (1...12 km) the correlation of camera distance and accuracy is not as clear—a slight trend seen in As shown in Fig. 10, without the refinements, in the range CBH < 1 km 12 ASI-pairs with camera distance up to 1.6 km perform better than the ASI network in terms of RMSD and BIASs overlaid by strong scattering. The variation of error metrics found between these systems may indicate further influences of the setup on accuracy apart from As discussed in Sect. 4.2, in this range of reference CBH the ASI network could be improved by ASI-pairs with even smaller camera distance. The lower frequency of observations of intermediate and large CBH is expected to cause a part of the observed scattering of the metrics between the various applied refinements improve the accuracy notably. Figure 10 includes the error metrics received when simply averaging CBH measurements of all ASI-pairs. Firstly, sporadic large errors may occur only in some of The ASI network in both variants, with and without refinements, provides a significantly more accurate estimation of CBH in terms of RMSD and BIAS in most ranges of CBH compared to the simple approach. The individual ASI-pairs and also the ASI-network exhibit an RMSD of more than 180 m for all ranges of CBH. Based on this, we do not expect that the bin size of 100 m chosen for the distributions of conditional probability in Sect. 3.4 is a limiting factor to the accuracy of the evaluated systems and dominate the received metrics for these. Secondly, from the statistics and from an inspection of the ASI images observations of higher CBH layers are likely to be found in the presence of a lower layer. As discussed in Sect. 3.4 the ASI-based estimation of CBH in this study. Meanwhile, the underlying ASI-pairs measure CBH of the most dominant cloud layer in the sense of optical thickness and area in the analyzed field of view of the sky. When for example, a CBH of 10 km is present the corresponding spatial area included has side lengths of 15.7 km. For multi-cloud-layer conditions it is likely that within this window lower clouds are present which are recognized by an ASI-pair instead. More aggressive filtering of such multilayer situations included in the evaluation could reduce this influence but would further limit the database. The distance between the cameras used by an ASI-pair and the reference ceilometer are not found to have a significant influence on received accuracy in the evaluated data set. This was expected in part from the previously discussed effect that the can nowcast 30 s-averages of solar irradiance at a spatial resolution of 5 m × 5 m. According to the considerations of Nouri et al. (2019b) and with the sun elevations occurring at the site, deviations in CBH may cause deviations in the positions of cloud shadow edges of at least 100 m under favorable conditions for the ASI-pairs measure CBH of the most dominant cloud layer and also for the ASI-network. This deviation is much larger than the spatial resolution of these maps of solar irradiance. For certain applications, e.g., to control solar power plants (Nouri et al., 2020a), it may still be advantageous to provide maps of solar irradiance at a resolution finer than the uncertainty of cloud shadow edge positions, as the statistical properties of spatial variability may still be captured in these maps. Based on these findings the ASI-network combines the favorable properties of the involved-

4.4.2 Influence of the camera distance on performance metrics

Lastly we discuss how camera distance influences the performance metrics of the ASI-pairs. Over a single ASI-pair an improvement in accuracy is found as no ASI-pair can optimally cover the whole range of relevant CBH. With the achieved accuracy of the CBH measurements under all conditions at least a classification of the present cloud height is possible. CBH measurement by the ASI-network is found to provide a small BIAS if CBH < 8 km is of interest. Therefore and given the
Figure 11. RMSD (top) and BIAS (bottom) received by 42 ASI-pairs utilizing camera distances in the range of 0.8...5.7 km and by the ASI network with refinements (no camera distance applicable) for the period 30 June 2019 to 27 September 2019.
different nature of both measurements, the accuracy of CBH in different ranges of CBH and compare these results those of Kuhn et al. (2019) who studied the accuracy of ASI-pairs with camera distances in the range of 0.5, 2.56 km. Figure 11 provides RMSD and BIAS received from the ASI network is expected to improve further if an average CBH over a range of hours is of interest.

4.5 Discussion of deviations in CBH measurement

For low CBH (CBH < 2 km) accuracy of the measurement by and ASI-pairs decreases with and distinguishes the latter by camera distance. This meets the expectation from Kuhn et al. (2019). Kuhn’s study was limited to a maximum camera distance of 2.56 km. Additionally, Metrics of the ASI network, with refinements, are given by horizontal lines. Kuhn et al. (2019) analyzed the accuracy of CBH measurement was only analyzed for three ranges of CBH defined by the limits {0, 3, 8, 12} km.

We noticed that a finer classification of CBH as used Overall, in the present study yields more insights for small CBH. Figure 8 upper row provides the relative frequency of CBH readings from two exemplary ASI-pairs given a reference CBH. The camera distances of the ASI-pairs are 0.8 km (left) and 5.3 km (right) respectively. For reference CBH below a minimum value of around 2 km the ASI-pair with camera distance 5.3 km in most cases provides unreasonable readings scattering around 5.8 km.

For ASI-pairs with smaller camera distance a similar behavior is observed while the respective minimum CBH reduces with reduced the magnitudes of RMSD and BIAS range well below the values found by Kuhn et al. (2019).

For the CBH ranges 0...1 km and 1...2 km, Fig. 11 shows that BIAS is very small for ASI-pairs with small camera distance. Accordingly, both RMSD and BIAS steadily increase. However, beginning at a camera distance of around 1.1 km and 2.5 km respectively, BIAS increases linearly with camera distance as shown in Fig. 11 for CBH ∈[0, 1] km. Even for the, Consequently, the same trend is visible for RMSD in these ranges of CBH. From the analysis in Sect. 4.2, this effect is clearly connected to the minimum CBH specific to an ASI-pair with camera distance 0.8 km a significant minimum CBH of 0.5 km is found (compare Fig. 8, left). In line with the discussion above for CBH ∈[1, 2] km both metrics only increase from a camera distance of 2.5 km on the camera distance. While the in study of Kuhn et al. (2019) the lowest CBH range covered 0...3 km, which reduces the influence of minimum CBH, a qualitatively similar relationship of camera distance and accuracy was found. Minimum CBH of

For intermediate and large CBH (1...12 km) the ASI-pair for this camera distance is identified to be 1/km correlation of camera distance and accuracy is less clear – a slight trend seen in RMSD and BIAS is overlaid by strong scattering. The variation of error metrics found between these systems may indicate further influences of the setup apart from camera distance. On the other hand, the limited set of observations of high clouds may not be sufficiently representative to identify the influence of camera distance in the presence of other disturbances present in this benchmark, such as low clouds which may be present in spite of the applied filter.

For intermediate and large CBH (Overall, in the range of CBH > 4 km), increased camera distance slightly improves the accuracy of CBH estimation. On average a reduction in RMSD of 500 m is suggested over the interval of studied camera distances. No significant influence is noticed for BIAS. From Kuhn et al. (2019) the influence of camera distance on accuracy was expected to be more significant in this range of CBH. The influence of CBH on accuracy of the measurement considers

Line 85: Is the 3-month period enough to monitor all available conditions? What would be a suggestion to other users about the range of conditions that needs to be captured for good training?
Authors' response:

One idea of our method was that it should not be necessary to train the model based on a dataset which represents the conditions during the operation or validation. The method should work best if the ASI-pairs exhibit the same behavior at a given reference CBH during model development and validation. I.e. distributions of conditional probabilities at a given reference CBH should be comparable for both data sets.

Apart from that the data sets used for modeling and validation are both considered to be qualitatively representative of the months which are of greatest interest to solar applications at the studied latitude, as they may provide the greatest energy yield, based on sky conditions and sun elevation.

Changes in manuscript:

p. 17, ll. 412-418:

29 June 2019 are used. CBH measured by the ceilometer serves as reference CBH. It is considered not to be essential that the training period is representative of the period to which the method is applied. However, we expect that the method works best if the included ASI-pairs exhibit a similar distribution of measurement deviations given the same reference CBH in both periods. For solar applications and the latitude of this study, we consider the used dataset and its split reasonable. The summer and shoulder months provide the main share of the annual solar yield at the site and are therefore in the focus of the nowcasting system under development. In that sense, the training dataset is considered to be for the large part representative of conditions relevant to solar applications at similar latitudes.

Reviewer:

Line 108: “by arbitrary selecting a tuple of ASIs”. From the text, you seem to be selecting all possible combinations of ASIs not only some arbitrary pairs. Moreover, I am not sure if tuple is the proper name as, in my mind, a tuple could include more than 2 objects. Consider rephrasing.

Authors’ response:

The description we used was misleading and should be understood as indicated by the reviewer. We replaced the term by “iteratively”. Further we now pointed out in the same paragraph, that all 42 ASI-pairs are considered for the estimation procedure.

Indeed, the term tuple is not precise. Throughout the text, tuples are intended to have only two members. We replaced the term in general by “tuple of 2 ASIs”.

Changes in manuscript:

p.1 l.10:

10 In this study, the deviations of 42 ASI-pairs are studied in comparison to a ceilometer and characterized by camera distance. The ASI-pairs are formed from seven ASIs and feature camera distances of 0.8...5.7 km. Each of the 21 ASI-pairs consists of two ASIs formed from seven ASIs yielding two independent ASI-pairs as the ASI used as main and auxiliary camera respectively is swapped. Deviations found are compiled into conditional probabilities telling how probable it is to receive a certain reading.

p. 5 ll. 127-131:

For this study, these ASIs are arranged into several ASI-pairs as defined by arbitrarily selecting a tuple of ASIs (two ASIs out of the 21 tuples are available) and forming two independent ASI-pairs from each tuple by swapping its main camera. The main camera of an ASI-pair is central to the measurement of CBH through an ASI-pair, described in more detail in Sect. 3.4.1, and defines the center of the area for which CBH is estimated. From 21 ASI-pairstuples of 2 ASIs, 42 ASI-pairs are received. All 42 ASI-pairs are included in the estimation procedure. The paired cameras’ distance and the orientation of the camera-ASI-pair’s axis characterize the ASI-pairs. The orientation of a camera-ASI-pair’s axis is defined.

p. 6, caption of Fig. 6:

Figure 2. Frequency distribution of camera-axis the bearing angles of the ASI-pairs’ axes in the set of available ASI-pairs (over north, left) and of available camera distances (right) resulting when arranging the seven ASIs in the urban area into 42 ASI-pairs (from each ASI-pair tuple: two different ASI-pairs result by switching the main camera, counts of ASI-pairs with switched main camera are marked orange, striped.

p. 17 l. 419:

The seven ASIs available in the urban area are arranged into 42 ASI-pairs. Each tuple of two ASIs, that is selected from the set of seven ASIs, yields 2 independent ASI-pairs by swapping the ASI used as main camera (see Sect. 3.1).

Specific comment 3
Reviewer:

Line 111: “Camera axis”. Does this refer to the line connecting the two ASIs that form a pair? If yes, then it should be called “pair-axis” or similar. “Camera axis” sound to me as the name for the direction that a single camera is looking.

Authors’ response:

Indeed, the term is ambiguous and was adapted now to “ASI-pair’s axis”.

Changes in manuscript:

pp. 5-6 ll. 132-135, caption Fig. 2:

more detail in Sect. 3.4.1, and defines the center of the area for which CBH is estimated. From 21 ASI-tuple-stuples of 2 ASIs, 42 ASI-pairs are received. All 42 ASI-pairs are included in the estimation procedure. The paired cameras' distance and the orientation of the camera ASI-pair's axis characterize the ASI-pairs. The orientation of the camera ASI-pair's axis is defined as seen from the main ASI and given in degree north. Figure 2 shows the distribution of orientations of camera ASI-pair's axes (left) and camera distances (right) in the set of available ASI-pairs. This set covers almost all possible orientations of camera

\[\text{Figure 2. Frequency distribution of camera ASI-pair's axes.}
\]

Available camera distances 0.8...5.7 km cover most of the range 0.02...5.5 km that is used in literature (Kuhn p. 33 ll. 798, 800, 803, 805):

Beside camera distance the further orientation of the camera ASI-pair's axis to the present direction of cloud movement was considered as an influence on accuracy in Kuhn et al. (2019). Based on that study ASI-pairs may measure CBH more accurately if their camera ASI-pair's axis is aligned with the direction of cloud motion. To study this effect the direction of cloud motion was retrieved from ASI UOL as discussed described in Sect. 3.2. Then the dataset was restricted to times in which clouds moved filtered to timestamps with cloud motion from west to east. Accuracies of ASI-pairs with similar camera distance but different orientation of the camera ASI-pair's axis were compared. In this comparison no correlation of camera alignment over the direction of cloud motion and accuracy was recognized.

For completeness, please provide some more information about the instrument: E.g. Is the instrument part of DWD network you mentioned before? How is the CBH calculated from the data? Are you using the manufacturer’s algorithm or a custom one? What is the minimum overlap height? What is the minimum height that CBH can be detected? References?

Authors’ response:

We added a short description about the used instrument. It is operated by DLR since 2018. The manufacturer’s algorithm is used with the default configuration. The algorithm is outlined in the instrument’s manual. The firmware version is v0.747. A prior study stated that full overlap is given at a CBH of 1500 m and above. Based on an overlap correction, the manufacturer allows to set a minimum CBH down to 0 m. We use the default setting of 45 m. We also contacted the manufacturer for further information on the used algorithms in the meantime but did not receive a response, yet. If required, this can be handed in at a later time.

Changes in manuscript:

p. 6, ll. 137-141:

The used ceilometer is of type LUFT CHM 15 k Nimbus+(firmware v0.747) is operated by DLR since 2018. CBH is measured by the manufacturer’s Sky Condition Algoritam (Luft, 2018) in the default configuration. Heese et al. (2010) specifies for a ceilometer of the same type, that full overlap of the laser’s and the receiver’s field of view is reached at a height of 1500 m. However relying on an overlap correction, the manufacturer specifies a minimum CBH of down to 0 m. In this study the manufacturer’s default minimum CBH of 45 m is used.

Reviewer:

Line 143-144: The accuracy discussion is not enough for an instrument sued as reference. The differences reported in Martucci et al. 2010 seem to be coming from different algorithm or even definition of CBH used by each instrument. Moreover, the bias they find is not only 160 meters, but also has a range component (Y=0.925X + 160). Finally, Martucci et al used a rather old model of the instrument you are using here. Therefore, you should give more details about the CBH algorithm used with Ceilometer data and discuss the possible differences in definition of CBH as used for ceilometer and for ASIs.

Authors’ response:

Indeed, there have been several updates to the firmware after 2010. Some of these indicate changes to the algorithm of CBH measurement. We now summarized the results of two more recent studies which evaluated the CBH measurement by the ceilometer type used here. Based on these authors’ findings, we also provided differences in the algorithms used by the manufacturers. Further, we explained that prior validations of the method used in this study to measure CBH by the ASI-pairs, were performed by an instrument of the same type. This may avoid inconsistencies when comparing the results of the present study to those prior ones.
Changes in manuscript:

pp. 7-9, l. 174-203:

Regarding the accuracy of the instrument, a benchmark by Martucci et al. (2016) exhibited a bias of the instrument in general. de Huij et al. (2016) and Görsdorf et al. (2016) noted that there is no generally accepted, quantifiable definition of CBH, yet. Further, due to a lack of reference measurements, benchmarks may typically focus on the consistency of CBH measurements by different types of ceilometers. In a benchmark performed by Martucci et al. (2016), the measurement of a Vaisala CL31 ceilometer CBH_{CL31} showed a significant deviation from the reading CBH_{LAD40} of the instrument compared to another manufacturer's ceilometer of 1.01 m. With this in mind, we still consider the instrument to be sufficiently accurate for the scope of this study.

This trend was given by CBH_{CL31} = 100.315 m + 0.925 × CBH_{LAD40}. However, the measurement procedure of the instrument used here, was modified by firmware updates in the meantime. Görsdorf et al. (2016) presented results from a more recent measurement campaign, CoLiEx2015, which took place in 2015. In this experiment, the measurements of six types of ceilometers were compared. For stratus and stratocumulus clouds as well as fog, deviations between the instruments of up to 70 m were observed. For each of these conditions, the CHM 15 k, used here, provided the smallest measurements of CBH in terms of mean deviation from the median of all tested instruments. More severe deviations of several kilometers between the instrument types were observed during conditions with heavy rain.

In an acceptance test, de Huij et al. (2016) measured CBH by two CHM 15 k, by a Vaisala LD40 ceilometer, by a UV lidar (Leosphere ALS450) and by visibility sensors mounted in various altitudes on a tower of 213 m height. For CBH of up to 200 m, the CHM 15 k typically measured a CBH 50...50 m smaller than the one of the LD40. However, the CHM 15 k was in better agreement with the estimate based on visibility sensors. Görsdorf et al. (2016) and de Huij et al. (2016) suggest, that the negative mean deviation of the CHM 15 k attested by all these studies, for clouds in the range CBH < 3 km, is mostly caused by the manufacturers’ algorithms to detect CBH from backscatter profiles. Whereas, according to the manufacturer (Lufft, 2018), the CHM 15 k detects the rising edge of a backscatter peak that exceeds a threshold, other manufacturers’ devices may rather recognize the peak’s maximum.

For the range of CBH in 3...12 km, an inspection of timeseries depicted by de Huij et al. (2016) indicates very good agreement of the measurements from CHM 15 k and the UV lidar, used there. As a further test of de Huij et al. (2016), performed at a resolution of 60 s, high clouds, detected by the UV lidar in a range of 6...7.5 km, were to be detected by the CHM 15 k within a tolerance of ±3 classes in bh code (WMO Table 1677). This tolerance corresponds to a CBH-range of ±105 m centered around the discretized reference CBH. CHM 15 k was attested a probability of detection of > 98% and a false alarm rate of 0%. Based on these studies, the accuracy of the reference instrument is expected to be adequate for the range of CBH < 3 km and also for the range of CBH > 3 km, a rather good performance of the instrument is indicated. The experimental results of this study will in particular be compared to prior studies which used a ceilometer of the same type. This is expected to avoid possible inconsistencies related to the used reference.

pp. 9-10, ll. 204-251
From all ASIs available in the urban area, we form independent ASI-pairs that measure CBH by a stereoscopic triangulation method. The method used here, which was introduced by Kuhn et al. (2018b) and further refined by Nouri et al. (2019a). The algorithm used here to estimate CBH by the individual ASI-pairs has been described and validated in the latter publication. Nouri et al. (2019a) evaluated an ASI-pair with a camera distance of 495 m. For four ranges of reference CBH, defined by the bin edges 0, 3, 6, 9, 12 km, RMSEs of 0.6, 1.4, 3.2, 3.1 km were found for 10 min average CBH. The study did not provide information on BIAS. Further, in that validation, higher clouds were more frequent and no observations at a reference CBH of less than 1 km occurred. The studies of Kuhn et al. (2018b) and Nouri et al. (2019a) were performed in Almeria, Spain. Both studies validated the ASI-based measurement of CBH using a ceilometer of type Luft CHM 15 k as reference. At this point we recapitulate aspects of the procedure which are important for the remaining publication. For a more detailed description, we refer to Nouri et al. (2019a).

Images from both cameras—ASIIs (e.g., UOL and FLE, see Fig. 3, left) are first projected into horizontal planes yielding orthogonal images (Fig. 3, center) by a well-established method described e.g. by Luhmann (2000). Then, the difference in the red-channel of consecutive images compared to the image recorded 30 s before is calculated for each camera of each ASI. Areas in the difference images of the two cameras, in which the red-channel changes most significantly (99-percentile) within the 30 s between consecutive images, are used as features (illustrated in Fig. 3, right) to be matched by block-wise correlation. With the known camera distance, a shift received in cross-correlation is translated into a height of the feature over ground.

In practice, the triangulation relies on cloud edges which are visible from both perspectives and provide sufficient contrast. Therefore, the method responds stronger to optically dense clouds, especially in the proximity of the sun (Kuhn et al., 2018b), as found by Kuhn et al. (2018b). Moreover, we do not exactly measure CBH but the height of these distinct cloud edges. We expect to introduce a small bias when using this cloud height as CBH. Nouri et al. (2019a) analyzed sources of deviations when estimating CBH by an ASI-pair. In accordance with that study, we expect this bias to be acceptable compared to other uncertainties and to be in the order of 100 m.

In the present study, according with the system used by Nouri et al. (2019a), we use a cascading procedure to estimate CBH robustly also in conditions with low sky coverage. We first project the field of view of each camera up to First, the main ASI's orthogonal image is restricted to a square-shaped area (Fig. 3, red dashed shape) defined by a maximum zenith angle of 67°,

measured at the center of each image side, into an orthoimage of square shape side of the square. In a cross-correlation, each of the nine squares confined by dotted or dashed lines (also known as windows, Fig. 3, bottom, right) from the orthoimage of the main ASI is matched with an area of identical shape from the orthoimage of the second ASI (Fig. 3, red dashed shape). In the correlation, the central area (or window, top, right). With the known camera distance, the shift is converted into a measurement of CBH.

If the estimation of CBH failed for one of the windows, valid readings from neighboring ones are averaged ignoring any window for which the estimation failed. In cases with no valid measurement in any of the windows, the orthogonal images of both ASIs are evaluated up to a maximum zenith angle of 77.8° (measured at the center of each image side, green shapes in Fig. 3, central red dotted box from ). These orthoimages from both cameras are matched in the cross-correlation and the ASI-pair returns a uniform CBH. This second step can yield a valid measurement of CBH in cases when only few clouds are present to be matched. This step mainly intends to increase the robustness of the CBH measurement. This step is not expected to increase the capability of an ASI-pair to detect very low clouds in relation to the camera distance, as the window size used in this step is very large.

As a modification of the orthoimage of the main camera is matched with a window of identical dimensions from the method by Nouri et al. (2019a), we only use CBH provided for the central point of the orthoimage of the second camera. This central main ASI, corresponding to a zenith angle of 0°. This procedure is followed for both the ASI-pairs and for the ASI network using these ASI-pairs. We expect that ASI-based measurement of CBH is most accurate for this central point. This point receives CBH primarily from matches involving the central window of the orthoimage-main ASI’s orthoimage, which is less affected by image distortion. The central window of the main camera-ASI’s orthoimage covers zenith angles up to 38.1°, measured at the center of each window side. Therefore, a CBH measurement for a square-shaped area around the main camera-ASI’s location is yielded. For example, the area’s side lengths measure 1.6, 4.7, 7.8, 15.7 km for a respective CBH of 1, 3, 5, 10 km.

Lines 161 – 176: Have you compared the results from the three method (center box, side boxes, full image) to validate your expectation that they yield similar results?

Authors’ response:

Unfortunately, we did not validate these sub-algorithms separately. As described in our response to Specific Comment 9 we now pointed out clearer that the method to estimate CBH, used by the ASI-pairs, is only modified very slightly over the publication which introduced this method and implementation:

Therefore, we would like to refer to this study for further validation results. As part of a future study, it would be interesting to investigate the characteristics of these sub-algorithms. In our expectation, CBH will be measured more accurately by matches which are detected at small zenith angles.

Further, CBH measurement received for this central image area, which is used here, were also in the focus of the validation carried out in the publication named above, due to the cloud conditions at that site and due to the positions chosen for ASIs and ceilometer.

Changes in manuscript:

p. 10, ll. 243-248:

As a modification of the orthoimage of the main camera is matched with a window of identical dimensions from the method by Nouri et al. (2019a), we only use CBH provided for the central point of the orthoimage of the second camera. This central main ASI, corresponding to a zenith angle of 0°. This procedure is followed for both the ASI-pairs and for the ASI network using these ASI-pairs. We expect that ASI-based measurement of CBH is most accurate for this central point. This point receives CBH primarily from matches involving the central window of the orthoimage-main ASI's orthoimage, which is less affected by image distortion. The central window of the main camera-ASI’s orthoimage covers zenith angles up to 38.1°, measured at the center of each window side. Therefore, a CBH measurement for a square-shaped area around the main camera-ASI’s location is yielded. For example, the area’s side lengths measure 1.6, 4.7, 7.8, 15.7 km for a respective CBH of 1, 3, 5, 10 km.

Lines 161 – 176: Please provide the relations connecting a) the ASI-pair distance with b) the minimum altitude that each method can be applied, due to purely geometric considerations.

Authors’ response:

We calculated the expected minimum CBH which can be detected relying on the central window as well as when relying on all of the nine windows inside the cropped image of the main ASI. We additionally calculated the minimum CBH which is achieved if matches only succeed if matched windows cover zenith angles not larger than 67°. We further stated that the third iteration of the matching procedure in which the ASI image is evaluated up to a zenith angle of 77.8° is not expected to reduce minimum CBH as this step matches a very large windows.

Changes in manuscript:

p. 10, ll. 236-242:

window for which the estimation failed. In cases with no valid measurement in any of the windows, the orthogonal images of both ASIs are evaluated up to a maximum zenith angle of 77.8° (measured at the center of each image side, green shapes in Fig. 3. central-red-dotted-box). These orthoimages from both cameras are matched in the cross-correlation and the ASI-pair returns a uniform CBH. This second step can yield a valid measurement of CBH in cases when only few clouds are present to be matched. This step mainly intends to increase the robustness of the CBH measurement, This step is not expected to increase the capability of an ASI-pair to detect very low clouds in relation to the camera distance, as the window size used in this step is very large.

p. 10-11, ll. 252-265:

If the estimation of CBH fails for: Only based on geometry and the evaluated image areas, this central window ; we use the CBH that is measured by matching the peripheral windows (Fig. 3, peripheral-red-dotted-boxes) of the same orthoimage with the orthoimage of the second camera. These peripheral windows of an orthoimage have the same shape as the central window (see could provide readings down to a minimum CBH of 0.25 \( \times \) d. Where d is the camera distance. However, under such extreme conditions the matching procedure may fail very frequently. The central peripheral windows, shown in Fig. 3. central peripheral-red-dotted-boxes). If a valid estimation of CBH is received for multiple peripheral windows, we use the average CBH from these windows.

For cases with still no valid measurement, images of both cameras are evaluated up to a maximum zenith angle of approximately cover zenith angles 38°-1.67°. The matched area from the auxiliary ASI’s orthogonal image has identical shape and can cover a zenith angle up to 77.8°(measured at). Based on this, we estimate the minimum CBH, which an ASI-pair can measure, to be 0.18 \( \times \) d. However, from our experience, a large fraction of clouds observed at zenith angles larger than 67° are not matched successfully between the ASIs and typically rejected. If the matching procedure could only be successful, if also the window of the second ASI included zenith angles not larger than 67°, then CBH could be measured down to 0.32 \( \times \) d using the peripheral windows and 0.64 \( \times \) d using the central window.

Line 303: Why use theta for true CBH and not a symbol based on h?

Authors’ response:

We adapted the nomenclature as suggested, as it may be clearer (replacing $\theta, \hat{\theta}, \theta_{\text{likeliest}}, \theta_{\text{refined}}$ by $h_{\text{true}}, \hat{h}_{\text{true}}, h_{\text{likeliest}}, h_{\text{refined}}$). Theta was used as this symbol may be used frequently with maximum likelihood estimation for the true/estimated parameter.

Changes in manuscript:

p. 14-15, ll. 337-350:

\[ P(\text{CBH} \mid \theta) = P(\text{CBH} \mid h_{\text{true}}), \] (red marked box prior to step 1 in Fig. 5). Note that $P(\text{CBH} \mid \theta)$ was $P(\text{CBH} \mid h_{\text{true}})$ will be modeled in Sect. 3.4 measuring CBH $h_{h_{\text{true}}}$ by a ceilometer which provided $h_{\text{est}} = \hat{h}_{\text{true}}$. Thus, the likelihood $L_i(\theta) - L_i(h_{\text{true}})$ is obtained (Fig. 5, output of step 1):

\[ L_i(h_{\text{true}}) = P(\text{CBH} \mid h_{\text{true}}). \] (1)

Step 2: Likelihood is defined as the cumulative likelihood $C_i(h_{\text{true}})$ as the likelihood of receiving the present reading CBH $h_{\text{true}}$ given that $h_{\text{true}}$ is smaller or equal to an estimation of true CBH $h_{\text{true}}$. Accordingly in the implementation, likelihood is summed cumulatively over all bins of reference CBH $\theta$ to define cumulative likelihood $h_{\text{true}}$ (Fig. 5, step 2):

\[ C_i(h_{\text{true}}) = \sum_{\theta < h_{\text{true}}} L_i(h_{\text{true}}). \] (2)

Likewise, a complementary cumulative likelihood is defined

\[ \overline{C}_i(\theta) = \sum_{\theta > \hat{\theta}} L_i(\theta), \]

as the likelihood of receiving the present reading CBH $h_{\text{true}}$ given that $h_{\text{true}}$ is greater than an estimation of true CBH $h_{\text{true}}$:

\[ \overline{C}_i(h_{\text{true}}) = \sum_{h_{\text{true}} > \hat{\theta}} L_i(h_{\text{true}}). \] (3)

$C_i(\theta)$ and $\overline{C}_i(\theta)$ are used here as measures how likely it is that actual CBH $\theta$ is in the interval $|0 \text{ km}, \hat{\theta}|$ or $[\hat{\theta}, 12 \text{ km}]$, respectively.

pp. 15-16, ll. 364-401:
each joint-frequency grid cell but at least the cumulative value over a range of CBH is appropriate. Both functions $C_i(\theta)$ and $\tilde{C}_i(\theta)$. Both functions $C_i(h_{true})$ and $\tilde{C}_i(h_{true})$ are shown for three exemplary intervals of camera distance in Fig. 5 as output of step 2.

Step 3: The natural logarithm is then applied to $C_i(\theta)$ and summed over all $i$. We aim to determine the likelihood of receiving the combination of readings $CBH_i$ from all the intervals $i$ of camera distance to yield the given that $h_{true} \leq h_{true}$. This can be expressed as product of $C_i(h_{true})$ from all intervals $i$. As this product would often become zero in our numerical treatment, we instead calculate its natural logarithm, which we refer to as overall logarithmic cumulative likelihood $\log C_i(h_{true})$. This operation also allows to replace the product by a sum (Fig. 5, step 3) given the readings $CBH_i$ per interval $i$ of camera distance $i$.

$$\log C_i(h_{true}) = \sum_i \log C_i(h_{true}).$$

(4)

Analogously, an overall complementary logarithmic cumulative likelihood is computed given all readings $CBH_i$ per interval $i$ of camera distance

$$\log \tilde{C}_i(h_{true}) = \sum_i \log \tilde{C}_i(h_{true}).$$

(5)

Both functions are visualized exemplarily as output of step 3 in Fig. 5. In theory, the method could do without the application of a logarithm to $C_i$ and $\tilde{C}_i$ in Eq. and Eq. respectively. In that case, the sum would be replaced by a multiplication in the respective equations. However, this would introduce numerical problems regularly as handled products approach zero.

Step 4: The left-hand sides in Eq. and Eq. $\log C_i(h_{true})$ and $\log \tilde{C}_i(h_{true})$ are only known at discrete points. Linear interpolation yields continuous representations of these. An estimation of the likelihood actual CBH $\hat{\theta}_{true}$ is selected for which $\log C_i(\hat{\theta})$ and $\log \tilde{C}_i(\hat{\theta})$. Then finally, we aim to select the true CBH $h_{true}$, which makes it likeliest to receive the given combination of $CBH_i$. In our formulation of the problem, this means we intend to find a $h_{true}$ which simultaneously maximizes $\log C_i(h_{true})$ and $\log \tilde{C}_i(h_{true})$. Consequently, we accept $h_{true}$, for which $\log C_i(h_{true})$ and $\log \tilde{C}_i(h_{true})$ are equal (Fig. 5, step 4).

$$\hat{\theta}_{true} = \arg\min_{h_{true}} \left| \log C_i(h_{true}) - \log \tilde{C}_i(h_{true}) \right|.$$  

(6)

Besides this estimation of CBH, a version of this procedure will be discussed that includes further refinements (in the following referred to as refined estimation). The refinement is motivated by the finding that some $h_{true}$ are not real CBH pairs are already accurate if actually a certain range of CBH is present as we will discuss in Sect. 4. First, the procedure presented above is modified to exclude ASI pairs with camera distance greater than 4.5 km as these ASI pairs cause large deviations for CBH < 4 km and only provide a limited benefit exhibit only a moderate advantage at greater CBH. Results from this procedure are accepted as refined estimation $\hat{\theta}_{true}$ if estimated CBH is within 3, 12 km. Otherwise, the arithmetic average of CBH measured by ASI pairs is excluded from the refined estimation of $h_{true}$. On the other hand, ASI pairs with specific camera distance is used. The most appropriate small camera distance are already accurate if only small CBH occur as we will discuss in Sect. 4. We inspected conditional probabilities of the ASI pairs for an interval of CBH are identified by an inspection of the conditional probabilities (exemplarily viewed as input to step 1 in Fig. 5) This and identified the ASI pairs which are most appropriate for an interval of CBH. Based on this, the refined estimation is restricted to remain within the specific interval of CBH from the unrefined estimation in which it is applied received from the arithmetic average of CBH measured by ASI pairs with corresponding small camera distance, if the first iteration of $h_{true}$ yielded a sufficiently small CBH. In summary, the refinement procedure to receive the final estimation of CBH $\hat{\theta}_{true}$ reads $\hat{\theta}_{true}$ reads.

$$\hat{\theta}_{true} = \begin{cases} h_{true} \\ \min(3 \, \text{km}, \text{mean}(h_{true}^{[1, 2] \text{km}})) \quad h_{true} \in [3, 12] \text{ km} \\ \min(1.5 \, \text{km}, \text{mean}(h_{true}^{[1, 2] \text{km}})) \quad h_{true} \leq 3 \text{ km} \land \text{mean}(h_{true}^{[1, 2] \text{km}}) > 1.5 \text{ km} \\ \min(1.5 \, \text{km}, \text{mean}(h_{true}^{[1, 2] \text{km}})) \quad h_{true} \leq 3 \text{ km} \land \text{mean}(h_{true}^{[1, 2] \text{km}}) \leq 1.5 \text{ km} \end{cases}.$$

Reviewer:

Lines 350-354: The uniformity constraint is very reasonable during algorithm training, not so during evaluation! It is very interesting to evaluate the algorithm in variable cases and understand what the outputs are, if it is biased towards the low or high clouds etc.

Authors’ response:

First of all, we would like to apologize as a statement in the manuscript was misleading. The filter excluding variable situations is applied in the modelling of conditional probabilities (now Sect. 3.4) and in Sect. 4.4 to compare performance metrics from ASI-pairs and ASI network. In Sect. 4.1-4.3 this filter is not applied. We now corrected this statement and moved it from Sect. 4.1 to Sect. 4.4.

The scatter-density plots shown in Sect. 4.2 may provide insights regarding effects occurring in variable cases. Based on Reviewer Comment 1, minor comment 7 we also added performance metrics to these plots. To enable the reader to evaluate the performance of the ASI-based estimation of CBH under these conditions (e.g. concerning biases) more quickly, we also added percentiles to all scatter-density plots.

Specific comment 19

Reviewer:

Line 377: As shown from the two pairs, in cloud-free conditions some ASI-pairs output the value of 12km, while others 2km (probably due to local low clouds). Why do you suggest that the 4km output of the network is a reasonable prediction of a layer coming at least 30 minutes later? Is this layer captured by any pair in the network? It could also be a lucky combination of these two extreme values? In general, how does the network handle cloud-free conditions?

Authors’ response:

Our description may not have been precise in this point. We now added a plot (Fig. B1) in the appendix which shows the measurements of CBH from the ASI-pairs and from the ASI network as well as from the ceilometer during this clear period in more detail. We also added a short passage in Sect. 4.1 to describe closer which period we referred to. From Fig. B1 it is visible that the ASI-pairs measure a broad range of values between the extreme values of 2 km and 12 km, before around
17:00. Most ASI-pairs measure an intermediate CBH. After 17:00 the spread between the measurements of the ASI-pairs reduces. From around 17:05 the ASI network and some of the ASI-pairs measure a CBH of around 3 km. This CBH (3.1 km) is later also measured by the ceilometer. During this period the approaching cloud layer may be detected before its arrival in the urban area.

During very clear periods, the ASI network is likely to return a CBH which is very large, in the range of 10 km. For an application this is not problematic, in our opinion, because another image processing step is used which is able to detect the absence of clouds. We added a short explanation on this.

Changes in manuscript:

p. 22, ll. 564-571:

Around 17:00, a nearly clear sky is visible (compare Fig. 7, right). Consequently, the ceilometer does not provide any valid CBH. The ASI-pairs provide a CBH that scatters over a wide range, while the ASI network provides a CBH that is assumed to be reasonable. The ASI-pairs provide a CBH that scatters over a wide range, while the ASI network provides a CBH that is assumed to be reasonable. A similar reading of CBH is also recognized by a fraction of the ASI-pairs. From around 17:05, the ASI network detects a CBH of 3 km. With 3.1 km, the following CBH measurements of the ceilometer around 17:30 confirm the suggested CBH of the approaching cloud layer. (see Fig. B1 for a detail view of the CBH measurements during this almost clear sky period). This situation reflects the expected behavior of the ASI network under mostly clear conditions. However, for a completely clear sky, the ASI network partly produces invalid readings (NaN) and partly it detects a large CBH of around 10 km. In this case, a consecutive image processing step detects the absence of clouds. This step is not part of the present study.

Appendix B, p. 38, ll. 940-942, Fig B1:
Specific comment 20
Reviewer:

Line 395: The main ASI-based CBH retrieval limits the instrument to a maximum zenith angle of 67 degrees. For the CLO-FLE pair, given the 4.2km distance of the instruments, the minimum detectable clouds should be around 1.4 km (if I calculate correctly). In the September cases many clouds are below this limit, so probably the second or third sub-algorithm was used (using e.g. the complete FOV of the camera). Could this be the reason of the overestimation? If yes, does the full-FOV retrieval add anything to the estimate or could just be skipped?

Authors’ response:

We share the reviewer’s opinion, that the behavior seen for CLO-FLE in situations with CBH much smaller than 2 km is connected to the minimum CBH which this system can detect. This minimum CBH may indeed be determined by the sub-algorithm relying on the main ASI’s cropped orthogonal image. The usage of the full FOV to retrieve CBH is not expected to improve an ASI-pairs capability to
detect very low clouds noticeably. We now pointed out in Sect. 3.1, that this sub-algorithm is mainly intended to increase the robustness of the method. It may yield a valid measurement in some cases when the first sub-algorithms failed. We condensed the discussion of the minimum CBH in Sect. 4.2 as shown below. See also our response to Specific Comment 22.

Changes in manuscript:

p. 10, ll. 236-242:

window for which the estimation failed. In cases with no valid measurement in any of the windows, the orthogonal images of both ASIs are evaluated up to a maximum zenith angle of 77.8° (measured at the center of each image side, green shapes in Fig. 3, central red dotted boxes). These orthoimages from both cameras are matched in the cross-correlation and the ASI-pair returns a uniform CBH. This second step can yield a valid measurement of CBH in cases when only few clouds are present to be matched. This step mainly intends to increase the robustness of the CBH measurement. This step is not expected to increase the capability of an ASI-pair to detect very low clouds in relation to the camera distance, as the window size used in this step is very large.

p. 10-11, ll. 252-265:

If the estimation of CBH fails for Only based on geometry and the evaluated image areas, this central window, we use the CBH that is measured by matching the peripheral windows (Fig. 3, peripheral red dotted boxes) of the same orthoimage with the orthoimage of the second camera. These peripheral windows of an orthoimage have the same shape as the central window (see could provide readings down to a minimum CBH of 0.25 × d. Where d is the camera distance. However, under such extreme conditions the matching procedure may fail very frequently. The central peripheral windows, shown in Fig. 3, center; peripheral red dotted boxes). If a valid estimation of CBH is received for multiple peripheral windows, we use the average CBH from these windows.

For cases with still no valid measurement, images of both cameras are evaluated up to a maximum zenith angle of approximately cover zenith angles 38.1, 67°. The matched area from the auxiliary ASI’s orthogonal image has identical shape and can cover a zenith angle up to 77.8°(measured at). Based on this, we estimate the minimum CBH, which an ASI-pair can measure, to be 0.18 × d. However, from our experience, a large fraction of clouds observed at zenith angles larger than 67° are not matched successfully between the ASIs and typically rejected. If the matching procedure could only be successful, if also the window of the second ASI included zenith angles not larger than 67°, then CBH could be measured down to 0.32 × d using the peripheral windows and 0.61 × d using the central window.

Reviewer:

Line 405: What I understand from the plot is that the low clouds are detected by the ceilometer and not by the ASI-pair, not the other way around. If this is true, the ceilometer site should have persistent low not present over the ASI-pair. Is this reasonable from the local meteorological conditions? What seems more reasonable is that ASI-pair cannot detect low clouds, e.g. due to geometric and algorithm considerations. Please provide more details.

Authors’ response:

We assume that the reviewer refers to the areas on the far left of the scatter-density plots (e.g. reference CBH < 0.5 km for DON-MAR and reference CBH < 2 km for UOL-HOL) and we agree with the analysis of the reviewer. At this point, we intended to discuss another area of these plots and now indicated these areas more precisely in the manuscript. When reference CBH ranges around 3...12 km, the ASI-based systems frequently detect low clouds close to the 5-percentile line, i.e. far below the main diagonal of the plot. In these cases, the ASI-based systems provide a CBH which is too small. As described in previous sections, we expect that in these cases the ASI-based systems recognize low clouds present in their field of view. At the same time there might be a gap in the low cloud layer at the location of the ceilometer. Therefore, the ceilometer may recognize a larger CBH.

Specific comment 22

Reviewer:

Line 408-410: This doesn’t sound very surprising since the minimum altitude where your ASI have overlapping images at 67deg FOV should be around 1.7km. Please discuss such issues, preferable in a previous section, before presenting the results.
Authors' response:

As suggested by Specific Comment 11, we now calculated the minimum CBH which may be related to the sub-algorithms in Sect. 3.1. We reworked the discussion of minimum CBH in Sect. 4.2. and adapted it to refer to these values of minimum CBH expected from geometry.

p. 10, ll. 236-242:

window for which the estimation failed. In cases with no valid measurement in any of the windows, the orthogonal images of both ASIs are evaluated up to a maximum zenith angle of 77.8° (measured at the center of each image side, green shapes in Fig. 3, central red dotted box). These orthoimages from both cameras are matched in the cross-correlation and the ASI-pair returns a uniform CBH. This second step can yield a valid measurement of CBH in cases when only few clouds are present to be matched. This step mainly intends to increase the robustness of the CBH measurement. This step is not expected to increase the capability of an ASI-pair to detect very low clouds in relation to the camera distance, as the window size used in this step is very large.

p. 10-11, ll. 252-265:

If the estimation of CBH fails for, only based on geometry and the evaluated image areas, this central window, we use the CBH that is measured by matching the peripheral windows (Fig. 3, peripheral red dotted boxes) of the same orthoimage with the orthoimage of the second camera. These peripheral windows of an orthoimage have the same shape as the central window (we could provide readings down to a minimum CBH of 0.25 × d, where d is the camera distance. However, under such extreme conditions the matching procedure may fail very frequently. The central peripheral windows, shown in Fig. 3, center, peripheral red dotted boxes), if a valid estimation of CBH is received for multiple peripheral windows, we use the average CBH from these windows.

For cases with still no valid measurement, images of both cameras are evaluated up to a maximum zenith angle of approximately cover zenith angles 38.1, 67°. The matched area from the auxiliary ASIs orthogonal image has identical shape and can cover a zenith angle up to 77.8° (measured at...). Based on this, we estimate the minimum CBH, which an ASI-pair can measure, to be 0.18 × d. However, from our experience, a large fraction of clouds observed at zenith angles larger than 67° are not matched successfully between the ASIs and typically rejected. If the matching procedure could only be successful, if also the window of the second ASI included zenith angles not larger than 67°, then CBH could be measured down to 0.32 × d using the peripheral windows and 0.61 × d using the central window.

Line 417: “in the dataset used for modelling”?

Authors’ response:

As we understand the comment, it is not clear at this point why the “dataset used modelling” is discussed in this context. As also suggested by the following Special Comment 24, we rephrased this passage. We hope this makes the intended statement clearer, also in this perspective.

Changes in manuscript:

p. 26, ll. 642-650:

In the range of reference CBH $> 10 \text{ km}$, the ASI network constantly returns CBH of around $10 \text{ km}$. In the studied climate (see Fig. 4) and accordingly in the dataset used for modelling readings of reference CBH in this range are comparably rare. Therefore, conditional probabilities used in the estimation are modeled inaccurately. The estimation procedure uses cumulative likelihood; this avoids frequent strong peaks (see Fig. 4). Therefore, corresponding grid cells of the conditional probability distributions, used by the estimation procedure, were approximated coarsely based on a small number of observations. The ASI network’s combination method using cumulative likelihood is intended to avoid deviations resulting from these inaccuracies and yields, thus, a more conservative but in this case biased estimation of CBH. However, this approach also suppresses the estimation of extreme CBH readings, which causes a bias under these conditions. For the analyzed sites, deviations found in this range of CBH are of minor importance. For low values of reference CBH, ASI network and ASI pair DON-MAR both appear to perform similarly at high accuracy. Only for

Lines 42-54: As written now, the paragraph starts as if to present ceilometers but ends up presenting various CBH estimation techniques and ends up with ASI-based forecasting requirements. A slight editing is needed to make the text clearer.

Authors’ response:

We rewrote this paragraph in part to put a stronger focus on possible sources of CBH to be considered for nowcasting. We moved this specification of nowcasts up.

Changes in manuscript:

p. 2, ll. 34-35:
The method to measure CBH, presented in this study, is used as part of an ASI-based nowcasting system of the solar resource. ASI-based nowcasting is typically applied if variations of irradiance have to be predicted for lead times immediately ahead (0–20 min) and at highest temporal and spatial resolution (e.g., 30 s and 5 m respectively as used by Nouri et al., 2020). Such nowcasts can reduce the uncertainty of supply from solar power plants and can support efficient balancing of energy supply.

p. 2-3, ll. 45-58:

CBH is commonly required in ASI-based nowcasting, can be estimated in multiple ways. Most commonly, CBH is measured by ceilometers or other LiDARs. In Germany, the meteorological service Deutscher Wetterdienst (DWD) operates a network of ceilometers which has a distance between stations of approximately 60 km in the region of the measurement site Oldenburg (Chan et al., 2018). Ceilometers are specialized instruments that come at a high price and provide CBH zenith-wise for the location of their installation. Therefore, we do not consider ceilometers as an option to provide CBH in real time for most solar power plants or cities with many rooftop installations. Further common approaches to measure CBH, which could be applied for operational use in nowcasting, include weather balloons and the estimation of CBH based on a recognized cloud genus (World Meteorological Organization, 2018). Satellites can measure CTH of the highest cloud layer (Hamann et al., 2014) but require estimations of cloud vertical extent (see e.g. Noh et al., 2017) to provide cloud base height (CBH). ASIs can directly measure CBH but require estimations of cloud vertical extent if CTH is of interest. This approach is especially reasonable if ASIs are used at a site for further purposes such as In ASI-based nowcasting, the double use of ASIs for the estimation of CBH besides cloud recognition is considered advantageous in a trade-off between system costs and accuracy. ASI-based nowcasting is typically applied if variations of irradiance have to be predicted for lead times immediately ahead (0–20 min) and at highest temporal and spatial resolution (e.g., 30 s and 5 m respectively as used by Nouri et al., 2020).

ASI-based estimation of CBH may follow different principles. Some approaches first measure the angular velocity of clouds in the sky-image of a single ASI and estimate CBH with an external source of cloud velocity. Wang et al. (2016) derives cloud velocity by three photocells placed at known distances from each other. Kuhn et al. (2018b) measures cloud velocity by a cloud speed sensor based on nine photocells and by a shadow camera system and compares the accuracy of received CBH. Tomographic reconstruction approaches (Mjia et al., 2018) or similarly voxel carving approaches (Nouri et al., 2018) first model 3-dimensional representations of clouds from which their base height can be retrieved.

Authors’ response:
We reformulated as shown below.

Changes in manuscript:

p. 21, ll. 537-539:

First, characteristics of CBH-measurements from the ASI network and from individual ASI-pairs are compared to the CBH-measurement of the reference ceilometer based on insightful days. Then, the coincidence of CBH-measured measurements of CBH by ASI network and ASI-pairs with CBH measured by the ceilometer, is analyzed against the ceilometer by scatter-density plots. Subsequently, CBH derived by the network and by all individual ASI-pairs are validated against the ceilometer by RMSE and BIAS. The accuracy of an ASI-pair and of the ASI network are analyzed for the application.
