23 **Abstract**

24 The comparative reactivity method (CRM) has been developed more than a
25 decade to measure OH reactivity (i.e. OH loss frequency) in both laboratory and field
26 studies. However, accurate OH reactivity quantification remains challenging under real
27 ambient condition, especially for OH reactivity measurements in high-NO_x (e.g. >10
28 ppbv) environments, as ambient NO enhance regeneration of OH radicals in the CRM
29 reactor. To resolve this problem, we design a new improved CRM reactor (ICRM) and
30 add NO into the system continuously, so that the HO₂ radical concentration is
31 suppressed. We confirmed the appropriate level of NO by determining the maximum
32 decrease in the pyrrole level caused by regenerated OH radicals from NO + HO₂. VOC-
33 induced RO₂ radicals in the ICRM reactor were also found to react with NO, which lead
34 to the re-generation of OH radicals thus the underestimation of OH reactivity. This
35 effect was quantified by the calibration of representative VOC species at different NO
36 levels, and the correction coefficients obtained were used to correct the measured OH
37 reactivity. All these efforts resulted in reducing the uncertainty of the NO-artifact
38 correction by at least an order of magnitude compared to the original CRM system.
39 Additionally, these technological improvements also considerably reduced the
40 systematic errors from pyrrole photolysis that exists in the original system. A new
41 operation mode was proposed for ICRM, which is able to avoid the interference
42 resulting from OH radicals produced by photolysis of residual humidity and save time
43 for ambient measurement. The ICRM system was employed in a field campaign to
44 measure OH reactivity and performed well with ambient NO levels ranged from 0 to
45 50 ppbv, which were typically observed in urban and suburban atmosphere.

46 **1 Introduction**

47 The hydroxyl radical (OH) is the most important oxidant in the daytime
48 troposphere. It initiates the chemical removal of primary gaseous pollutants and in
49 turn produces a host of secondary pollutants (A. Hofzumahaus, 1991; Atkinson, 2000;
50 Roger Atkinson, 2003). The OH reactivity is defined as the sum of all OH reactive trace
51 gas concentrations multiplied by their respective reaction rate coefficients with OH, as
52 shown in Eq. 1. The OH reactivity is a fundamental property of the atmosphere in that
53 it defines the overall loss frequency of OH radicals and hence the lifetime of OH. As
54 such it is a useful atmospheric parameter for evaluating the level of reactive pollutants
55 and it is closely related to atmospheric oxidation capacity and formation of secondary
56 pollutants including ozone and secondary aerosols (Sinha et al., 2012; Yang et al., 2016;
57 Pfannerstill et al., 2019).

$$58 R_{OH} = k_{CO}[CO] + k_{NO}[NO] + k_{NO_2}[NO_2] + k_{SO_2}[SO_2] + k_{O_3}[O_3] + \sum_i^n k_{VOC_i}[VOC_i]$$

59 (1)

60 Equation 1 defines the OH reactivity where R_{OH} is the total OH reactivity, k_{CO} ,
61 k_{NO} , k_{NO_2} , k_{SO_2} , k_{O_3} , and k_{VOC_i} represent the reaction rate coefficients between OH
62 radicals and CO, NO, NO₂, SO₂, O₃, and volatile organic compounds (VOCs) species
63 i , respectively. [CO], [NO], [NO₂], [SO₂], [O₃], and [VOC _{i}] are the concentrations of
64 CO, NO, NO₂, SO₂, O₃, and VOCs species i , respectively.

65 Currently, two general methods are used to measure OH reactivity: (1) direct
66 measurements of OH decay rates by laser-induced fluorescence (LIF) technique; (2)
67 measuring the relative change of a reference substance with and without ambient air
68 present by the comparative reactivity method (CRM). The LIF based technology has
69 been used to measure OH reactivity in a variety of different environments and has
70 provided many new insights into the budget of OH reactivity (Kovacs et al., 2001;
71 Kovacs et al., 2003; Sadanaga et al., 2004; Sadanaga et al., 2005; Ingham et al., 2009;
72 Lou et al., 2010). However, the cost, complexity, and large size of LIF systems are
73 deterrents to the widespread deployment for field measurements (Sinha et al., 2008).

74 Such detector systems need to be built and cannot be bought directly from a supplier.
75 The CRM method measures OH decay rate indirectly by using the relative reaction rate
76 of a reference substance (pyrrole) with self-generated OH radicals in the presence and
77 absence of ambient air. The reference substance can be measured by an online
78 instrument, such as proton transfer reaction mass spectrometry (PTR-MS) (Sinha et al.,
79 2008; Sinha et al., 2009; Kumar et al., 2014) or a gas chromatograph (Nolscher et al.,
80 2012a; Praplan et al., 2017a; Praplan et al., 2019b). The CRM technique has proven to
81 be a useful supplementary technique to measure the total OH reactivity in ambient air,
82 with a more economical and portable setup than the LIF-based systems. Based on inter-
83 comparison between various OH reactivity techniques in the SAPHIR chamber, the LIF
84 type-instruments are generally more sensitive and less noisy than CRM instruments
85 (Fuchs et al., 2017).

86 The CRM approach has been applied to numerous field campaigns in recent years
87 to measure OH reactivity (Dolgorouky et al., 2012; Nölscher et al., 2014; Michoud et
88 al., 2015; Kim et al., 2016; Zannoni et al., 2016; Praplan et al., 2017b; Yang et al., 2017a;
89 Zannoni et al., 2017; Kumar et al., 2018; Pfannerstill et al., 2018; Pfannerstill et al.,
90 2019; Praplan et al., 2019a). However, this method is not suitable for the environment
91 with high-level NO_x, due to the pen-ray mercury lamp used to generate OH radicals in
92 CRM system also generates approximately equivalent amounts of HO₂ radicals that
93 may react with sampled NO to produce additional OH radicals (Sinha et al., 2008; Yang
94 et al., 2017a), which cause an enhanced consumption of pyrrole in the CRM system and
95 result in an underestimation of OH reactivity in sampled ambient air when NO exceeds
96 certain levels (Sinha et al., 2008). This NO interference prevents the CRM method from
97 providing high-quality data in emission exhausts and urban areas with high NO levels.
98 As a result, applications of the CRM method have been generally restricted to high
99 reactivity/low NO_x environments, including forests (Sinha et al., 2010; Kim et al., 2011;
100 Nolscher et al., 2012b; Praplan et al., 2019b; Pfannerstill et al., 2020), moderately
101 polluted cities (NO < 10 ppb) (Sinha et al., 2008; Praplan et al., 2017b), pristine marine
102 environments (Sinha et al., 2012; Zannoni et al., 2015), emission sources (e.g. gasoline

103 evaporation) (Wu et al., 2015), branch cuvette studies (Nölscher et al., 2013), and
104 chamber studies (Nölscher et al., 2014) with little or no NO_x present. One solution to
105 this issue is to deliberately remove NO, before the sampled air is introduced into the
106 reactor. However, the present technology is not able to remove NO selectively without
107 affecting other reactive species (i.e., VOCs). The effect of NO on measured OH
108 reactivity can be quantified by NO-correction experiments and the resulting correction
109 curve applied to adjust ambient measurements according to simultaneously measured
110 NO levels (Hansen et al., 2015; Yang et al., 2017a). However, the uncertainty of
111 measured OH reactivity due to NO correction increases with NO concentration (Hansen
112 et al., 2015; Michoud et al., 2015). Hansen et al. (2015) reported that the total
113 uncertainty increases by up to a factor of 3 at NO_x mixing ratios higher than 40 ppbv.
114 Therefore, it calls for an improvement of the traditional CRM reactor for accurately
115 quantifying OH reactivity at high NO_x conditions. In addition to the NO effect,
116 photolysis of pyrrole and VOCs, and the humidity difference between zero air and
117 ambient air also influence measured OH reactivity (Sinha et al., 2008; Hansen et al.,
118 2015; Zannoni et al., 2015).

119 The main purpose of this study is to improve the original CRM system to make it
120 suitable for using in high-NO_x conditions. We modified the structure of the original
121 CRM glass reactor and add a certain amount of NO into the system to remove the
122 generated but unwanted HO₂ radicals. We further characterized the improved CRM
123 (ICRM) system by quantitatively evaluating the effect of the reaction of sample VOC-
124 induced RO₂ with NO on measured OH reactivity. Additionally, the interference of
125 pyrrole photolysis was also systematically evaluated. Finally, the ICRM system was
126 deployed to measure OH reactivity under high-NO_x conditions (0-50 ppbv) during a
127 field campaign in the Pearl River Delta region of China.

128 **2 Experimental and Methodology**

129 **2.1 The original CRM reactor**

130 The schematic of the original CRM reactor is shown in Fig. 1a. Gas-phase pyrrole

131 mixed with zero air or ambient air is introduced through arm C at a constant flow. Arm
 132 A consists of a pen-ray spectral mercury lamp (**Analytik Jean; 90-0012-01**), over
 133 which nitrogen (humidified or dry) is passed through arm B at a constant flow rate.
 134 When humidified nitrogen is flowing and the mercury lamp is turned on, H₂O is
 135 photolyzed into OH and H radicals by the mercury lamp at 254 nm. The total air flow
 136 in the reactor exits through arm F and the concentration of pyrrole is monitored with a
 137 PTR-MS. A detailed description of the original CRM method has been reported by
 138 Sinha et al. (2008).

139 Figure 1(b) shows the four work modes of the original CRM method (Sinha et al.,
 140 2009). In C0 mode, the mercury lamp is turned off and high-purity dry nitrogen is
 141 introduced into the reactor through arm B. Pyrrole is introduced into the reactor with
 142 dry zero air through arm C. In C1 mode, the mercury lamp is turned on while everything
 143 else remains the same as C0. Pyrrole concentration decreases during C1 mode due to
 144 its photolysis reaction. In C2 mode, nitrogen flow in C1 is changed to humidified
 145 nitrogen to generate OH radicals, and the pyrrole concentration decreases to C2. In the
 146 final step, ambient air is introduced to the reactor through arm C in C3 mode. Based on
 147 pseudo-first-order assumptions (i.e., [pyrrole] ≥ [OH]), total OH reactivity (R_{OH}) is
 148 calculated as Eq. 2:

$$149 \quad R_{OH} = C1 \times k_{pyr+OH} \times \frac{C3-C2}{C1-C3} \quad (2)$$

150 Where k_{pyr+OH} is the rate coefficient for the reaction of pyrrole with OH radicals
 151 ($1.28 \times 10^{-10} \text{ cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$ (Dillon et al., 2012)), and C1, C2, and C3 represent
 152 pyrrole concentrations at the corresponding steps described above, respectively.

153 In C2 and C3 mode, OH radicals are produced by the photolysis of water vapor at
 154 atmospheric pressure as shown in R1. The generated H radicals from R1 reacts with O₂
 155 of zero air or ambient air to generate HO₂ radicals, as shown in R2. When NO is present
 156 in the sampled ambient air, it can recycle OH by reacting with HO₂ (R3).

160 An underlying assumption of the CRM approach is that the influence of the species
161 in ambient air on the production of OH radicals in the reactor is ignorable. The
162 theoretical OH mixing ratio in the original CRM reactor is about 5 ~ 20 ppbv, which
163 depends on the introduced pyrrole concentration to ensure the Pyrrole/OH ratio is
164 2:1~3:1. However, the additional OH radicals produced via R3 can react with pyrrole
165 to cause an additional decrease in pyrrole relative to C2 mode, thus lead to the
166 underestimation of OH reactivity.

167 **2.2 The improved CRM reactor**

168 In order to remove the interference of the reaction of HO₂ radicals with NO as
169 discussed above, we modified the pipe structure of the original CRM reactor (Fig. 1c).
170 We kept the length and volume of the glass reactor of the ICRM system similar to the
171 original CRM system, but added a branch inlet G (1/4 inch OD glass; length 3 cm) in
172 arm A to introduce steam of NO standard (Air Liquide; stated uncertainty 3%; 10.8
173 ppmv) mixed with zero air at a constant flow of 120 ml·min⁻¹. The typical flow rate
174 inside the ICRM reactor is approximately 660 ml·min⁻¹. The flow rate of nitrogen (Air
175 Liquide; 99.9995% purity) through arm B is 250 ml·min⁻¹. The input pyrrole (Linde
176 Spectra Environment Gases; stated uncertainty 5%; 5.37 ppm) flow rate is 2.5 ml·min⁻¹.
177 The total flow rate of pyrrole and zero air (Air Liquide; 99.9995% purity) through
178 arm C is 290 ml·min⁻¹. With this modified structure of arm A, the HO₂ radicals,
179 produced by the reaction of the generated H radicals near the mercury lamp and O₂ in
180 introduced zero air, were converted to OH radicals by reacting with NO in the
181 downstream of arm G. The interference induced by R3 can then be eliminated.

182 Arm A consists of one 1/2 inch OD (ID: 0.62 cm, length: 7 cm) glass tube and one
183 1/4 inch OD (ID: 0.32 cm, length: 5 cm) glass tube. The longer arm A is beneficial for
184 longer reaction time of HO₂ with NO, but lower OH concentrations passing into the
185 reactor due to wall loss. We chose an appropriate length of arm A (12 cm) to ensure
186 appropriate OH concentration (4 ppbv) and reaction time of HO₂ with NO (~ 0.1 s).
187 The purpose of the two-section structure is to ensure that the UV light is mostly
188 confined within a 1/2 inch OD glass tube of arm A, as the diameter of arm A goes from

189 wide to slender. The new structure of arm A leads to lower OH concentrations
190 (decreased by approximately 50%) passing into reactor compared with the original
191 CRM system due to wall loss, but OH radicals produced from the reaction of HO₂
192 radicals with NO can partially compensate for this loss.

193 **2.3 The detection of pyrrole by PTR-MS**

194 The accuracy of pyrrole measurement is critical in determining OH reactivity for
195 CRM method. Here we used PTR-MS to detect pyrrole concentration. With a proton
196 affinity greater than water (Pyrrole: 209.2 kcal·mol⁻¹; Water: 165.2 kcal·mol⁻¹) (Sinha
197 et al., 2008), pyrrole is chemically ionized by proton transfer with H₃O⁺ ions and the
198 product ions are detected using a quadrupole mass spectrometer. As highlighted by
199 Sinha et al. (2009), the sensitivity of PTR-MS instruments toward pyrrole is dependent
200 on humidity, and the pyrrole signal must be carefully calibrated for relative humidity
201 changes within the CRM reactor. The approach described by de Gouw and Warneke
202 (2007) was employed in this study to account for the effect of ion source and humidity
203 on the sensitivity of PTR-MS toward pyrrole (de Gouw et al., 2007). This approach
204 involves normalization of the pyrrole signal to a sum of reagent ion signals (H₃O⁺+X_R
205 × H₃O⁺ · H₂O) that leads to a normalized signal for pyrrole that is independent of
206 humidity. X_R, a scaling factor for the H₃O⁺ · H₂O signal, is determined experimentally
207 by measuring the pyrrole signal from a standard mixture under different humidity
208 conditions. In this study, a relatively higher electric field parameter of the drift tube (i.e.
209 E/N) value of 153 Td was used to measure pyrrole, which can minimize the humidity
210 effect from water clusters in the PTR-MS instrument. As shown in SI, the best estimate
211 for X_R parameter was determined to be zero (Fig. S1), indicating negligible role for
212 H₃O⁺ · H₂O in pyrrole detection by PTR-MS in this study.

213 **2.4 Other instruments of the ambient measurement campaign**

214 In order to test and validate the ICRM system for OH reactivity measurements
215 under high NO conditions, we conducted field measurements of OH reactivity at a
216 receptor site in the Pearl River Delta (PRD) region of China (Yang et al., 2017b; Tan et

217 al., 2019). Meanwhile, non-methane hydrocarbons (NMHCs) and oxygenated volatile
218 organic compounds (OVOCs) were also measured by online gas chromatograph mass
219 spectrometer and flame ionization detector (GC-MS/FID) (Wang et al., 2014a) and
220 proton transfer reaction time-of-flight mass spectrometry (PTR-TOF-MS) (Yuan et al.,
221 2017), respectively (Table S1). Inorganic trace gases, including CO, NO₂, NO, SO₂ and
222 O₃, were measured by Thermofisher 48i CO analyzer, 2B Technologies Model 405nm
223 NO_x analyzer, Thermofisher 42i NO_x analyzer, Thermofisher 43i SO₂ analyzer, and
224 Thermofisher 49i O₃ analyzer, respectively. Detailed descriptions of these instruments
225 can be found in previous studies (Wang et al., 2014b; Birks et al., 2018).

226 **2.5. Zero dimensional box model**

227 To test our understanding of the chemical processes occurring inside the ICRM
228 reactor, results from laboratory experiments were compared with simulation from zero-
229 dimensional (0-D) box model. The MCM v3.3.1 (Wolfe et al., 2016) was used as
230 chemical mechanism in the box model. The use of the detailed mechanism aims at better
231 representing the chemistry of peroxy radicals. In the box model, the initial
232 concentrations of OH, HO₂, pyrrole, VOCs, CO, and NO were supplied, and the time-
233 dependent variations of different compounds in the reactor are simulated. The initial
234 concentrations of OH (4 ppbv), HO₂ (4 ppbv), and pyrrole (21 ppbv) are determined
235 based on results from our experiments. The residence time in the reactor was about 11
236 s according to the volume of the reactor (120 cm³) and the flow of introduced gases
237 (660 ml·min⁻¹). An MCM subset was extracted for inorganic reactions, and reactions
238 for propane, propene, and toluene. C₃H₅O₂ was used as a surrogate for the peroxy
239 radicals from pyrrole, as the degradation of pyrrole is not included in MCM.

240 **3 Results and discussion**

241 **3.1 Determination of the amount of NO addition**

242 In addition to HO₂ produced from the reaction of H radicals with O₂, RO₂ produced
243 from the reaction of pyrrole with OH also react with NO to recycle HO₂ and OH (R4-
244 R6), and consume pyrrole. In order to eliminate the effect of HO₂ and RO₂ radicals, NO

245 supply with an appropriate concentration through arm G is needed. We optimized NO
 246 concentration by testing the dependence of the change of the pyrrole concentrations on
 247 the concentration of NO introduced through arm G (as described below and Fig. 2).
 248 Figure 1d shows three work modes of the ICRM method. During the experiment, the
 249 pyrrole concentration in the C1 mode (where N₂ and zero air were humidified and
 250 mercury lamp is turned off) was 22 ppbv, which decreased to 18 ppbv when the mercury
 251 lamp was turned on at 0 ppbv NO, implying that the generated OH radicals depleted ~
 252 4 ppbv pyrrole. We varied the NO concentrations mixed with the zero air entering arm
 253 G which resulted in NO concentrations in the reactor ranged from 0 to 150 ppbv, and
 254 found out the appropriate NO level to consume all HO₂ and RO₂ produced in the glass
 255 reactor. NO was mixed with zero air rather than nitrogen, as oxygen in zero air can
 256 transform H radicals in arm A to HO₂ radicals. Pyrrole concentration decreases with the
 257 increase of NO concentrations, reaching a minimum when NO concentration is circa
 258 40 ~ 50 ppbv, and increased again when NO concentration exceeds 50 ppbv.

264 where RH represents pyrrole in the reactor or introduced ambient VOCs into the reactor.

265 The NO addition experiments are simulated in the box model. The simulated
 266 pyrrole concentrations as a function of NO concentration is consistent with laboratory
 267 experiments: with pyrrole concentrations decreasing at first and then increasing (Fig.
 268 S2). When NO is not present in the reactor, the self-reactions of peroxy radicals
 269 (HO₂+HO₂, HO₂+RO₂) dominate the sink of HO₂ and RO₂ (Fig. S3). As NO is
 270 introduced into the reactor, the reaction of NO with HO₂ or RO₂ competes with the self-
 271 reactions of peroxy radicals. With more NO introduced, the produced OH radicals from
 272 the reaction of HO₂ with NO increase, leading to the decrease of pyrrole concentration
 273 (Fig. S3). As the NO concentration exceeds 50 ppbv, pyrrole concentrations increase

274 again, due to large excess NO competes with pyrrole for reaction with OH radicals. The
275 remaining NO concentration outflowing from the reactor increases with the introduced
276 NO concentrations (Fig. S2), indicating that excessive NO is needed to compete with
277 the self-reactions of peroxy radicals. Based on laboratory measurement, the remaining
278 NO concentration outflowing from the reactor is ~18 ppbv when the introduced NO
279 concentration at 50 ppbv. The laboratory measurements and simulated results both
280 suggest that 40 ~ 50 ppbv is the lowest NO concentration needed to transform HO₂ and
281 RO₂ to OH to the largest extent. The higher introduced NO concentration had a
282 negligible effect on the increase in OH production from HO₂ and RO₂. Thus, we
283 introduce 50 ppbv NO concentration into the ICRM reactor in the experiments in this
284 study. Under this optimized condition, the pyrrole concentration decreased to 12.3 ppbv,
285 indicating the total OH radical concentration including production from UV lamp and
286 from the reaction of HO₂ with NO is about 10 ppbv in the ICRM system. The
287 concentration of pyrrole in this scenario is regarded as the C2 mode for ICRM system.
288 It worth noting that the determined NO concentration can vary slightly as OH
289 generation performance changes (e.g. humidity change in the region of the pen-ray
290 mercury lamp).

291 Under the determined optimal NO level through arm G, it is necessary to ensure
292 that the OH production from HO₂ and pyrrole-induced RO₂ will not manifest itself
293 when ambient NO is introduced through arm C. For this purpose, we compared
294 measured and true OH reactivity of NO by passing a series of NO concentrations (0 ~
295 700 ppbv) mixed with zero air through arm C into the reactor (Fig. 3). In this test, no
296 other reactive gases were introduced into the system except NO. Measured OH
297 reactivity of NO ($k_{\text{NO}} = 9.7 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ according to IUPAC lasted
298 evaluation in November 2017) agreed well with the corresponding true values,
299 indicating that HO₂ radicals have been fully consumed, and pyrrole peroxy radicals
300 were effectively converted to carbonyls and nitrates by NO introduced through arm G.

301 **3.2 Calibration for OH reactivity of VOCs**

302 Several reactive VOC species were used to validate and calibrate the ICRM system,

303 including methane, propane, propene, toluene, and mixed gases including 16 VOC
304 species (acetaldehyde, methanol, ethanol, isoprene, acetone, acetonitrile, methyl vinyl
305 ketone, methyl ethyl ketone, benzene, toluene, o-xylene, α -pinene, 1,2,4-
306 trimethylbenzene, phenol, m-cresol, naphthalene). These VOC species were introduced
307 into the system through arm C at various reactivity ($0 \sim 200 \text{ s}^{-1}$). Figure 4 (a) presents
308 the plots of the measured ($R_{\text{meas}}, \text{s}^{-1}$) versus true OH reactivity ($R_{\text{true}}, \text{s}^{-1}$) of these species.
309 R_{meas} is lower than R_{true} for almost all species with the slopes of linear fittings ranging
310 from 0.60 to 0.72. The slopes of methane, propane, propene, toluene, and mixed gases
311 are 0.60, 0.64, 0.64, 0.64, and 0.72, respectively. The OH reactivity calibration of SO_2
312 and CO indicates that the linear fitting slope of R_{meas} versus R_{true} is 0.35 and 0.40,
313 respectively (Fig. 4 b), which is lower than that of VOCs. It is worth mentioning that
314 the intercept of the line in Fig. 4 is not zero which indicates that at low OH reactivity
315 the ICRM methods lacks sensitivity.

316 Equation 2 is valid only under near pseudo-first-order conditions (i.e. when
317 $[\text{pyrrole}] \gg [\text{OH}]$). In this study, the $[\text{pyrrole}]$ to $[\text{OH}]$ ratio is set at 2.5, which will
318 cause significant systematic errors. We plot the calculated reactivity, obtained by
319 applying Eq. 2 to the numerical simulations of the pyrrole concentration (C2 and C3)
320 at $[\text{Pyrrole}]/[\text{OH}] = 2.5$ after OH had reacted to zero, versus the true reactivity. The
321 correction curve indicates that the calculated reactivity underestimates the true
322 reactivity by about 5%. After considering this interference, the slope of calibration
323 shown in Fig. 4 (a) and 4 (b) decreased to $0.57 \sim 0.68$ for VOCs, 0.38 for SO_2 and 0.33
324 for CO, respectively. Therefore, the deviation of pseudo-first-order conditions cannot
325 explain the calibrated slopes for VOCs, CO and SO_2 being lower than one.

326 The lower calibrated slopes for VOCs than one can be related to secondary
327 chemistry of VOC-generated RO_2 radicals with NO. When more VOCs are introduced
328 into the reactor, additional RO_2 radicals produced from the reaction of VOCs with OH
329 will react with excessive NO in the reactor thus increase the recycled OH (R4-R6). The
330 recycled OH from RO_2 will deplete pyrrole thus leading to a R_{meas} lower than the R_{true} .
331 We deduce that this is the reason for the linear fitting slopes in Fig. 4 lower than one.

332 For specific VOC species, the decrease in pyrrole concentration due to recycling OH
333 depends on the true OH reactivity of VOCs, NO concentrations and the efficiency of
334 organic nitrate production ($\text{RO}_2 + \text{NO} \rightarrow \text{RONO}_2$) in this system. The consistency in
335 the linear fitting slopes of different VOC species indicates that the $\text{RO}_2 + \text{NO}$ reactions
336 for the investigated VOCs are similar. This is in agreement with the simulated results
337 (Fig. S4). Similarly, the produced HO_2 from the reactions of CO and SO_2 with OH will
338 end up recycling OH in the excess NO environments and thus reduce the fitting slopes.
339 The lower fitting slope of SO_2 and CO than that of VOCs is because SO_2 and CO react
340 with OH to produce HO_2 , which has higher efficiency to produce OH by reacting with
341 NO than RO_2 that goes through two steps ($\text{RO}_2 \rightarrow \text{HO}_2$, and $\text{HO}_2 \rightarrow \text{OH}$). Here, we define
342 the linear fitting slopes in Fig. 4 as correction coefficients with regard to the calibration
343 for OH reactivity of VOC, CO and SO_2 (characterized by α_{VOC} , α_{CO} and α_{SO_2}) at ambient
344 $\text{NO} = 0$ ppbv.

345 To further evaluate the performance of the ICRM system with elevated NO_x
346 concentrations in ambient air, a series of NO concentrations were introduced into the
347 reactor through arm C both with constant reactivity from different VOC species and
348 with different reactivities provided by the same species. Of all experimental conditions,
349 the R'_{meas} (The R'_{meas} is defined as the corrected R_{meas} by correction coefficient α_{VOC})
350 was observed to decrease with increased NO concentration, and thus the difference
351 between R_{true} and R'_{meas} ($R_{\text{true}} - R'_{\text{meas}}$) increases with increased NO concentrations for
352 the four VOC standard gases (Fig. 5a and b). This is because the reaction rate of RO_2
353 with NO increases with NO concentrations leading to enhancement of the recycled OH.
354 Similar to previous study (Michoud et al., 2015; Praplan et al., 2017b; Yang et al.,
355 2017a), the difference between R_{true} and R'_{meas} ($R_{\text{true}} - R'_{\text{meas}}$) increases with NO
356 concentrations for different VOC species and different reactivity levels. Besides, the
357 difference between R_{true} and R'_{meas} ($R_{\text{true}} - R'_{\text{meas}}$) also increases with NO concentrations
358 for CO and SO_2 with slope of 0.11 and 0.10 respectively (The R'_{meas} is defined as the
359 corrected R_{meas} by correction coefficient α_{CO} and α_{SO_2}) (Fig. 5 c). However, the
360 difference of NO effects between VOCs and CO (and SO_2) as shown in Fig. 4 and Fig.

361 5 has not been reported in previous studies about CRM system.

362 Previous studies have reported that NO had a large effect on the difference between
363 R_{true} and R_{meas} in the CRM systems (Note that the R_{meas} is not corrected in previous
364 studies) (Hansen et al., 2015; Michoud et al., 2015; Yang et al., 2017b). This NO-effect
365 is not only due to the reaction of HO₂ with NO, but also due to the reaction of pyrrole-
366 produced and VOC-produced RO₂ with NO. Figure S5 compares the effect of NO on
367 ($R_{true} - R_{meas}$) in the original CRM system (reported by previous studies) with that in the
368 ICRM system (this study). Far larger NO effects were reported in the original CRM
369 system than in the ICRM system. For example, the presence of ambient NO at 50 ppbv
370 leads to R_{meas} lower than the R_{true} by $70 \sim 232 \text{ s}^{-1}$, at least an order of magnitude higher
371 than the NO artifact in the ICRM system, which leads to R'_{meas} lower than the R_{true} by
372 8.8 s^{-1} . This is because both HO₂ and pyrrole-induced RO₂ are fully removed by the
373 introduced NO in advance in the ICRM system, thus the remaining influencing factor
374 is the reaction of ambient VOCs-induced RO₂ with NO. The uncertainty due to the NO-
375 artifact correction in the ICRM system was predicted to be far lower than that of the
376 original CRM system, as the absolute change of OH reactivity caused by NO is reduced
377 by removing HO₂ and pyrrole-induced RO₂. Despite the ICRM system not being able
378 to remove the NO effect entirely, it does lead to a significant decrease in the uncertainty
379 of the NO-artifact correction.

380 Due to the different behaviors of VOCs, SO₂ and CO at high NO conditions, in
381 order to get accurate OH reactivity, it is necessary to conduct NO-correction for VOCs,
382 SO₂, and CO individually. Note that this issue may also present in the original CRM
383 system, but it was ignored in previous studies. For the ICRM system, we use the
384 following formula to determine the true OH reactivity of VOCs:

$$385 R_{meas} = R_{true\ NO+NO_2} + R_{true\ O_3} + \alpha_{CO}(R_{true\ CO} - f_1[NO]) + \alpha_{SO_2}(R_{true\ SO_2} -$$
$$386 f_1[NO]) + \alpha_{VOC}(R_{true\ VOC} - f_2) \quad (3)$$

$$387 R_{true\ VOC} = \frac{1}{\alpha_{VOC}}(R_{meas} - R_{true\ NO+NO_2} - R_{true\ O_3} + \alpha_{CO}f_1[NO] +$$
$$388 \alpha_{SO_2}f_1[NO] + \alpha_{VOC}f_2 - \alpha_{CO}R_{true\ CO} - \alpha_{SO_2}R_{true\ SO_2}) \quad (4)$$

389 where R_{meas} is the measured OH reactivity by the ICRM system as defined above.

390 The $R_{true\ VOC}$ is the true OH reactivity of VOCs. $R_{i\ true}$ was calculated from measured
 391 concentrations of species i ($i=NO, NO_2, O_3, SO_2$ and CO) multiplied by the rate
 392 coefficient of the reaction of species i with OH. The R_{meas} and R_{true} of NO_x ($=NO+NO_2$)
 393 was close to 1:1 as shown in Fig. 3 and Fig. S6. α_{CO} , α_{SO_2} , and α_{VOC} are the
 394 correction coefficients with regard to the calibration for OH reactivity of CO, SO_2 and
 395 VOC at ambient $NO = 0$ ppbv, respectively. Note that the α_{VOC} is the mean slope of
 396 Fig. 4a. f_1 and f_2 are the correction coefficients which regard to the effect of ambient
 397 NO on $(R_{true} - R'_{meas})$. Note that the f_1 is the mean value Fig. 5c, and the f_2 is the
 398 fitting result both Fig. 5 a and b ($f_1 = 0.105$; $f_2=0.20*[NO]-4.8*10^{-4}*[NO]^2$, as shown
 399 in Fig S5). After getting $R_{true\ VOC}$, the total OH reactivity (R_{tot}) was then calculated as
 400 the summation of $R_{true\ VOC}$, $R_{true\ NO+NO_2}$, $R_{true\ O_3}$, $R_{true\ SO_2}$, and $R_{true\ CO}$:

$$401 \quad R_{tot} = R_{true\ VOC} + R_{true\ NO} + R_{O_3} + R_{true\ NO_2} + R_{true\ CO} + R_{true\ SO_2} \quad (5)$$

402 In this study, we calibrated four individual representative VOC species (methane,
 403 propane, propene, toluene). In addition, we also calibrated the mixed standard gases
 404 with 16 VOC species including representative oxygenated VOCs (acetaldehyde,
 405 methanol, ethanol, acetone, acetonitrile, methyl vinyl ketone, methyl ethyl ketone),
 406 biogenic VOCs (isoprene, α -pinene), typical aromatics (benzene, toluene, o-xylene,
 407 1,2,4-trimethylbenzene, naphthalene, phenol, m-cresol). The calibration slope is close
 408 to those of the four individual VOC species, indicating that the $RO_2 + NO$ reactions for
 409 these investigated VOCs should be similar. Nevertheless, given that there are different
 410 VOCs compositions in different environment such as forest, urban area and emission
 411 sources, calibrations for more individual VOCs species might be also needed.

412 **3.3 Additional potential interference related to NO addition**

413 In order to assess the extent of any additional interferences due to NO addition,
 414 we further consider the following effects.

415 In arm A, the photolysis of O_2 introduced through arm G by the mercury lamp
 416 produces O_3 . Besides, the NO introduced through arm G reacts with HO_2 to generate
 417 NO_2 , which can also photolysis to generate NO and oxygen atoms, and subsequently

418 O₃. We monitored O₃ concentration through the arm F using an O₃ monitor. O₃
419 concentration flowing out of arm F was less than 5 ppbv, which has a negligible
420 influence on the pyrrole concentrations and the R_{meas} , considering the pyrrole+O₃
421 reaction rate constant $k_{\text{O}_3+\text{pyrrole}}=1.57\times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 1984)
422 is several orders of magnitude slower than the pyrrole + OH reaction rate constant
423 ($k_{\text{pyrrole}+\text{OH}}=1.28\times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$). The ozone concentration was low, as excess
424 NO was introduced to the reactor and the remaining NO titrates O₃ back to NO₂.

425 In the C3 mode of the ICRM, sample ambient O₃ can react with the high-levels
426 NO in the reactor, which might interfere with R_{meas} . We characterize this interference
427 by introducing a series of O₃ concentrations into the reactor through arm C. As O₃
428 concentrations lower than 40 ppbv, O₃ has a negligible effect on OH reactivity (Fig. 6).
429 Interestingly, R_{meas} first increases and then decrease with increasing O₃ concentrations.
430 The reaction rate coefficient of OH with NO₂ is slightly higher than with NO, which
431 are $1.2\times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 2004) and $9.7\times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$
432 at 298K, respectively. With the increase of introduced O₃ concentration, higher NO₂ is
433 produced, which causes an increase in R_{meas} . As NO is consumed completely by O₃,
434 excessive O₃ can further react with NO₂ to produce NO₃ radicals, which can deplete
435 pyrrole ($k=1.80 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Cabanas et al., 2004) and lead to the
436 decrease in R_{meas} . Overall, OH reactivity exhibited little change ($< 2 \text{ s}^{-1}$) with the
437 increase of O₃ concentrations (0 ~ 160 ppbv), indicating that the introduced O₃ plays a
438 negligible role in R_{meas} . This is another advantage of ICRM compared with the original
439 CRM, which needs an ozone correction as the reaction of O₃ with HO₂ gives OH back
440 (Fuchs et al., 2017).

441 According to model simulation, the produced NO₂ from the reaction of NO with
442 HO₂ increases with introduced NO concentrations (Fig. S2). The produced NO₂ can
443 deplete OH ($\text{OH} + \text{NO}_2 \rightarrow \text{HNO}_3$) and thereby lead to an increase in the pyrrole
444 concentration. When introduced NO with a concentration of 50 ppbv, the produced NO₂
445 was 25 ppbv, corresponding to 6.2 s^{-1} OH reactivity (Fig. S2). However, this process
446 doesn't interfere with the R_{meas} as the produced NO₂ is the same in both C2 and C3

447 modes leading to this effect canceling out in the two modes.

448 Finally, the reaction time between HO₂ and NO should be noted. The initial HO₂
449 concentration is about 4 ppbv. The lifetime of HO₂ at 50 ppbv NO is at the time scale
450 of 0.1 s, given that the reaction rate constant of NO+HO₂ is $8.1 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1}$
451 s^{-1} (Sander, 2006). The reaction time of NO+HO₂ in arm A is estimated to be around \sim
452 0.1 s, during which most of HO₂ will be consumed. Hence there will be only a small
453 fraction of HO₂ entering the main body of the reactor.

454 **3.4 Photolysis of pyrrole**

455 Photolysis of pyrrole in the CRM method introduces additional uncertainties and
456 complexity in the determination of OH reactivity (Sinha et al., 2008; Hansen et al.,
457 2015; Michoud et al., 2015; Zannoni et al., 2015). To investigate the effect of the ICRM
458 system on the interference from photolysis, we turn the mercury lamp off and on to test
459 the variation in pyrrole concentrations under dry conditions (no humidification).
460 Compared with the condition where the mercury lamp is turned off, pyrrole
461 concentrations decreased by $< 3\%$ after the mercury lamp was turned on (Fig. S7),
462 which caused R_{meas} increase of 0.55 s^{-1} when the R_{true} was 20 s^{-1} . This result indicates
463 that the photolysis of pyrrole is weak enough to be negligible in the ICRM system. This
464 smaller photolysis of pyrrole closely relates to the improved design of reactor structure.
465 Arm A consists of two section of glass tube with 1/2 inch OD and 1/4 inch OD,
466 respectively (Fig. 1c). UV light is mostly confined in 1/2 inch OD glass tube of arm A,
467 as the glass tube is constructed with decreasing diameter following the direction of gas
468 flow. This reduces the amount of UV light getting into the main reaction part of the
469 reactor. The improved structure of arm A leads to lower OH concentrations (decreased
470 by approximately 50%) passing into reactor due to wall loss, but the OH radicals
471 produced from the reaction of HO₂ radicals with NO can partially compensate for this
472 loss. In comparison, the pen-ray mercury lamp was very close to the main body of the
473 reactor in the original CRM reactor, to maximize the OH entering the reactor by
474 minimizing wall loss. However, this will lead to the photolysis of pyrrole, as high as
475 25% (Sinha et al., 2008; Hansen et al., 2015). The change of the structure of arm A also

476 ensures that the photolysis of H₂O, HONO, NO₂, and VOCs inside the ICRM reactor is
477 weaker than that in the original CRM system. In this system, OH reacts with introduced
478 NO or ambient NO to produce HONO, which can reproduce OH and NO by photolysis.
479 As we have improved the structure of arm A to avoid UV light entering main body of
480 the reactor, photolysis of HONO is expected to be low. In addition to our design change,
481 previous studies have reported that the photolysis of pyrrole can be also lowered to
482 below 5% by changing the UV mercury lamp position in the setup (Michoud et al.,
483 2015; Zannoni et al., 2015).

484 In the original CRM system, C1 instead of C0 is used as the initial amount of
485 pyrrole in order to avoid the interference of pyrrole photolysis. The C1 mode, where
486 dry N₂ and zero air are used meanwhile the mercury lamp is turned on, was measured
487 every 12 h for a duration of 2 h (Sinha et al., 2008; Hansen et al., 2015). The length of
488 the duration is necessary to reach the driest conditions possible to minimize residual
489 OH in the reactor. It should be noted that this procedure can result in an underestimation
490 of C1, as it is difficult to remove all trace amounts of water molecules from surfaces
491 and in nitrogen and zero air flowing through the reactor, which is able to produce extra
492 OH by photolysis (Hansen et al., 2015; Michoud et al., 2015; Zannoni et al., 2015). The
493 underestimation of C1 will result in an overestimation of OH reactivity. The
494 significantly smaller photolysis of pyrrole for the ICRM system allows us to measure
495 the C1 mode differently. Here, the condition that N₂ and zero air are humidified while
496 the mercury lamp is turned off is regarded as C1. The new C1 mode is able to avoid the
497 interference resulting from OH radicals produced by photolysis of residual humidity
498 since the mercury lamp is turned off and OH will not be produced. Besides, the C1
499 mode in ICRM is measured every 12 h for a duration of 15 min, which also saves time
500 compared with C1 mode in original CRM.

501 **3.5 Humidity difference between zero air and ambient air**

502 The variation of humidity between the C2 (wet zero air) and C3 (ambient air)
503 measurements could result in a change in OH production rate in the CRM reactor, which
504 in turn could lead to a C2 measurement not representative of the OH production rate

505 observed during the C3 measurement (Sinha et al., 2008; Dolgorouky et al., 2012).
506 Although the use of a catalytic converter or dynamic humidification of zero air can help
507 to reduce differences in humidity between C2 and C3 modes, small differences still
508 exist (Michoud et al., 2015). Besides, while catalytic converters can be used to generate
509 zero air with the same humidity as ambient air, these converters cannot remove NO_x
510 species and thus are not suitable for OH reactivity measurements in urban and suburban
511 areas with high NO_x conditions (Hansen et al., 2015).

512 To investigate the influence of humidity differences between C2 and C3 on the
513 R_{meas} in the ICRM system, we test the response of pyrrole concentration to humidity by
514 introducing zero air with different humidities through arm C at mode C2. The ratio of
515 $\text{H}_3\text{O}^+(\text{H}_2\text{O})$ to H_3O^+ (m37/m19) is selected to represent the level of different humidity.
516 Figure 7 (a) presents the dependence of pyrrole concentrations on m37/m19 at mode
517 C2. Pyrrole concentrations slightly decrease with the increase in m37/m19. It must be
518 noted that this dependence is not due to the humidity dependence of the PTR-MS
519 sensitivity toward pyrrole, but the change in OH production in the reactor, as the
520 normalization procedure of pyrrole signal described in Sect. 2.3 was applied to all
521 pyrrole measurements. The maximum difference of m37/m19 between C2 mode and
522 C3 mode is about 0.01 corresponding to RH changing by $\sim 30\%$ (Fig. 7 b), which lead
523 to pyrrole changed by ~ 0.26 ppbv and thus the R_{meas} changed by $\sim 1.9 \text{ s}^{-1}$ when the R_{true}
524 is 20 s^{-1} . This result indicates that the influence of humidity change on OH
525 concentrations and subsequently R_{meas} cannot be ignored even though the structure of
526 arm A was improved to decrease the numbers of photons entering the main body of the
527 reactor. Therefore, humidity correction is needed to accurately R_{meas} . The humidity
528 difference between C2 and C3 mode can be corrected by the function derived from the
529 relationship between OH reactivity and m37/m19 (as shown in Fig. 7 a).

530 **3.6 Instrument performance in ambient measurements**

531 The detection limit of ICRM was determined to be 2.3 s^{-1} for an averaged pyrrole-
532 to-OH ratio of 2.3 according to the method proposed by Michoud et al. (2015) (Fig S8).
533 This means that the minimum detection limit for the reactivity of sample air would be

534 about 5 s^{-1} (typically diluted in the glass reactor by a factor 2). During the measurement,
535 daily calibration was conducted by introducing a constant concentration of various
536 VOCs standards (propane, propene or toluene) through arm C at C2 mode and
537 determining the ratio of R_{meas} to R_{true} (i.e. α_{VOC}). As shown in Fig. S9, $R_{\text{meas}} / R_{\text{true}}$ is
538 relatively stable during the measurement, ranging from 0.60 to 0.70, implying this
539 method has high stability, despite the structural differences of the VOCs species
540 introduced.

541 Figure 8 a presents a time series of R_{tot} , calculated OH reactivity (R_{cal}), and ambient
542 NO. R_{tot} was acquired based on Eq. 5, and R_{cal} is calculated by the sum of all measured
543 reactive trace gas concentrations multiplied by their respective reaction rate coefficients
544 with OH. The new system worked well even at high NO concentrations ($> 20 \text{ ppbv}$).
545 The average R_{tot} for the entire campaign was 27.3 s^{-1} . The R_{tot} is higher than the R_{cal} by
546 27% during the campaign, with larger differences observed in the morning and at night
547 than in the afternoon. As shown in Fig. 8 b, the R_{tot} has an obvious diurnal variation
548 with higher levels at night and morning than that in the afternoon. This is because air
549 pollutants from anthropogenic emissions were accumulated at night and morning due
550 to lack of oxidative consumption, whereas were depleted rapidly during the afternoon
551 due to rising levels of oxidant, i.e. OH radicals. This diurnal pattern of R_{tot} is similar to
552 that of the previous measurement results in the Pearl River Delta (Lou et al., 2010; Yang
553 et al., 2017a) and Beijing (Williams et al., 2016). Overall, the diurnal variation of the
554 $R_{\text{true VOC}}$ (calculated by Eq.4) is similar to that of the calculated OH reactivity of
555 inorganic gas (Fig. 8 b) and the concentration of NO_x (Fig. 8 c). A comparison between
556 the R_{tot} determined by the ICRM method and the laser-induced fluorescence method
557 will be of interest in future studies, particularly because LIF type systems can also
558 experience difficulties at high NO when OH decay rates are rapid. Further discussions
559 on the OH reactivity results of this campaign will be given in another publication.

560 **4 Conclusion**

561 In this study, we presented an improved comparative reactivity method (ICRM)
562 which is suitable for measuring OH reactivity under high- NO_x conditions. The major

563 improvements of ICRM compared to the original CRM system are as follows:
564 (1) The HO₂ and RO₂ radicals produced from H radicals reacting with O₂ and OH-
565 oxidation of pyrrole, respectively, were removed continuously to the largest extent. In
566 this study, 50 ppbv NO was inject into the ICRM reactor through an additional arm G
567 between arm A and the reactor. Under this NO level, the interference due to the reaction
568 of HO₂ and RO₂ from pyrrole with NO was minimized.
569 (2) The OH recycling always happens to some extent when sampled VOCs are
570 introduced into the reactor in the presence of NO, causing the measured OH reactivity
571 (R_{meas}) deviate from the true OH reactivity (R_{true}). We quantified this effect by
572 calibrating several representative VOC species, CO and SO₂ to obtain the slope of R_{meas}
573 versus R_{true} . Different VOC species produce similar slopes, which are significantly
574 higher than the slopes of CO and SO₂. Using the average value of the derived slopes of
575 the different species as a correction factor, we obtained the more accurate R_{meas} .
576 Additionally, the effect of ambient NO on the difference between R_{true} and R'_{meas} was
577 quantified.
578 (3) Transforming the structure of the glass reactor to reduce the amount of ultraviolet
579 light generated by the mercury lamp reaching the main body of the glass reactor. This
580 effort resulted in eliminating the interference of pyrrole photolysis existed in the
581 original system. Under this condition, the new C1 mode used was able to avoid the
582 interference resulting from OH radicals produced by photolysis of residual humidity
583 and save lots of time compared with the original C1 mode. The ICRM system was
584 employed in a field campaign to measure OH reactivity and performed well even if
585 ambient NO concentrations are high.

794

795

796 **Figure 1.** Schematic and work mode of the original CRM method (Sinha et al., 2008,

797 a and b) and the ICRM method (this study, c and d).

798

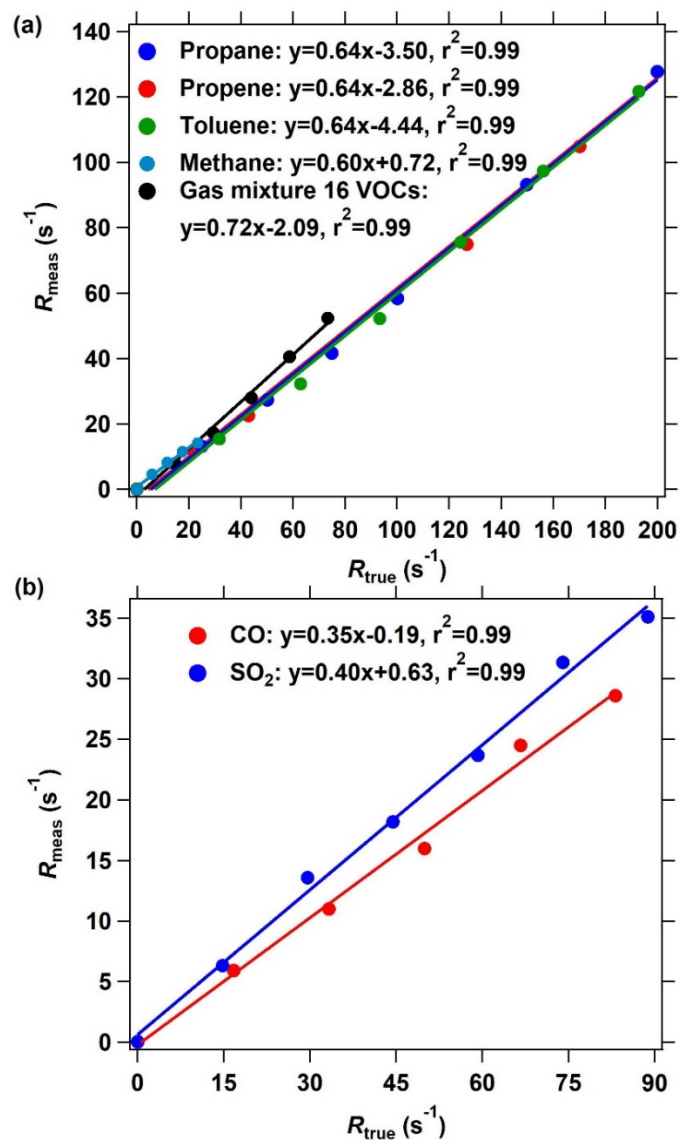

799 **Figure 2.** The response of pyrrole concentration to different NO concentrations
 800 introduced through arm G into the reactor. For the ICRM system, the C2 mode is
 801 corresponding to the pyrrole concentration = 12.31 ppbv at NO = 50 ppbv where the
 802 HO₂ radicals were removed constantly.

803

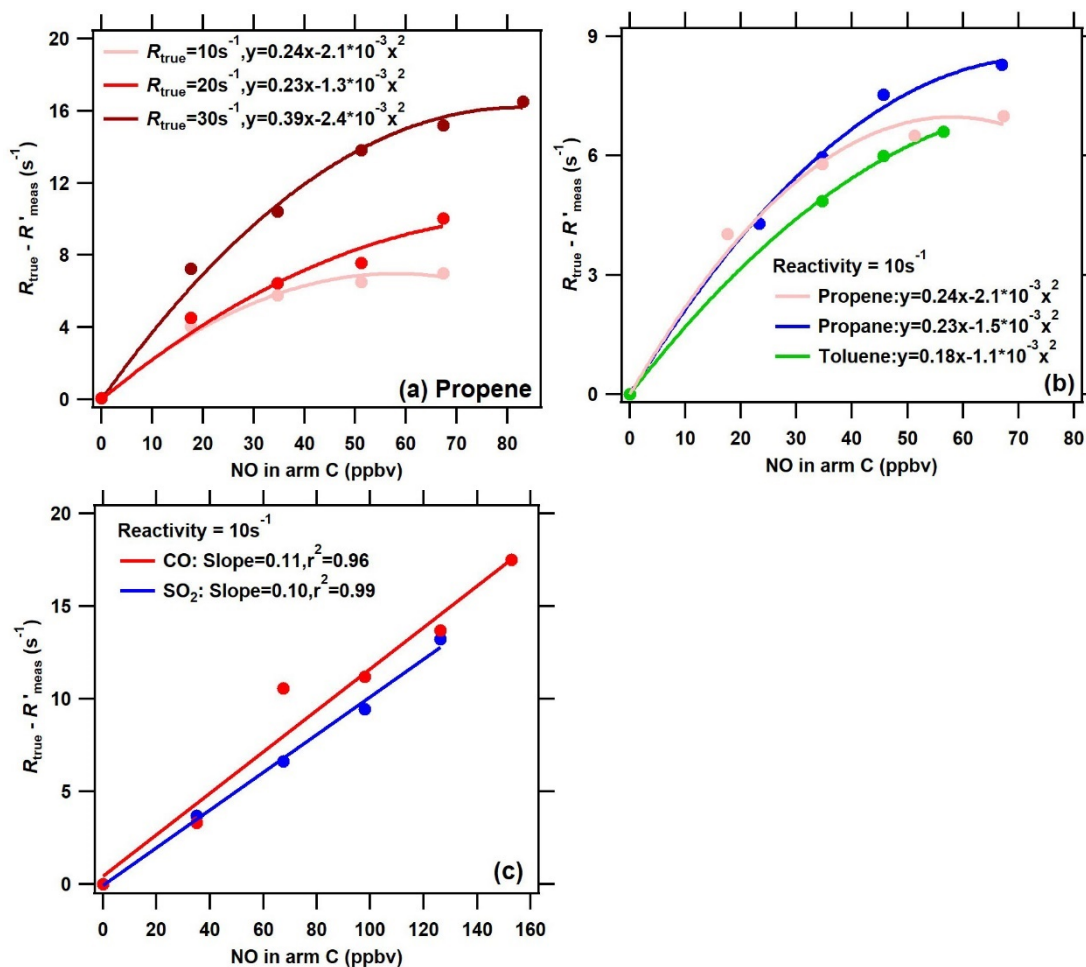

804 **Figure 3.** Comparison of measured and true OH reactivity of NO at different NO
 805 concentrations introduced through arm C. The measured OH reactivity of NO was
 806 calculated based on the new C2 mode shown in Fig. 2 in the ICRM system.

807

808

809 **Figure 4.** The OH reactivity calibration of the improved CRM system using different
 810 standard gases. **(a)** The calibrating results of organic species including methane,
 811 propane, propene, toluene, and a mixture of 16 VOC species through arm C. **(b)** The
 812 calibrating results of inorganic species including CO and SO₂. The measured OH
 813 reactivity was calculated based on the C2 mode shown in Fig. 2 in the ICRM system.

814

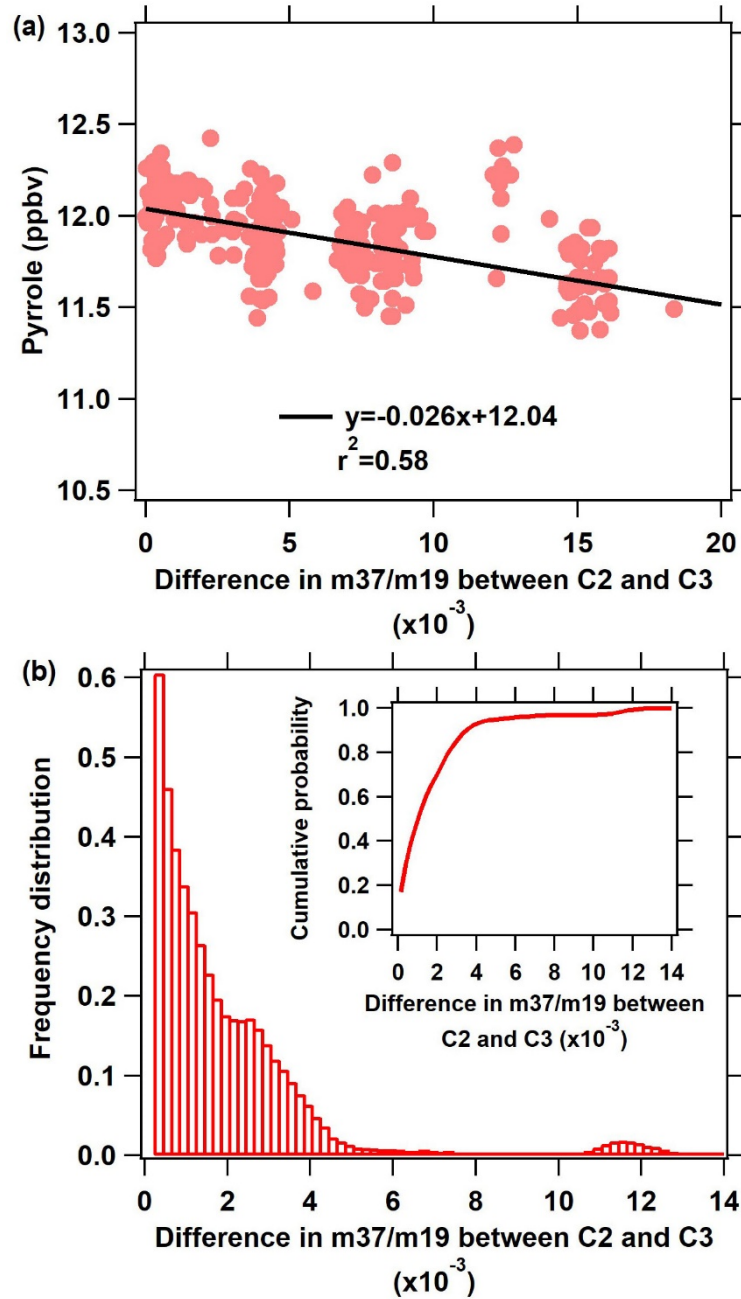

815 **Figure 5.** The difference between true OH reactivity (R_{true}) and the corrected measured
 816 OH reactivity (R'_{meas}) using the calibration factor α_1 ($R'_{\text{meas}} = (\frac{1}{\alpha_{\text{VOC}}} * R_{\text{meas}})$) as a
 817 function of NO concentrations in arm C in the conditions of (a) different levels of VOCs
 818 reactivity for the same species (propylene), (b) different VOCs species for the same
 819 OH reactivity level (10 s^{-1}), and (c) different inorganic species (Red: CO; Blue: SO₂)
 820 for the same OH reactivity level (10 s^{-1}). Note that NO, CO, SO₂, and VOCs were
 821 introduced into the reactor through arm C.

822

823 **Figure 6.** Interference of different O_3 concentration (introduced into the reactor through

824 arm C) on measured OH reactivity in the ICRM system.

825

826 **Figure 7. (a)** Pyrrole concentration during zero air measurements (C2) as a function of

827 the difference in m37/m19 between C2 and C3 humidity indicator (m37/m19). **(b)**

828 Frequency distribution of the difference in m37/m19 between C2 and C3 during the

829 measurement.

830

831

832

833 **Figure 8.** The measurement results of OH reactivity and ambient NO at the Heshan site
 834 from October 19 to October 31, 2019. (a) The time series of total OH reactivity (R_{tot}),
 835 calculated reactivity (R_{cal}), and ambient NO concentration; (b) Mean diurnal profile of
 836 OH reactivity of $R_{true\ VOC}$, $R_{NO_x+CO+SO_2+O_3}$, and R_{tot} ; (c) Mean diurnal profiles of
 837 measured NO, NO_2 , and NO_x .
