**Abstract.** We develop a new way to retrieve the cloud index from a large variety of satellite instruments sensitive to reflected solar radiation, embedded on geostationary as non geostationary platforms. The cloud index is a widely used proxy for the effective cloud transmissivity, also called clear-sky index. This study is in the framework of the development of the Heliosat-V method for estimating downwelling solar irradiance at the surface of the Earth (DSSI) from satellite imagery. To reach its versatility, the method uses simulations from a fast radiative transfer model to estimate overcast (cloudy) and clear-sky (cloud-free) satellite scenes of the Earth's reflectances. Simulations consider the anisotropy of the reflectances caused by both surface and atmosphere, and are adapted to the spectral sensitivity of the sensor. The anisotropy of ground reflectances is described by a bidirectional reflectance distribution function model and external satellite-derived data. An implementation of the method is applied to the visible imagery from a Meteosat Second Generation satellite, for 11 locations where high quality in situ measurements of DSSI are available from the Baseline Surface Radiation Network. Results from our preliminary implementation of Heliosat-V and ground-based measurements show a correlation coefficient reaching 0.948, for 15-minute means of DSSI, similar to operational and corrected satellite-based data products (0.950 for HelioClim3 version 5 and 0.937 for CAMS Radiation Service).

## 1 Introduction

Downwelling surface solar irradiance (DSSI) is one of the Essential Climate Variables defined by the Global Climate Observing System (GCOS, 2016). It is the solar part of the downwelling irradiance at the surface of the Earth and on an horizontal unit surface. The solar irradiance is defined as the integration on the spectral interval 290-3000 nm, accordingly to WMO (2014). DSSI considers the irradiance coming from all directions of the hemisphere above the surface: the irradiance coming from the direction of the Sun, plus a diffuse component due to scattering caused by the atmosphere (clouds, gases, aerosols) and reflection by the surface.

The knowledge of DSSI variations in space and time is of primary importance for various fields such as Earth sciences, renewable solar energy industries, agriculture, or some medical fields. To meet all these needs, an ideal information on DSSI would feature high spatio-temporal resolution, a coverage of the entire Earth's surface, and the longest time period possible.

Long time series of data are notably useful to identify statistics of long-term inter-annual to multi-decadal variability and  
25 possible trends, if bias and standard deviation of the error requirements are reached.

Different approaches already exist to produce such DSSI data. Sources of data mainly include ground pyranometric mea-  
surements, *e.g.* from national meteorological and hydrological services, numerical weather prediction (NWP) modeling, *e.g.*  
the Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2) (Gelaro et al., 2017) and the Eu-  
ropean Centre for Medium-range Weather Forecasts (ECMWF) reanalyses ERA-5 (Hersbach et al., 2020), and satellite-based  
30 remote sensing, *e.g.* methods listed by Sengupta et al. (2017). Satellite-based methods are an efficient and accurate way to  
produce kilometric and sub-hourly resolved multidecadal time series of DSSI. A more comprehensive review of pros and cons  
of different approaches is notably described in Huang et al. (2019).

The imagery produced by satellite radiometers provides a unique perspective on DSSI. Upwelling radiances coming from  
each location on Earth are acquired several times per day by a wide set of satellite imagers. This can particularly be achieved  
35 thanks to imagers embedded on meteorological geostationary (GEOs) and polar orbiting satellites like the Polar Operational  
Environmental Satellites (POES) from the National Oceanic and Atmospheric Administration (NOAA), and the MetOp series  
operated by the European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT). Another approach  
exists since 2015, thanks to the Deep Space Climate Observatory (DSCOVR) satellite mission: its Lissajous orbit around the  
L1 Lagrangian point between the Earth and the Sun makes it possible to picture the whole sunlit hemisphere of the planet, with  
40 a single satellite radiometer (Marshak et al., 2018; Hao et al., 2020).

Imagery of the Earth produced by satellite sensors exists for about six decades, and led early to the development of methods  
for estimating DSSI (Tarpley, 1979).

Today, the information from multi-channel satellite measurements offers the possibility to derive cloud physical properties  
and then compute cloud attenuation of the solar radiation with methods like the Fast All-sky Radiation Model For Solar Appli-  
45 cations (FARMS) (Xie et al., 2016), Heliosat-4 (Qu et al., 2017), Zhang et al. (2018), or Hao et al. (2019). Such methods are  
especially advantageous for highly reflective regions, where clouds are difficult to discriminate from the ground. Nevertheless,  
they require information on more than one spectral channel, limiting their versatility in the choice of satellite sensor.

The use of radiative transfer models and look-up tables is also quite common in the field of satellite-based estimation  
of DSSI, but usually requires pre-existing informations on cloud properties or a cloud mask (*e.g.* ISCCP-F (Zhang, 2004),  
50 GEWEX-SRB (Pinker and Laszlo, 1992; Cox et al., 2017), CLARA (Mueller et al., 2009), Cloud\_cci (Stengel et al., 2020;  
Stephens et al., 2001)).

Another group of methods, labeled as "cloud-index methods", are able to produce estimates of downwelling surface solar  
irradiance from the visible imagery of satellite radiometers without external knowledge on cloud physical and optical proper-  
ties. This gives them potential to retrieve multi-decadal time series including from the imagery of oldest 2-channel sensors like  
55 the Meteosat Visible and Infrared Imager (MVIRI). Cloud-index methods emerged quite early, notably with the seminal work  
of Möser and Raschke (1983) and the first Heliosat method (Cano et al., 1986; Cano, 1982). The cloud index quantity derives  
from the radiances measured by spaceborne sensors, and relates them to the extinction of the DSSI caused by clouds. The  
greater the cloud index, the greater the extinction, and the smaller the DSSI. More precisely, the cloud index can be used as an

empirical proxy for effective cloud transmissivity. The latter, also named "clear-sky index" within the scientific community of  
 60 solar energy, is defined as the ratio of the all-sky surface irradiance to the clear-sky surface irradiance (Long and Turner, 2008;  
 Beyer et al., 1996), *i.e.* the DSSI in cloud-free conditions.

**Figure 1.** The calculation of a cloud index for a given location. The cloud index is the ratio between the distances "measurement to clear-sky" (red arrow) and "overcast-sky to clear-sky" (black arrow).

The cloud-index concept is based on the idea that the presence of a cloud brightens locally pixels of satellite shortwave  
 imagery. In general, the value that quantifies reflectances of a given location observed from the top of the atmosphere (TOA),  
 is comprised between a low and a high boundary values. The low boundary value  $X_{\min}$  is taken as the clear-sky case and the  
 65 high one  $X_{\max}$  as the most cloudy case. The attenuation of downwelling surface solar irradiance by clouds is roughly given as  
 a linear function of the difference between the measured value  $X_{\text{sat}}$  and the clear-sky boundary, relatively to the cloudy case -  
 clear case difference, as illustrated in Figure 1. The cloud index  $n$  is then given as:

$$n = \frac{X_{\text{sat}} - X_{\min}}{X_{\max} - X_{\min}} \quad (1)$$

Differences between cloud-index methods mainly rely on :

- 70 – modifications of the relationship between the cloud index and the effective cloud transmissivity (Zarzalejo et al., 2009;  
 Perez et al., 2002; Gupta et al., 2001; Rigollier and Wald, 1998);
- the choice of the variable used to calculate the cloud index, for example TOA albedo (Darnell et al., 1988), reflectance  
 (Wang et al., 2014; Gupta et al., 2001; Möser and Raschke, 1984), Lambert equivalent reflectivity (LER) (Herman et al.,  
 2018; Dave, 1978) or raw satellite numerical counts (Pfeifroth et al., 2017; Perez et al., 2002);
- 75 – the way to retrieve the  $X_{\max}$  and  $X_{\min}$  for the chosen variable.

If very different approaches are used to estimate the upper boundary, the lower boundary is "archive-based", in most literature we reviewed: it is a minimum based on a time series of past satellite imagery. Such an approach is hardly applicable to non geostationary satellites due to variable viewing geometries and a low revisit time. As an example, Wang et al. (2014) use a climatology of surface albedo to derive DSSI from the Ozone Monitoring Instrument (OMI), embedded on the sun-synchronous satellite Aura.

In this paper, we aim at finding an alternative to the need for archives of satellite imagery. It would then be easier to consider imagery from non-geostationary spaceborne platforms and produce a worldwide coverage. It would also let the results more reproducible, by making each instantaneous estimate independent of the preceding time series. Other drawbacks are frequent in archive-based methods such as systematic underestimations of the lower boundary  $X_{\min}$  (e.g. unusual dark shadows on the ground taken as the clear-sky reference), contamination of  $X_{\min}$  by clouds for cloudiest regions and of course, the difficulty to find a trade-off between a large time window that ensures the observation of clear sky instants, and a small one that captures the temporal variability of  $X_{\min}$ .

But the development of an alternative to such archive-based approaches also means dealing with new issues: previous methods based on archives can be less dependent on absolute calibration of the original imagery (Pfeifroth et al., 2017; Perez et al., 2002) and consider implicitly the anisotropy of  $X_{\min}$ . The pixel-to-pixel estimation of  $X_{\min}$  is a surrogate for modeling the influence of viewing geometry on measured reflectances, while the slot-by-slot temporal characterization of  $X_{\min}$  pictures the influence of varying solar-viewing geometry for the diurnal cycle of each pixel's reflectivity.

We aim at developing an alternative "stateless" method to extend the application field of the cloud-index approach to a wider variety of orbits and optical shortwave sensors. In order to limit the effects of molecular scattering, ozone absorption and polarization present in the ultraviolet, and of the absorption of radiation by clouds in the near infrared, the method considers satellite imagery in the spectral range 400-1000 nm ( $\lambda < 1000$  nm). This range is also wide enough to permit the use of imagery from many meteorological satellite imagers launched since the beginnings of spaceborne Earth observation (e.g. different generations of the Advanced Very High Resolution Radiometer and of GOES, Meteosat and Himawari radiometers). Heliosat-V makes an extensive use of simulations from a radiative transfer model to estimate the upper boundary variables  $X_{\min}$  and  $X_{\max}$ , which are here reflectances at the top of the atmosphere. This notably relies on the hypothesis that the absolute calibration of the satellite measurements is sufficiently well-known to ensure the quality of DSSI retrievals. It also means that the spectral sensitivity of the sensor and the anisotropy of reflectances caused by surface and atmospheric components have to be explicitly described to produce accurate estimates.

The impact of the anisotropy of surface reflectance has notably been shown for estimates of a cloud index derived from measurements of the ultraviolet/visible Global Ozone Monitoring Experiment 2 (GOME-2) and OMI by Lorente et al. (2018). The latter study also highlights the improvement of simulated shortwave clear-sky reflectances at the TOA, when using a model of bidirectional reflectance distribution function (BRDF) parameterized with data derived from the Moderate Resolution Imaging Spectroradiometer (MODIS) spaceborne instruments.

The method foreseen to compute the cloud index of Heliosat-V and eventually the DSSI is described in Section 2, along with the protocol of validation. Validation results are presented in Section 3 for simulated reflectances at the top of the atmosphere and for downwelling surface solar irradiance estimates. Section 4 is dedicated to the discussion of results, and Section 5 to the conclusion and perspectives.

## 115 2 Methods

### 2.1 The cloud index $n$

As stated in the introduction, Heliosat-V is a method approximating the attenuation of DSSI radiation by clouds with a cloud index,  $n$ . Here, the cloud index components are reflectances considered at the top of the atmosphere (TOA), and corresponding to the satellite radiometer viewing geometry and spectral sensitivity. Reflectances are defined by the relation:

$$120 \quad \rho = \frac{\pi L}{E_0 \cos(\theta_s)} \quad (2)$$

with  $L$  the upwelling radiance at TOA for a given spectral channel,  $E_0$  the downwelling spectral solar irradiance at the top of the atmosphere on a perpendicular plan weighted by the spectral response function (SRF) of the channel, and  $\theta_s$  the solar zenith angle for a given location (*i.e.* latitude and longitude) and a given time.  $E_0$  varies mainly with the Sun-Earth distance, computed here with the Solar Geometry 2 algorithm (Blanc and Wald, 2012). The cloud index is then defined as:

$$125 \quad n = \frac{\rho_{\text{sat}} - \rho_{\text{clear}}}{\rho_{\text{ovc}} - \rho_{\text{clear}}} \quad (3)$$

where  $\rho_{\text{sat}}$  is the reflectance measured by the radiometer for the given spectral channel, while  $\rho_{\text{clear}}$  and  $\rho_{\text{ovc}}$  are estimates of the reflectance that would be measured by the same sensor for, respectively, a clear-sky scene, and an overcast scene, *i.e.* with an optically thick cloud covering the whole pixel considered. The notion of "optically thick cloud" will be described in detail in the subsection 2.3.

130 Because of its definition, the cloud index may also be calculated with radiances. We consider here reflectances in order to visualize the anisotropic nature of different scenes. It has also the advantage to be a normalized quantity, so we can compare results for different radiometric channels and different SZAs.

The relationship between  $n$  and DSSI varies slightly from one method to another, in particular for highest and lowest values of  $n$ . The core of the relationship for intermediate values of  $n$  follows usually:

$$135 \quad G = G_c (1 - n) \quad (4)$$

where  $G$  is the all-sky DSSI and  $G_c$  is the DSSI in clear-sky conditions and is provided by an external model. The external model used in this paper will be presented and discussed in section 2.4. The clear-sky index  $K_c$  is largely used to simplify the reading and is defined as:

$$K_c = \frac{G}{G_c} \quad (5)$$

140 so we can rewrite Equation (4) as:

$$G = G_c K_c \quad (6)$$

Several modifications of the relation  $K_c(n)$  have been proposed, *e.g.* by Rigollier and Wald (1998) (reported in Rigollier et al. (2004)); Gupta et al. (2001); Perez et al. (2002); Zarzalejo et al. (2009). In this paper, we keep the original and simple relation  $K_c = 1 - n$  introduced by Darnell et al. (1988) as its optimization is out of the scope of this work. In the following  
145 subsections, we describe the method used to compute  $\rho_{\text{clear}}$ ,  $\rho_{\text{ovc}}$  and  $G_c$ .

## 2.2 The clear-sky reflectances $\rho_{\text{clear}}$

We use a radiative transfer model to estimate what a spaceborne optical imaging system would measure in clear-sky conditions, for a given radiometric channel. Using simulations in cloud indices has previously been done notably to retrieve effective cloud fractions from the OMI instrument (Lorente et al., 2018; Veefkind et al., 2016; Stammes et al., 2008). We apply the same  
150 approach to satellite radiometers.

Radiative transfer simulations are able to estimate reflected radiation at the top of the atmosphere (TOA) considering the non-lambertian nature of the atmosphere and of Earth's surfaces. For the implementation of the method applied here, we use the model *uvspec* within the software package libRadtran (version 2.0.2) (Emde et al., 2016) and the one-dimension solver DISORT (Buras et al., 2011). We chose to use 32 streams for DISORT as a good compromise between time computation  
155 and a good angular representativeness of simulated radiances. For the spectral description, radiative transfer simulations are made following the so-called REPTRAN spectral approximation (Gasteiger et al., 2014). This parameterization enables the production of fast computations of radiative transfer adapted to the spectral sensitivity of satellite radiometric channels.

The spectral description of downwelling solar irradiance at the top of the atmosphere is provided by data from Kurucz (1992) for simulating  $\rho_{\text{clear}}$ . The composition of the atmosphere is prescribed by time series of total atmospheric columns  
160 of ozone and water vapour from the Monitoring Atmospheric Composition and Climate (MACC) reanalysis (Inness et al., 2013) distributed by the ECMWF. The atmospheric abundance profiles of O<sub>2</sub>, CO<sub>2</sub> and NO<sub>2</sub> are kept to the fixed values of the Air Force Geophysics Laboratory (AFGL) midlatitude summer profile (Anderson et al., 1986), along with the temperature, pressure and air density profiles.

Partial aerosol optical depths (AOD) are provided at the wavelength 550 nm, for 5 types of aerosols (black carbon, dust, sea  
165 salt, organic matter, sulfate) by the Monitoring Atmospheric Composition and Climate (MACC) reanalysis. A more recently developed product Copernicus Atmospheric Monitoring Service (CAMS) reanalysis exists, with two supplementary classes "ammonium" and "nitrate" added to the aerosol categories of the service. It is worth mentioning that we do not use it, even such change would not affect the method itself.

An algorithm developed by Lefèvre et al. (2013) translates MACC partial aerosol optical depths information into aerosol  
170 mixtures designed for the Optical Properties of Aerosols and Clouds (OPAC) software package (Hess et al., 1998). These mixtures are associated to aerosol properties: scattering and absorbing coefficients, single scattering albedo, asymmetry parameter and the Angström coefficient. The total AOD at 550 nm is then calculated as the sum of partial AOD at 550 nm provided by

CAMS. As libRadtran needs a total AOD input for the simulated wavelength, the OPAC Angström coefficient of the given mixture is used to estimate the AOD at the required wavelength.

175 The reflective properties of land surfaces are described with the RossThick-LiSparse (Ross-Li) model of bidirectional reflectance distribution function (Roujean et al., 1992; Lucht et al., 2000). It is then possible to consider the variations of the surface reflectance depending on viewing and solar zenith angles and on the azimuthal difference of both geometries  $\Delta\phi$ . The Ross-Li model decomposes the BRDF of a surface into a sum of three components: an isotropic contribution, independent of viewing and solar geometries; a volumic contribution, following a mathematical model of an idealized canopy; and a geometric  
180 contribution, considering the shadows induced by the roughness of the surface.

Algorithms have been developed to estimate the parameters  $f_{\text{iso}}$ ,  $f_{\text{vol}}$  and  $f_{\text{geo}}$  that weight respectively each of the contributors to the surface reflectance for all lands. This has notably been made with the imagery produced by the Moderate Resolution Imaging Spectroradiometer (MODIS) embedded on Terra and Aqua satellites (Wanner et al., 1997; Lyapustin et al., 2018).

We test here simulations with data from the Algorithm for Modeling MODIS Bidirectional Reflectance Anisotropies of the  
185 Land Surface (AMBRALS) (Wanner et al., 1997) with its derived product MCD43C1 v6 (Schaaf et al., 2002).

This product provides  $f_{\text{iso}}$ ,  $f_{\text{vol}}$  and  $f_{\text{geo}}$  parameters with a  $0.05^\circ$  resolution (about 6 km at the equator), a daily sampling rate, 16-day average and for seven spectral channels, including 4 channels in the 400-1000 nm spectral interval considered for the Heliosat-V method (Fig. 3). Owing to libRadtran documentation (Mayer et al., 2017), the values of each parameter are assigned to the central wavelength of its channel and a linear spectral interpolation is applied for the radiative transfer calculations. For  
190 wavelengths shorter than the  $0.47 \mu\text{m}$  MODIS channel, values are considered spectrally constant. For wavelengths longer than  $0.85 \mu\text{m}$ , the interpolation is made between parameters at MODIS channels  $0.86 \mu\text{m}$  and  $1.24 \mu\text{m}$ .

### 2.3 The overcast-sky reflectances $\rho_{\text{ovc}}$

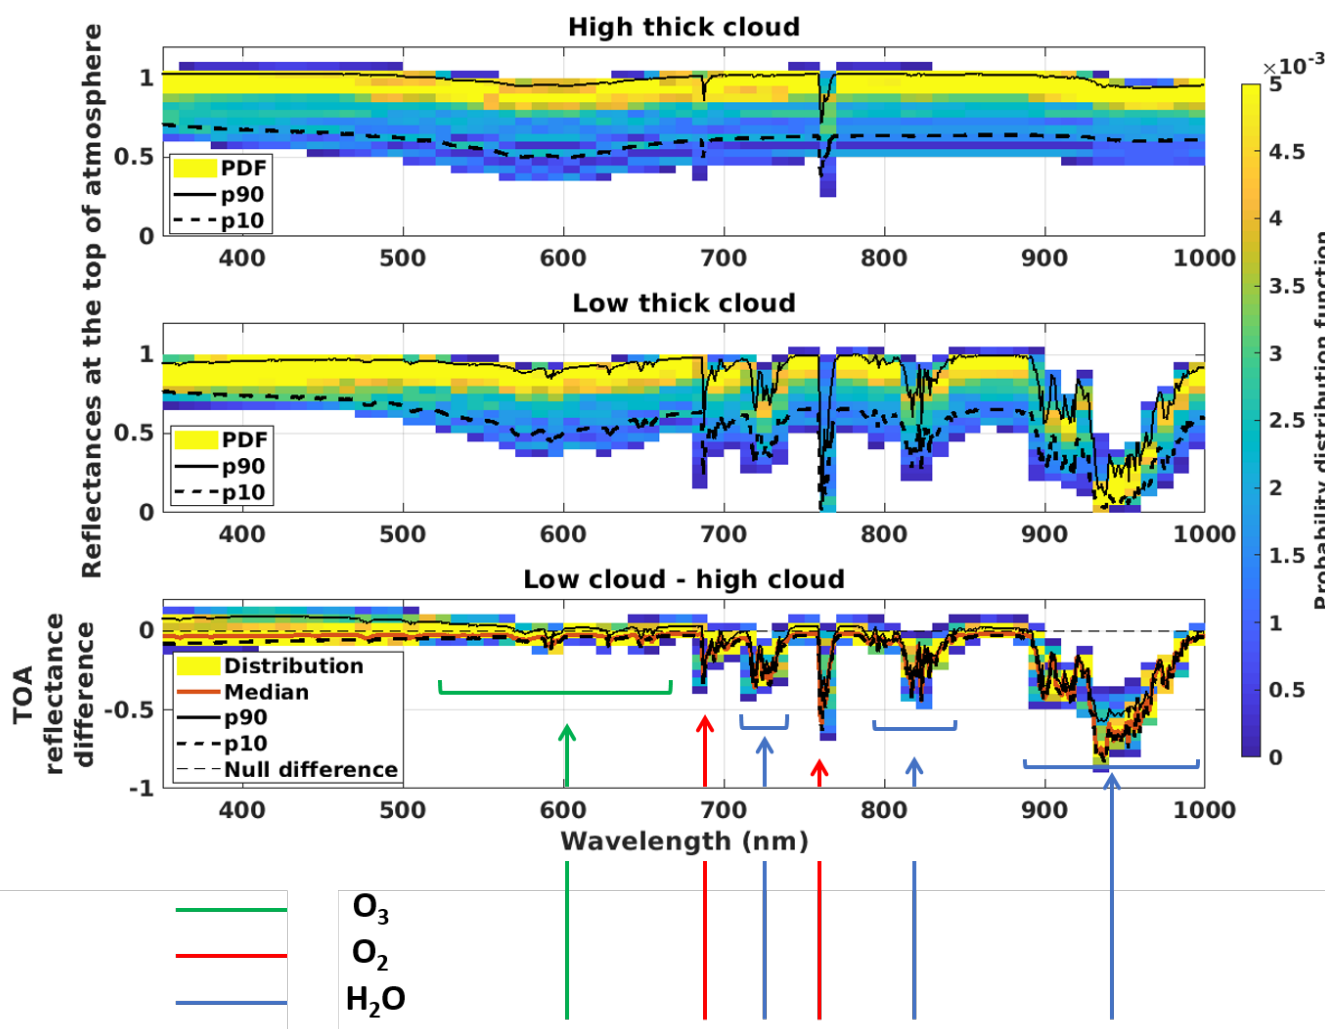

Cloud-index methods in the literature use various ways to estimate the TOA reflectances in overcast conditions  $\rho_{\text{ovc}}$  (Perez et al., 2002; Lefèvre et al., 2007; Pfeifroth et al., 2017). One way to approximate it without the use of archives of satellite  
195 imagery has been proposed within the Heliosat-2 framework (Lefèvre et al., 2007). An empirical relation based on the work of Taylor and Stowe (1984) was developed, considering a dependency of  $\rho_{\text{ovc}}$  with the single solar zenith angle  $\theta_s$ .

$$\rho_{\text{ovc,HS2}} = 0.85 - 0.13 [1 - \exp(-4 \cos(\theta_s)^5)] \quad (7)$$

However, spectral radiative transfer simulations of  $\rho_{\text{ovc}}$  show that there is also a significant dependency between the TOA cloudy reflectances and other variables. In Figure 2, we represent 2-dimension histograms of TOA reflectances calculated  
200 from such simulations, with a solar zenith angle set to  $30^\circ$  as an example. For most wavelengths, a significant spread of the distribution is observed (Fig. 2, two upper rows), corresponding only to different viewing geometries defined by a linear meshgrid in cosine of viewing zenith angle ( $\theta_v$ ) and difference  $\Delta\phi$  of solar and viewing azimuth angles (Table 1).

In this paper, we assume a cloud optical thickness (COT) of 150 to define optically thick clouds and overcast conditions. This assumption relies on COT statistics from retrievals by the International Satellite Cloud Climatology Project (ISCCP) and  
205 surface measurements of irradiance shown by Trishchenko et al. (2001). The simulations for a low thick cloud (cloud top

**Figure 2.** Two upper rows : distributions of simulated TOA reflectance spectra in overcast conditions  $\rho_{ovc}$  for the different viewing geometries in the look-up table and for a solar zenith angle of  $30^\circ$ , with a thick liquid cloud ( $COT = 150$ ). First row:  $CTH = 15$  km ; cloud base height ( $CBH$ ) = 2 km. Second row:  $CTH = 0.5$  km ;  $CBH = 0.2$  km . Third row: error on  $\rho_{ovc}$  caused by a misattribution of cloud height to the "low thick cloud" category. Green, red and blue arrows indicate spectral regions with main absorption features from  $O_3$ ,  $O_2$  and  $H_2O$ , respectively.

height ( $CTH$ ) at 500 m) and a high thick cloud ( $CTH$  at 15 km) show in general a good agreement, except in absorbing bands of  $O_2$  (mainly at 690 nm ( $O_2$ -B band) and 762 nm ( $O_2$ -A band)) and  $H_2O$  (mainly at 725 nm, 820 nm and 950 nm) and for short wavelengths where scattering becomes increasingly significant (*e.g.* Jin et al. (2011)). For these wavelengths, the TOA

reflectances with low clouds can be much lower than for high clouds, for a given cloud optical thickness. But outside these  
210 specific spectral regions, the height of clouds will not affect significantly the results of the method.

An alternative way is therefore to produce look-up tables (LUT) from radiative transfer simulations, an approach notably  
applied in the framework of the Heliomont cloud-index method to the Spinning Enhanced Visible and Infra-Red Imager (SE-  
VIRI) High Resolution Visible channel (HRV) (Stöckli, 2014). It is then possible to take into account the viewing geometry  
and also the spectral variability of  $\rho_{ovc}$ . Assumptions have to be made on the properties of the optically thick clouds as the  
215 Heliosat-V method is designed to work by using only one spectral channel in the range 400-1000 nm: cloud top height, phase  
of cloud, cloud optical thickness, cloud droplet radius or ice crystal shape and size.

Here we construct a liquid cloud LUT of  $\rho_{ovc}$ , setting different cloud and atmosphere properties, geometry and spectral  
grids, as described in Table 1. The optical properties of the clouds come from the precalculated Mie tables provided by the  
libRadtran software package.

220 As no information is provided on the actual cloud vertical structure,  $\rho_{ovc}$  are calculated as :

$$\rho_{ovc} = \frac{1}{2}(\rho_{ovc,high} + \rho_{ovc,low}) \quad (8)$$

where  $\rho_{ovc,high}$  and  $\rho_{ovc,low}$  are respectively derived from the high and low liquid cloud LUTs, interpolated on the viewing  
and solar geometries of the satellite time series and adapted to the spectral response function of radiometric channels.

An ice cloud LUT is also produced, to study the sensitivity of surface irradiance estimates to the assumed cloud phase. The  
225 ice cloud characteristics follow the parameterization by Yang et al. (2013). We use the "aggregate of 8 columns" ice crystal  
habit and the "severe" degree of roughness, which are notably used for the description of ice clouds in the look-up table of the  
MODIS collection 6 cloud product (Amarasinghe et al., 2017).

## 2.4 The clear-sky model of surface irradiance $G_c$

The clear-sky surface irradiance is given by the the version 3 of the McClear model (Gschwind et al., 2019). The McClear  
230 model is a fast and accurate model that provides clear-sky estimation of DSSI with an absolute bias below  $21 \text{ W m}^{-2}$  and  
a standard deviation error below  $25 \text{ W m}^{-2}$  for 6 BSRN stations used in this paper, namely: Brasilia, Carpentras, Palaiseau,  
Payerne, Sede Boker and Tamanrasset. The McClear model was fed with the partial optical depths at 550 nm for black carbon,  
dust, sea salt, organic matter and sulfate from MACC reanalysis. It is also fed by water vapor atmospheric total columns and  
the ozone total columns provided by ECMWF. Data was downloaded from the McClear web service (<http://www.soda-pro.com/web-services/radiation/cams-mcclear>).  
235

## 2.5 Set-up of validation

To study the validity of the method, we compare DSSI estimates from MSG satellite measurements with pyranometric DSSI  
data retrieved from measurement stations part of the reference Baseline Surface Radiation Network (BSRN) (Ohmura et al.,  
1998; Driemel et al., 2018). Considered stations are listed in Table 2 and displayed in the MSG field of view in Figure 4. Only

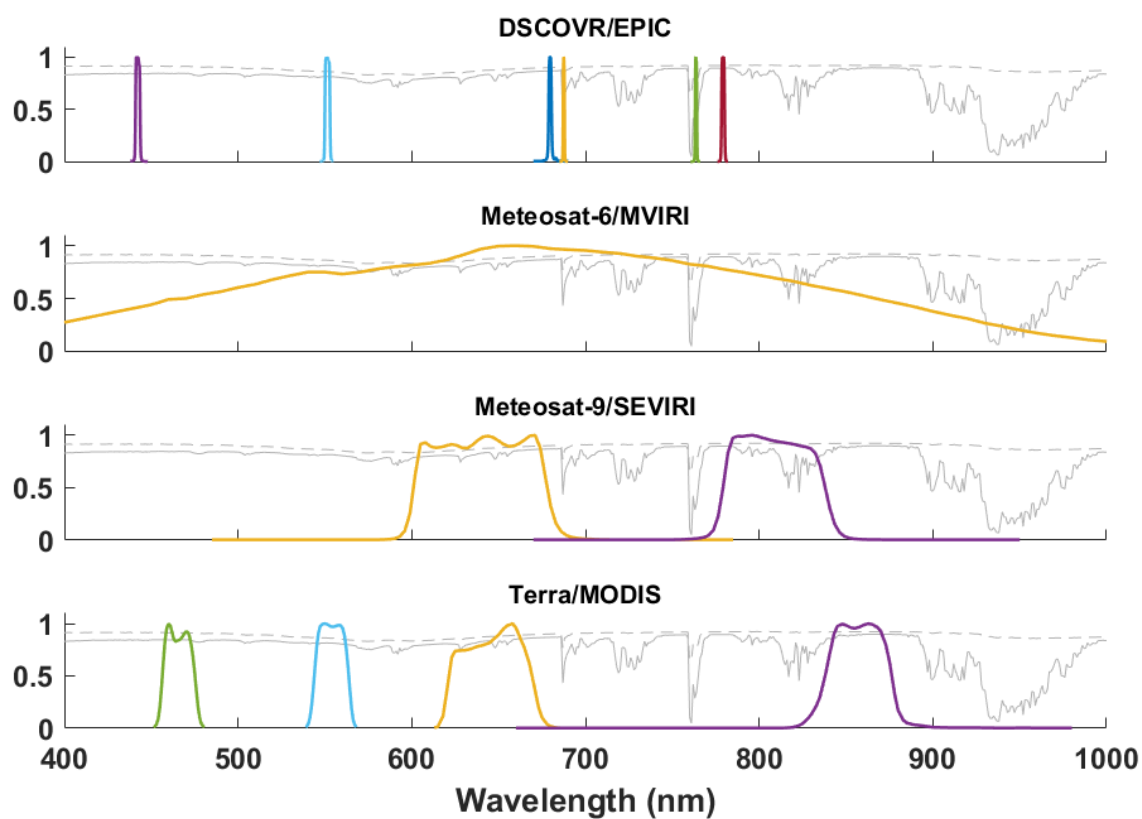

**Table 1.** Characteristics of the look-up table of cloudy TOA reflectances

Characteristics	Values
Cloud phase	liquid (ice only for sensitivity tests)
Cloud optical thickness (COT)	150
Cloud droplet radius	vertical profile between 8 and 12 $\mu\text{m}$
Cloud top height (CTH)	500 m ; 15 km
Solar zenith angle ( $\theta_s$ )	$0^\circ : 5^\circ : 85^\circ$
cosine of viewing zenith angle ( $\cos \theta_v$ )	0.1 : 0.1 : 1
difference of solar and viewing azimuth angles ( $\Delta\phi$ )	$0^\circ, 5^\circ, 10^\circ : 20^\circ : 170^\circ, 175^\circ, 180^\circ$
Spectral resolution	1 nm
TOA spectrum	Gueymard (2018)
Ozone total column	300 Dobson Units (DU)
Water vapour total column	$20 \text{ kg m}^{-2}$
Aerosols	default aerosol described in Shettle (1990)
Temperature and pressure profiles	AFGL midlatitude summer

**Table 2.** List of BSRN stations used for validation

Station	Code	Latitude	Longitude	Elevation
Brasilia	BRB	$15.6010^\circ \text{ S}$	$47.7130^\circ \text{ W}$	1023 m
Cabauw	CAB	$51.9711^\circ \text{ N}$	$4.9267^\circ \text{ E}$	0 m
Camborne	CAM	$50.2167^\circ \text{ N}$	$5.3167^\circ \text{ W}$	88 m
Carpentras	CAR	$44.083^\circ \text{ N}$	$5.590^\circ \text{ E}$	100 m
CENER	CNR	$42.8160^\circ \text{ N}$	$1.6010^\circ \text{ W}$	471 m
Lindenberg	LIN	$52.2100^\circ \text{ N}$	$14.1220^\circ \text{ E}$	125 m
Palaiseau	PAL	$48.7130^\circ \text{ N}$	$2.2080^\circ \text{ E}$	156 m
Payerne	PAY	$46.8150^\circ \text{ N}$	$6.9440^\circ \text{ E}$	491 m
Sede Boker	SBO	$30.8597^\circ \text{ N}$	$34.7794^\circ \text{ E}$	500 m
Sao Martinho da Serra	SMS	$29.4428^\circ \text{ S}$	$53.8231^\circ \text{ W}$	489 m
Tamanrasset	TAM	$22.7903^\circ \text{ N}$	$5.5292^\circ \text{ E}$	1385 m

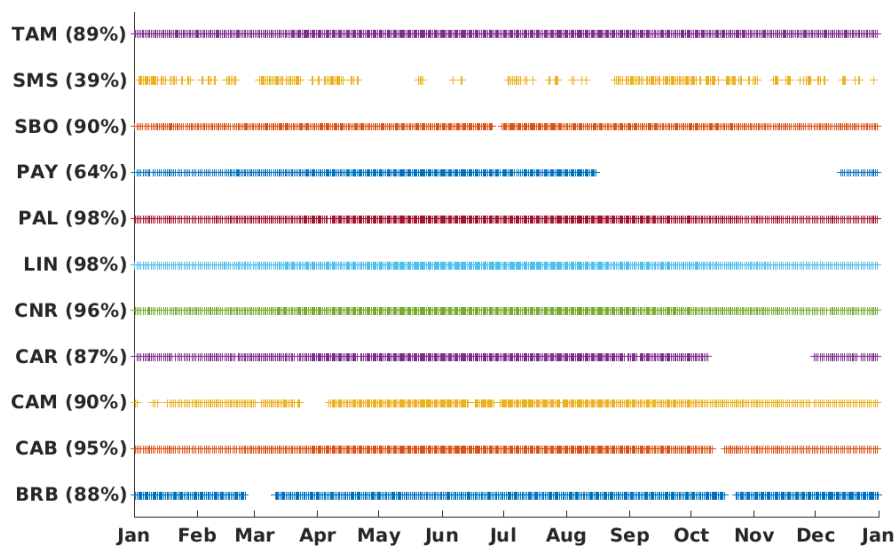

240 the highest quality BSRN measurements of surface irradiance are used, having passed a quality check (Lefèvre et al., 2013).  
 Figure 5 shows the time series when data are considered valid, for each station.

**Figure 3.** Colored lines: spectral response functions of different sensors in the spectral range considered by Heliosat-V. Gray lines : TOA reflectance spectra of typical scenes with a high (dashed line) and low altitude (solid line) thick cloud

**Figure 4.** BSRN ground stations used for validation in this study, in the field of view of Meteosat Second Generation ( $0.6 \mu\text{m}$  channel).

**Figure 5.** Time series used for the 15-min mean statistics between satellite estimates and quality-checked BSRN measurements during the year 2011. In parentheses : percentage of data conserved.

The method has been tested on images from the SEVIRI sensor, aboard the Meteosat-9 meteorological geostationary satellite belonging to the family of Meteosat Second Generation (MSG). We consider measurements in the solar channels  $0.6 \mu\text{m}$  and  $0.8 \mu\text{m}$  channels, for the year 2011 and for 11 locations in the field of view of the satellite, and corresponding to locations of  
245 pyranometric in situ sensors from the BSRN network.

We use the calibration coefficients provided by EUMETSAT that operates MSG. This is worth noting as some calibration methods recommend to use significantly different gain factors to compute radiances from raw numerical counts (*e.g.* Doelling et al. (2018)). The use of optimal calibration is out of the scope of our work. Still, we compared gains coefficients proposed by EUMETSAT  $g_{\text{EUM}}$  with those provided by Doelling et al. (2018)  $g_{\text{D2018}}$  for the measurements produced by the Meteosat-9  
250  $0.6 \mu\text{m}$  and  $0.8 \mu\text{m}$  channels in 2011. They show a mean disagreement, calculated as  $(g_{\text{EUM}} - g_{\text{D2018}})/g_{\text{D2018}}$ , of about -9 % for  $0.6 \mu\text{m}$  and -8 % for  $0.8 \mu\text{m}$  during this period (also illustrated on Fig. A1). Such errors will affect with the same magnitude the agreement between numerical simulations and measurements of clear-sky TOA reflectances, underlining the importance of absolute calibration for the Heliosat-V method.

To compare the results of our method to operational satellite-based products of surface irradiance, we use data from Helio-  
255 Clim3 version 5 (HC3v5) and CAMS Radiation (CAMS-RAD) DSSI databases. Both are derived from the imagery of the SEVIRI sensor and are produced by a Heliosat method: a modified version of Heliosat-2 for HC3v5 (Qu et al., 2014) and Heliosat-4 for CAMS-RAD. Both products and their descriptions are provided by the SoDa service (<http://www.soda-pro.com/>).

All validation results thereafter are produced for solar zenith angles lower than  $80^\circ$ .

### 3 Results

#### 260 3.1 The cloud index components

##### 3.1.1 Simulated TOA clear-sky reflectances $\rho_{\text{clear}}$

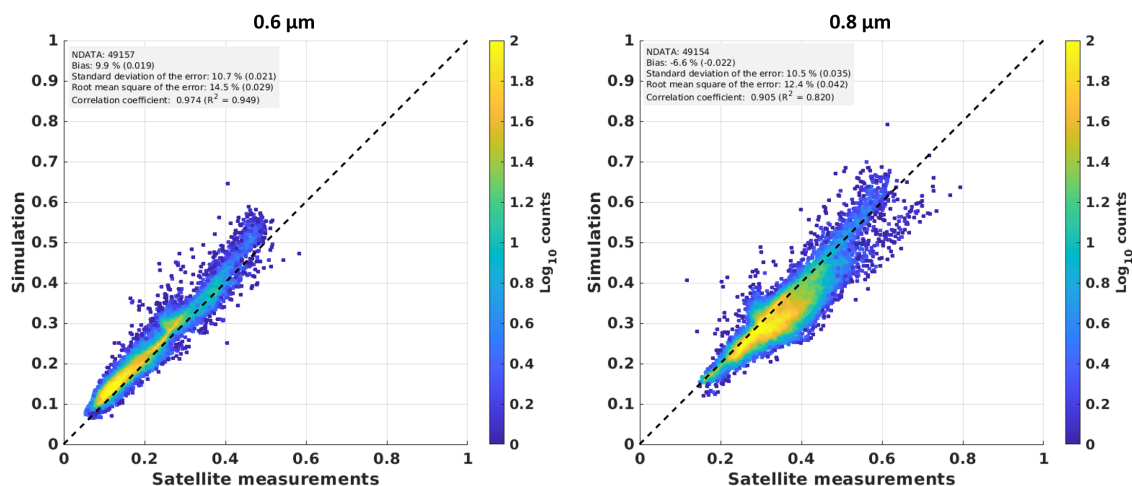

As an intermediate assessment, simulated clear-sky reflectances at the top of the atmosphere (TOA)  $\rho_{\text{clear}}$  are compared to satellite measurements. Cloudy instants are manually filtered out of the satellite time series. Results comprising all the manually filtered clear-sky instants in 2011 for all the eleven sites, are shown in Figure 6 as 2D reflectance histograms.

265 For the  $0.6 \mu\text{m}$  channel, the root-mean-square difference (RMSD) between simulated reflectances  $\rho_{\text{clear}}$  and reflectances  $\rho_{\text{sat}}$  measured in clear-sky conditions is about 0.03 (15 %), mainly due to a bias of about 0.02 (10 %). The relative value of the standard deviation of the difference (STD) is approximately 11 % for both  $0.6 \mu\text{m}$  and  $0.8 \mu\text{m}$  channels. However reflectances in the near infrared  $0.8 \mu\text{m}$  channel are significantly higher, so is the absolute value of STD. Both higher STD and bias for the  $0.8 \mu\text{m}$  will cause a lower precision in the calculation of the cloud index than for  $0.6 \mu\text{m}$ . Correlation coefficients are  
270 significantly high, both larger than 0.9 but the correlation is much better for  $0.6 \mu\text{m}$  with 0.974: the variability of  $\rho_{\text{clear}}$  is significantly better represented (almost 95 % of the total variance) than for  $0.8 \mu\text{m}$  (82 % of the total variance).

Figure 7 shows that estimates are able to reproduce partly the diurnal variability observed in clear sky conditions. When studying station by station, highest mean biases reach +0.035 for  $0.6 \mu\text{m}$  (Payerne) and -0.07 for  $0.8 \mu\text{m}$  (Camborne) (see also

Fig. B1). It is worth noting that we use MCD43C1v6 BRDF data regardless of their quality flags. We observe although that  
275 keeping only the highest quality data slightly improves statistics.

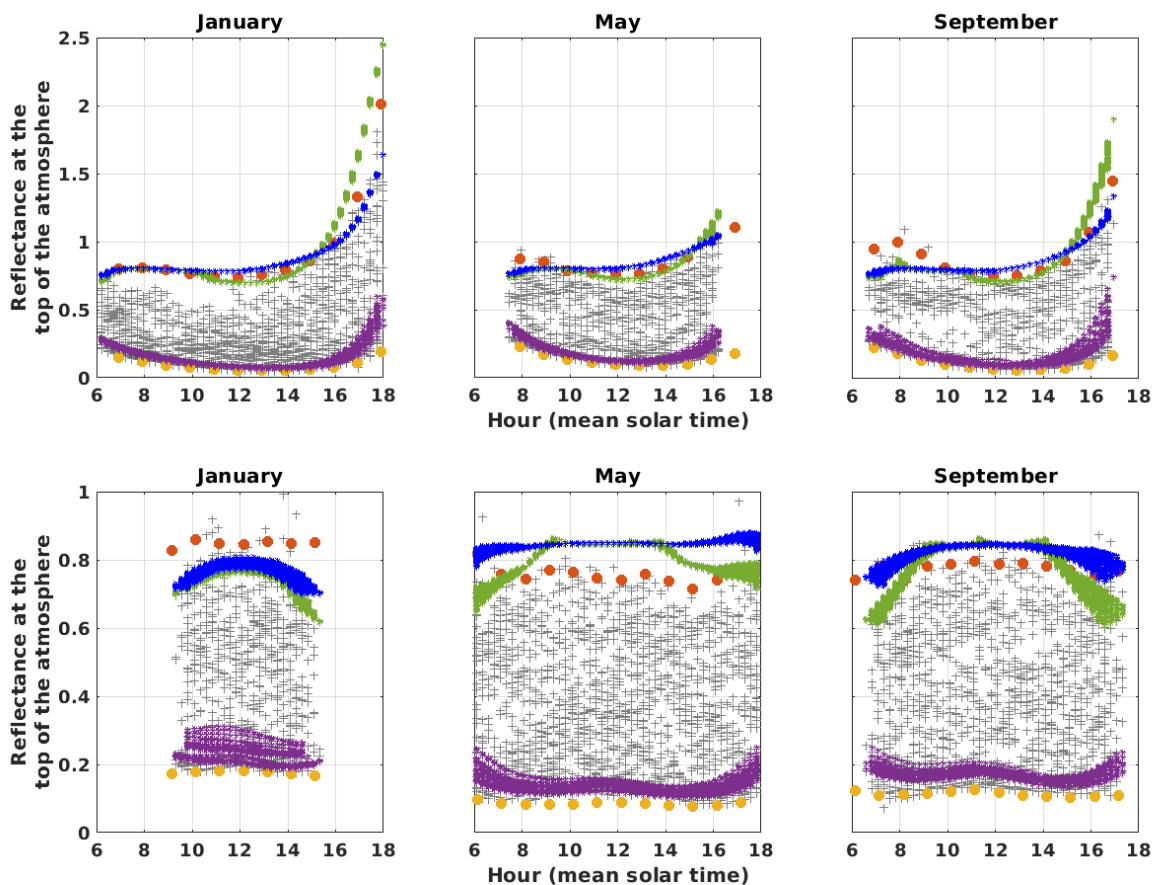

**Figure 6.** Simulation of clear-sky reflectances at the TOA ( $\rho_{\text{clear}}$ ) for MSG 0.6  $\mu\text{m}$  (left panel) and 0.8  $\mu\text{m}$  (right panel) spectral channels compared with actual satellite measurements. The comparison is done for all 11 locations, for the year 2011.

### 3.1.2 Simulated reflectances at the top of the atmosphere in overcast conditions $\rho_{\text{ovc}}$

The validity of  $\rho_{\text{ovc}}$  is more difficult to test than that of  $\rho_{\text{clear}}$  by comparing with satellite measurements as the occurrence of optically thick clouds can be rare depending on the location, the season and the hour of the day. We therefore use 9 years of Meteosat measurements, between 2011 and 2019 to extract the 1% most reflective scenes for each station, month and hour of  
280 the day (Fig. 7). The first row of Figure 6 shows a good agreement between most reflective satellite scenes of the São Martinho da Serra pixel and  $\rho_{\text{ovc}}$ . On the other hand, some stations show regularly values of measured reflectances beyond the  $\rho_{\text{ovc}}$  simulated boundary, as in the example of Camborne (Fig. 7, second row). Figure 7 illustrates also how  $\rho_{\text{ovc}}$  depends on the liquid or ice phase of the cloud, due to their different scattering phase functions.

### 3.2 Comparison of satellite-based estimates with ground-based measurements

285 Validation results are shown in Table 3, for 15-min averaged DSSI estimates. Satellite-based estimates are obtained with MSG 0.6  $\mu\text{m}$  imagery. Results for MSG 0.8  $\mu\text{m}$  imagery show generally lower quality in terms of correlation and STD (Fig. B2).

**Figure 7.** Simulated and measured reflectances at the top of the atmosphere above São Martinho da Serra (Brazil, upper row) and Camborne (United Kingdom, lower row) locations, for MSG 0.6  $\mu\text{m}$  channel and for January, May and September calendar months. Grey plus signs: MSG measurements (2011, Meteosat-9). Green asterisks: reflectances in overcast conditions  $\rho_{\text{ovc}}$ , derived from the liquid-cloud look-up table. Blue asterisks: same from the ice-cloud look-up table. Purple asterisks: reflectances in clear-sky conditions  $\rho_{\text{clear}}$ , derived from radiative transfer simulations. Yellow and orange dots are respectively hourly percentiles 1 and 99 of MSG satellite measurements from year 2011 to 2019.

We tested the sensitivity of the DSSI estimates to the cloud phase by using in one case the reference look-up table, featuring a liquid cloud, and for the test case, an ice cloud as described in Section 2.3. Results show only minor differences, pointing out a limited influence of the cloud phase on DSSI estimates (Fig. B3).

### 290 3.3 Comparison of satellite-based estimates with operational products HelioClim3 and CAMS Radiation

The results of the method are also compared to satellite-based DSSI products HelioClim3 version 5 (HC3v5) and CAMS Radiation Service (CAMS-RAD) on Table 4. Results for the new HSV method show statistics similar to HC3v5 and CAMS-

**Table 3.** Validation results for 15-min means of all-sky DSSI, for the year 2011. Results based on the imagery of Meteosat-9/SEVIRI 0.6  $\mu\text{m}$  channel.

Station	Number of samples	Mean BSRN $\text{W m}^{-2}$	Bias $\text{W m}^{-2}$ (%)	RMSD $\text{W m}^{-2}$ (%)	Correlation coefficient (R)
Brasilia	13570	504	25 (5)	137 (27)	0.883
Cabauw	13222	301	4 (1)	72 (24)	0.949
Camborne	12731	310	-3 (-1)	103 (33)	0.901
Carpentras	12642	452	41 (9)	80 (18)	0.969
CENER	14164	412	21 (5)	89 (22)	0.946
Lindenberg	13637	317	9 (3)	81 (26)	0.938
Palaiseau	13993	335	12 (4)	79 (24)	0.948
Payerne	9191	387	29 (8)	88 (23)	0.955
Sede Boker	13574	589	46 (8)	90 (15)	0.960
Sao Martinho da Serra	5864	501	8 (2)	102 (20)	0.936
Tamanrasset	13609	579	26 (5)	88 (15)	0.958
Total	136197	436	20 (5)	93 (22)	0.948

**Table 4.** Comparison between validation results of HSV with those of HC3v5 and CAMS-RAD, each one versus BSRN measurements. Statistics on 15-minute means of DSSI for the stack of 11 stations and the year 2011.  $N = 135107$ ; BSRN mean =  $424 \text{ W m}^{-2}$

Method/data product	Bias $\text{W m}^{-2}$ (%)	STD $\text{W m}^{-2}$ (%)	RMSD $\text{W m}^{-2}$ (%)	Correlation coefficient (R)
HSV 0.6 $\mu\text{m}$	20 (5)	91 (21)	93 (22)	0.948
HSV 0.8 $\mu\text{m}$	-6 (-2)	101 (24)	101 (24)	0.934
HC3v5	2 (0)	88 (21)	88 (21)	0.950
CAMS-RAD	0 (0)	98 (23)	98 (23)	0.937

RAD, for both estimates based on 0.6  $\mu\text{m}$  and 0.8  $\mu\text{m}$  channels, in terms of correlation and of STD. One may note very low values of bias for operational products. This is expected because CAMS-RAD and HC3v5 estimates are calibrated with DSSI measurements from a similar set of BSRN stations.

#### 4 Discussion

Cloud-index methods are sensitive to estimates of clear-sky reflectances at the top of the atmosphere (TOA)  $\rho_{\text{clear}}$ , to the accuracy of overcast reflectances  $\rho_{\text{ovc}}$  and to the contrast between clear-sky and overcast scenes.

300 Better results from the channel  $0.6 \mu\text{m}$  could be attributed to a smaller influence of the cloud top height, compared to the  $0.8 \mu\text{m}$  channel which is affected by water vapour absorption (Fig. 3). Also, the choice of a spectral linear interpolation between MODIS channels to simulate surface reflectances in SEVIRI channels is supposed to contribute significantly to biases observed in  $\rho_{\text{clear}}$  simulations, in particular for the  $0.8 \mu\text{m}$  channel with vegetated surfaces due to the red edge spectral pattern. Such biases could affect significantly DSSI estimates.

305 The surface reflectivity is lower for shorter wavelengths in general. Selecting a channel for which the surface reflectivity is low will favor a high contrast between clear-sky and overcast scenes, and improve the precision in the computation of the cloud index.

Our ability to reproduce reflectances at the top of the atmosphere in overcast conditions depends also on our knowledge of cloud properties, including their scattering phase function, tridimensional structure and top height.

310 But the introduction of radiative transfer simulations in the computation of the cloud index also enhances the importance of an accurate calibration of satellite radiance measurements. Using the gain coefficients developed by Doelling et al. (2018) for CERES-SYN1deg instead of EUMETSAT operational coefficients is sufficient to remove most of the mean bias observed between simulations and measurements of reflectances at the top of the atmosphere in clear-sky conditions, for the channel  $0.6 \mu\text{m}$ . Besides, this increases the mean bias for the  $0.8 \mu\text{m}$ . It is possibly due to a weaker compensation of the errors on the calibration and caused by the linear spectral interpolation applied between MODIS channels to reproduce reflexion properties of vegetated surfaces.

The simple relationship between the cloud index and the clear-sky index used here explains the significant amount of negative values of DSSI estimates. The improvement of this relation will be the object of a future study.

320 Finally, the quality of the results depends also on the quality of the clear-sky surface irradiance model : the example of the McClear model shows typical biases of 3 % for the studied stations, when compared to BSRN irradiance data (Fig. C1). The improvement towards a least biased estimation of the downwelling surface solar irradiance based on a cloud index will require better estimates of the attenuation of the solar radiation by the clear atmosphere.

## 5 Conclusion and perspectives

325 A method to compute the cloud index is described in the framework of the development of the future Heliosat-V method for estimating downwelling surface solar irradiance from satellite imagery. The cloud index is built to deal with a single radiometric channel in the spectral range 400-1000 nm. It also does not need archives of data to quantify the cloud effective transmissivity. This approach has advantages. First, the concept of the Heliosat-V cloud index enables the use of imagery from geostationary and non-geostationary platforms, an asset to reach an extended spatial coverage. Moreover, the approach has the potential to deal with long time series of imagery from radiometers characterized by different spectral sensitivities and viewing geometries.

330 Validation results using SEVIRI imagery show that DSSI can be estimated by a cloud index method that does not rely on archives of imagery, with a quality similar to operational satellite-based data products like CAMS Radiation Service and HelioClim3, in terms of RMSD and correlation. This is an encouraging step toward the application of a Heliosat method to

non geostationary satellite sensors. However, we note that there are differentiated errors depending on the spectral channel considered. This could be attenuated notably by an external knowledge on cloud top height and by improving the spectral interpolation of reflexion properties of vegetated surfaces.

335 To clarify the potential of the method for long time series of imagery, we will need to explore how sensitive to the quality of input data the results are. The knowledge on atmospheric composition in absorbing and scattering species and on surface reflectivity properties is notably lower for past periods like 1980's than for today. Also, the absolute calibration of satellite imagery can be more uncertain, without on-orbit calibrated instruments. Many inputs of the method have very different degrees of quality, depending on the period considered: the composition of the clear-sky atmosphere (aerosols and gases), surface  
340 properties, external clear-sky irradiance model. Further work is still to be done on multidecadal time series to study how the quality of such ancillary data affect the estimates of DSSI.

Also, producing global maps of DSSI requires to deal with non geostationary satellite imagery. First tests of the method have been made on the imagery of the Earth Polychromatic Imaging Camera (EPIC) embedded on the DSCOVR platform. They show encouraging results that will be extended and detailed in a future publication.

345 Global coverage of DSSI information obviously requires also to deal with ocean surfaces and snow covered regions, and this will need to be treated in the future.

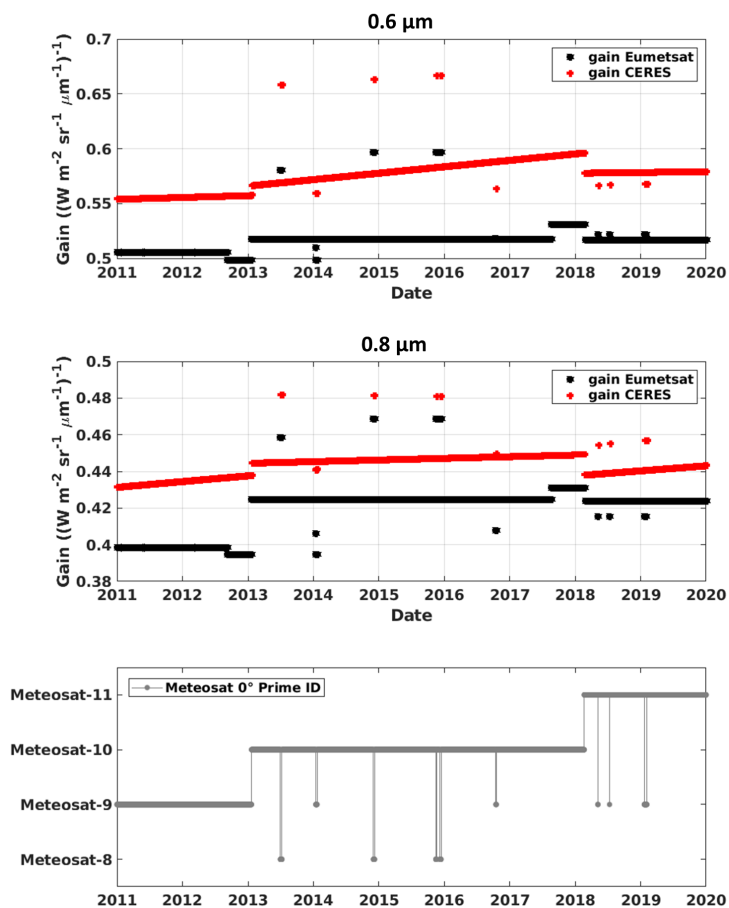

*Code availability.* Excerpts of code are available at <https://cloud.mines-paristech.fr/index.php/s/HAWmw7Fs927EtME>

*Data availability.* DSSI results derived from the implementation of Heliosat-V for validation on all 11 stations are available at <https://cloud.mines-paristech.fr/index.php/s/HAWmw7Fs927EtME>, along with simulated and MSG measured reflectances, cloud and clear-sky indices  
350 and clear-sky irradiance estimates from the McClear model. The manually filtered clear-sky instants are also provided for all 11 locations.

## Appendix A: Methods

### A1 Set-up of validation

**Figure A1.** First two rows: calibration gains provided by EUMETSAT (black stars) and by CERES-SYN1deg (Doelling et al., 2018) (red stars) for  $0.6 \mu\text{m}$  channel (first row) and  $0.8 \mu\text{m}$  (second row) of SEVIRI sensor aboard Meteosat-9, between 2011 and 2019. Third row: ID of the operational satellite at the longitude  $0^\circ$ .
