

Referee #2

The work of Kudo et al., is very important in the field of retrieving aerosol and trace gases properties from radiance measurements. A full method consisting of algorithms for these retrievals is presented for the first time and is evaluated using POM data. Results are validated by a closure study and by comparing in situ aircraft data from a campaign. Uncertainties are calculated and causes of errors are treated separately. In general, it is a very good manuscript that will make an impact on future works. I suggest accepting it for publication after minor revisions.

We thank you for taking the time to review our manuscript and for your useful comments. We revised the manuscript following your comments.

We found the bugs in the simulation of the surface solar irradiance from the retrieved parameters in section 5.1.3. All the surface solar irradiances were calculated again, and the results were improved. Please note that the results and discussions in section 5.1.3 were modified.

In particular

A) My main concern is the SSR closure study presented briefly in 5.1.3 and it could be a separate manuscript on its own. I assume it includes only clear sky data (otherwise it would also need cloud properties). I think it would be more useful to present also some results using V42 V5, in order to convince that the results of the new method are closer to actual conditions. Also, since aerosols (and  $o_3$ , PWV) accounts for a small part of the variability of Global Irradiance, I suggest presenting not the absolute values, but the differences from measured irradiances. There is a huge potential discussion here, about which how different properties affect the components of SSR, which might be a bit out of the scope of this study. But I think a wider discussion should be reserved for this study, since it is important and complex and not presented in such a brief.

- Only the clear sky data was used. I described this in section 2.1 of the revised manuscript (line 156).
- The results using the V42 and V5 retrievals were added to the revised manuscript (Figure 14, lines 594-606).
- We added Figure 15 which plots the relative differences of the global, direct, and diffuse irradiances as a function of the AOD, and the relation between the aerosol optical properties and the differences of the irradiances were discussed (Figure 15, lines 607-636).
- We agree that there is a huge potential discussion, but further studies are necessary to

understand the inconsistency between the simulated and measured irradiances. The main objective in the present study is to show the performance of new method. Your suggestions are important, and we will continue to investigate on this topic.

B) A general comment is that the discussion on the results and the corresponding figures/tables is very brief. I think an effort should be made to deepen a little the discussion for all figures 6-14

We added the discussion about the SSA (lines 475-479, 556-560), PWV (lines 573-583), and the radiative closure (lines 594-636). We need more specific comments for further improvements.

C) Since the use of PP data is a main advantage of the method, I would like to read a small discussion about the suggested measuring schedule of a photometer (regarding PP and ALM, zenith angle and measuring frequency) in respect to the estimated uncertainties, in order to best the exploit method.

The PP and ALM should be conducted every time. The PP data, in particular 940 nm is affected by the aerosol vertical profile. Conversely, we might be able to estimate the aerosol vertical profile by the synergy of PP and ALM data. We described this in the manuscript (lines 706-711).

L55 in the world => around the world

Thanks, we corrected it (line 55).

L77 please rephrase, for example “low altitude sites”

Thanks, we corrected it (line 77).

L158 Some details regarding the calibration of pyranometers should be provided. How close to a calibration are the months used in the study?

The instruments are regularly calibrated once in 5 years. The pyrhelimeter is calibrated in January 2017, and the pyranometer is calibrated in July 2016. These were added to the revised manuscript (line 162).

Section 3.1.2 is mainly discussing and explaining the terms of equation 4. I think it is more reasonable to have the equation and the discussion in the same section. I recommend reorganizing a bit the way the text is separated to sections here.

Since the terms of Eq. (4) are explained in the separate sections, 3.1.2, 3.1.3, and 3.1.4,

we'd like to keep this structure of the text. For the readability, we added the description that the details of each term in Eq. (4) are shown in the sections from 3.1.2 to 3.1.4 (lines 194-198).

L201 We gave the value => we assumed or employed the value

Thanks, we corrected it (line 210).

L209 These unnatural oscillations should be discussed and explained or at least provide some literature examples for them.

There are no literature describing the unnatural oscillations, but there is a literature describing the low signal-to-noise ratio of 1627 and 2200 nm. The unnatural oscillation is due to the low sensitivity of the detector at 1627 and 2200 nm. We added this (line 217).

L339 This means 8.3% of the simulations are rejected. I think these simulations should also be included in the error analysis, since they should reduce the quality of the algorithm. I understand it is difficult to quantify, if there is no output, but It is misleading to ignore such a number of runs, which I understand is expected at this frequency in operational runs.

The quality control is necessary in the real operation to remove the unrealistic results and to increase the product quality. Therefore, we should evaluate the retrieval results after the quality control. However, as you suggested in the next comments, we need to improve the quality control by using SSA.

The rejected data was 8.2 % in the simulations of the section 4.1, but the rejected data in the analysis of the section 5.1 was 0.07 % for ALM-SW, 0.61% for PPL-SW, 3.12 % for ALM-LW, and 4.37 % for PPL-LW, respectively. In order to prevent the reader from understanding that the rejected data is 8.2% in the operation, we added these values to the section 5.1 of the revised manuscript (lines 455-457).

Figure 1 and corresponding discussion. SSA is a parameter that has values up to 1, and variations in the scale of 0.03-0.05 could change the nature (absorbing) of aerosols. Differences up to 0.5-0.6 are unreasonable and should be filtered out by some QC algorithm (these are SSA values of 0.2 or 0.3). Probably you should implement this plot to a zoomed one in the reasonable range. Still the thickness of the main cloud of data seems to wide to have a robust retrieval, and it doesn't seem to get narrower at higher SZA or AOD (at least from what I can see at this scale). For AOD<0.2 the errors are higher. Differences for shown in table 3 are too high for water soluble aerosols. Probably

an acceptable approach could be to ignore SSA retrievals for very low AOD. Finally, I cannot understand why for the lower uncertainties are in the UV region and not in the visible.

- Thank you. The QC using SSA is a good idea. However, we cannot use it in this study because a deeper investigation is necessary to determine the threshold of SSA.
- We changed the axis range of Fig. 1.
- We agree that the errors of SSA do not become narrower in higher SZA and AOD.
- In general, the error of the retrieved SSA is smaller with higher AOD because the diffuse radiances become more sensitive to SSA (Dubovik et al., 2000). In the UV region, the AOD is high, and the diffuse radiances have the rich information on SSA. Dubovik, O., Smirnov, A., Holben, B. N., King, M. D., Kaufman, Y. J., Eck, T. F., and Slutsker, I. (2000), Accuracy assessments of aerosol optical properties retrieved from Aerosol Robotic Network (AERONET) Sun and sky radiance measurements, *J. Geophys. Res.*, 105 (D8), 9791– 9806, doi:10.1029/2000JD900040.

L365. After the discussion about the advantage of this method In retrieving bigger particles, I don't understand why this analysis is not up to 30 $\mu$ m.

In the retrieval of the aerosol optical properties, it is most important to decrease the errors of the retrieved VSD around the mode radius. Therefore, we showed only the errors of the retrieved VSD around the mode radius. In the revised manuscript (lines 389-392), we described the errors of the retrieved VSD at the radii larger than the coarse mode radius + one sigma. The errors were more than 100 % for Water-soluble and Biomass burning cases, but that for Dust case was -6+/-57 % for AOD < 0.2, and -9+/-24 % for AOD > 0.2. In the dust case, the error of the retrieved VSD was small.

L390 even for PWV and TO3. I assume this means even for these retrievals. Please restate to be clear.

The sentence was revised (lines 411-413). We mean the retrieved PWV and TO3 are also affected by the aerosol vertical profile.

Figure 8 The caption should be rewritten in a clearer way.

The caption was revised.

Figure 10: It seems that MRIv2 retrieves lower SSA even for high AOD, at all wavelengths above 500nm, compared to both V42 and V5. I strongly suggest narrowing the axis range, because all the info is concentrated in the upper right corner and it cannot

be seen.

Yes, the difference is about 0.05 in the high AOD cases. I revised the figure 10.

Figure 14: No units for both x and y axis.

Thanks, we corrected it.

L 565 giant particles. Since you refer to particles up to  $100\mu\text{m}$  and even retrieve SD up to  $30\mu\text{m}$ , It does not add up to name the  $10\mu\text{m}$  particles as giants.

We deleted “giant” (lines 655, 657).

L569-574 It seems that the fact that AOD was  $1/3$  compared to 16 August could explain a big part of the inconsistencies with the in situ measurements.

The cause of inconsistency between the retrieval and in-situ measurement is the horizontal heterogeneity of the transported dust and the spatial difference of the aircraft and sky radiometer observations (line 662). The sky radiometer observed the low AOD region of the transported dust.

Figure A2, please express the complex number with same number of significant digits.

Thanks, we corrected it.

**Abstract.** The Prede POM sky radiometer is a filter radiometer deployed worldwide in the SKYNET international network.  
20 A new method called, Skyrad pack MRI version 2 (MRI v2), is presented here ~~presented~~, to retrieve aerosol properties (size  
distribution, real and imaginary parts of the refractive index, single-scattering albedo, asymmetry factor, lidar ratio, and linear  
depolarization ratio), ~~and~~ water vapor and ozone column concentrations from the sky radiometer measurements. MRI v2  
overcomes two limitations of previous methods (Skyrad pack versions 4.2 and 5, and MRI version 1). One is the use of all the  
wavelengths of 315, 340, 380, 400, 500, 675, 870, 940, 1020, 1627, and 2200 nm, if available from the sky radiometers, for  
25 example, in POM-02 models. The previous methods cannot use the wavelengths of 315, 940, 1627, and 2200 nm. This enables  
us to provide improved estimates of the aerosol optical properties, covering almost all the wavelengths of solar radiation. The  
other is the use of measurements in the principal plane geometry in addition to the solar almucantar plane geometry that is  
used in the previous versions. ~~The m~~Measurements in the principal plane are regularly performed, however they are currently  
not exploited despite being useful in the case of small solar zenith angles, when the scattering angle distribution for almucantars  
30 becomes too small to yield useful information. Moreover, in the inversion algorithm, MRI v2 optimizes the smoothness  
constraints of the spectral dependencies of the refractive index and size distribution, and changes the contribution of the

diffuse radiances to the cost function according to the aerosol optical depth. These overcome issues with the estimation of the size distribution and single-scattering albedo in the Skyrad pack version 4.2. The scattering model used here allows for non-spherical particles, improving results for mineral dust and permitting ~~to evaluate~~ evaluation of the depolarization ratio.

35 An assessment of the retrieval uncertainties using synthetic measurement shows s that best performance is obtained when the aerosol optical depths is larger than 0.2 at 500 nm. Improvements over the Skyrad pack versions 4.2 and 5 are obtained for the retrieved size distribution, imaginary part of the refractive index, single-scattering albedo, and lidar ratio at Tsukuba, Japan, while yielding comparable retrievals of the aerosol optical depth, real part of the refractive index, and asymmetry factor. A radiative closure study using surface solar irradiances from Baseline Surface Radiation Network and the  
40 parameters retrieved from MRI v2 showed consistency, with a positive bias of the simulated global irradiance, about ~~+24~~  $Wm^{-2}$  (+31 %). Furthermore, the MRI v2 retrievals of the refractive index, single-scattering albedo, asymmetry factor, and size distribution have been found in agreement with integrated profiles of aircraft in-situ measurements of two Saharan dust events at the Cape Verde archipelago, during the SAVEX-D 2015 field campaign.

## 1 Introduction

45 Aerosols, water vapor, and ozone are the most impacting factors on the atmospheric radiative budget in the solar wavelength band under cloudless sky. Indeed, the scattering and absorption of solar radiation by aerosols, as well as absorption by water vapor and ozone, have an important effect in the ultraviolet, visible, and near infrared wavelength regions. It is essential to observe these temporal and spatial changes and to evaluate their impacts on the atmospheric radiative budget and climate change (IPCC, 2013).

50 The columnar properties of aerosol, ozone and water vapor can be retrieved by ground-based remote sensing using sun-sky radiometers. A sun-sky radiometer is a narrow-band filter photometer that measures the solar direct radiation and the angular distribution of the diffuse radiation usually at ultraviolet, visible, and near infrared wavelengths. Such instruments are deployed worldwide in the international networks of AERONET (Holben et al., 1998) and SKYNET (Nakajima et al., 2020). Specifically, the Prede POM sky radiometer is the standard instrument from SKYNET, and now more than 100 instruments of  
55 this kind are used in ~~around~~ the world. Methods to retrieve aerosol properties, ~~and~~ water vapor and ozone column concentrations from the sky radiometer have been developed in the last 30 years. Nakajima et al. (1996) developed the “Skyrad pack”, which is an all-in one package including methods for the calibration of the sky radiometer and for the retrieval of the aerosol physical and optical properties from the solar direct and diffuse radiation at the wavelengths of 340, 380, 400, 500, 675, 870, and 1020 nm. The products of the Skyrad pack version 4.2 (Skyrad v4.2) are the volume size distribution (VSD), real and imaginary  
60 parts of the refractive index (RRI and IRI), aerosol optical depth (AOD), single scattering albedo (SSA), and phase function. The AOD (related to the columnar burden of aerosols), SSA (ratio of scattering to scattering + absorption), and phase function (angular distribution of scattering) or asymmetry factor (ASM; a measure of preferred direction of forward/backward scattering) are necessary to evaluate the impact of aerosols on the atmospheric radiative balance. Kobayashi et al. (2006) later

developed the Skyrad pack MRI (Meteorological Research Institute) version 1 (MRI v1) as a derivative of the Skyrad pack mainstream series. MRI v1 is based on a statistical optimal estimation algorithm similar to the retrieval method employed within the NASA AERONET network (Dubovik and King, 2000). More recently, Kobayashi et al. (2010) introduced treatment for randomly oriented spheroidal particles in MRI v1, based on the data table developed by Dubovik et al. (2006). The phase function of dust particles estimated from spheroids is a more accurate representation than the spherical approximation used in previous versions of the software. Alongside, Hashimoto et al. (2012) upgraded the Skyrad pack version 4.2 to the version 5 (Skyrad v5). They also introduced the statistical optimal estimation algorithm and a data quality control method. The products available from the Skyrad v5 and MRI v1 are similar to the ones that can be derived from the Skyrad v4.2.

In addition to this, the sky radiometer can measure the direct and diffuse radiation at 315 and 940 nm, which is absorbed by ozone and water vapor. Khatri et al. (2014) developed a calibration method from measurements at 315 nm and retrieved total ozone (TO3) from the direct irradiance. Uchiyama et al. (2018a) calibrated the sky radiometer measurement at 940 nm by the Langley method from observations taken at a high mountain site. Campanelli et al. (2014, 2018) and Uchiyama et al. (2018a) developed the calibration methods based on the modified Langley method (Reagan et al. 1986; Bruegge et al., 1992; Halthore et al., 1997) and ~~applied~~ showed the application to ~~the low altitude sites other than high mountain~~. The modified Langley-based methods need the empirical equation to calculate the transmittance at 940 nm. Momoi et al. (2020) developed the on-site self-calibration method which does not require the empirical equation. They estimated the calibration constant at 940 nm by using the dependency of the angular distribution of the diffuse radiances normalized to the direct irradiance on the precipitable water vapour (PWV). All the methods showed the PWV was successfully retrieved from the calibrated sky radiometer measurement at 940 nm.

SKYNET has collaborated with international lidar networks, such as AD-Net (Sugimoto et al., 2015). In the frame of these activities, a synergistic method, SKYLIDAR, was developed to estimate the vertical profiles of extinction coefficient, SSA, and ASM from the sky radiometer and lidar measurements (Kudo et al., 2016). This enabled us to estimate the atmospheric heating rate by remote sensing techniques (Kudo et al., 2016; 2018). Another synergistic approach employs the particle extinction-to-backscatter ratio (lidar ratio; LIR) and the linear depolarization ratio (DEP). These are important aerosol optical properties observed by Raman lidars and High-Spectral-Resolution Lidars (HSRL) and have been used for the aerosol typing (e.g., Burton et al., 2012; Groß et al., 2015). Recently, the LIR and DEP are included in the version 3 of the AERONET products, and some aerosol typing studies have been already conducted (e.g., Shin et al. 2018). The relations between LIR, DEP, and aerosol types based on the lidar observations are utilized in these studies. Conversely, the LIR derived from sun-sky radiometer can be utilized instead of an assumed value to estimate the vertical profile of the extinction coefficient from conventional elastic backscatter lidars, which are deployed worldwide.

In this study, we developed a new method, the Skyrad pack MRI version 2 (MRI v2), to retrieve aerosol properties (VSD, RRI, IRI, AOD, SSA, ASM, LIR, and DEP), PWV, and TO3 from the sky radiometer data. Our method has two advantages, compared to Skyrad v4.2, v5, and MRI v1. Firstly, MRI v2 is able to use the observations at all the available wavelengths from the sky radiometer, from 315 to 2200 nm, and simultaneously retrieves the aerosol optical properties, the

PWV, and the TO3. This possibility was not available in Skyrad v4.2, v5, and MRI v1 where only the following wavelengths were exploited: 340, 380, 400, 500, 675, 870, and 1020 nm. Since the retrieved aerosol optical properties cover a good part of the solar wavelength region from 300 to 3000 nm, a detailed characterization of the radiative transfer in ~~the~~ short wavelengths under clear sky conditions is thus available from the sky radiometer measurements. Secondly, our method can be applied to both scanning patterns of the sky radiometer, i.e. solar almucantar and principal plane geometries. The preferred and most used scanning pattern is the almucantar geometry, but principal plane measurements are useful in the case of ~~the~~ small solar zenith angles because in that case the range of scattering angles obtained with the almucantar geometry is too small. Skyrad pack versions earlier than v3 allowed the users to analyze the scanning data in the principal plane geometries. However, the recent retrieval methods of Skyrad v4.2, v5, and MRI v1 could only be applied to the data obtained from the almucantar geometry, which prevented the analysis of the data routinely collected in the principal plane geometry. This reduced the amount of observations available particularly at the observational sites at the low latitudes.

The sky radiometer data used in this study is described in Sect. 2. The algorithms of the MRI v2 retrieval method and the simulation of the surface solar irradiance using the MRI v2 retrieved parameters are described in Sect. 3. The retrieval uncertainty is evaluated using the simulated data of the sky radiometer in Sect. 4. In Sect. 5, the results of the application of MRI v2 to the measurements at Tsukuba, Japan, and at Praia, Cape Verde are shown. The MRI v2 products are compared with the Skyrad v4.2 and v5 products, and the aircraft in-situ measurements. All the results are summarized in section 6.

## 2 Data

### 2.1 Observation at Tsukuba, Japan

Our newly developed method was applied to the measurements of the sky radiometer model POM-02 (Prede Co., Ltd., Tokyo, Japan) from February to October in 2018 at the Meteorological Research Institute, Japan Meteorological Agency (36.05°N, 140.13°E, about 25 m a.s.l.) in Tsukuba, Japan, about 50 km northeast of Tokyo. This instrument measures the solar direct irradiance and the angular distribution of the diffuse irradiances at the scattering angles of 2, 3, 4, 5, 7, 10, 15, 20, 25, 30, 40, 50, 60, 70, 80, 90, 100, 110, 120, 130, 140, 150, and 160° in the solar almucantar (ALM) or principal plane (PPL) geometries. The measurable maximum scattering angle depends on the solar zenith angle ( $\theta_0$ ) and is  $2\theta_0$  for ALM geometry. The measurable scattering angle for PPL geometry is  $\theta_0 + 60^\circ$  due to the motion range of the sky radiometer. For the comparison of the retrievals from the diffuse irradiances in the ALM and PPL geometries, we used a different observation schedule compared to the SKYNET standard one. The latter performs the scanning in the ALM geometry at every 10 minutes, while scanning in the PPL geometry is conducted in only the case that the solar zenith angle is less than 15°. Our procedure performs a scanning in the ALM and PPL geometries at every 15 minutes, regardless the value of the solar zenith angle. The measured wavelengths are 315, 340, 380, 400, 500, 675, 870, 940, 1020, 1627, and 2200 nm, and their full width at half maximum is  $3\pm 0.6$  nm for near ultraviolet wavelengths,  $10\pm 2.0$  nm for visible wavelengths, and  $20\pm 4.0$  nm for near infrared wavelengths, respectively (Uchiyama et al., 2018a).

130 Our retrieval method uses the atmospheric transmittances ( $T_d$ ) and the diffuse radiance normalized by the direct irradiances ( $R$ ).  $T_d$  is obtained from the direct irradiance measurement ( $V_d$ ) by giving the calibration constant ( $F_o$ ):

$$T_d(\lambda) = \frac{R_{es}^2 V_d(\lambda)}{F_o(\lambda)} = \exp[-m_o(\tau_R(\lambda) + \tau_A(\lambda) + \tau_G(\lambda))], \quad (1)$$

$$m_o = 1/\cos\theta_o \quad (2)$$

135 where  $\lambda$  is the wavelength,  $R_{es}$  is the sun-Earth distance in astronomical units,  $m_o$  is the optical air mass, and  $\tau_R$ ,  $\tau_A$ , and  $\tau_G$  are the optical depths of Rayleigh scattering, aerosol extinction, and gas absorption, respectively.  $R$  is calculated by

$$R(\theta, \lambda) = \frac{V_s(\theta, \lambda)}{V_d(\lambda) m_o \Delta\Omega(\lambda)} \quad (3)$$

140 where  $V_s$  is the diffuse irradiance measurement,  $\theta$  is the scattering angle, and  $\Delta\Omega$  is the solid view angle. The solid view angle is determined by scanning the distribution of radiation around the solar disk (Nakajima et al., 1996; Uchiyama et al., 2018b; Nakajima et al. 2020). The solid view angle of the sky radiometer is about  $2.4 \times 10^{-4}$  at wavelengths from 315 to 1020 nm and about  $2.0 \times 10^{-4}$  at wavelengths of 1627 and 2200 nm (Uchiyama et al., 2018b), and the corresponding field of view is  $1.0^\circ$  and  $0.95^\circ$ , respectively. The diffuse radiance measurement is described as  $V_s(\theta, \lambda)/\Delta\Omega(\lambda)$ , and the multiplication by  $1/V_d(\lambda)$  cancels the calibration constant included in  $V_s(\lambda)$  and  $V_d(\lambda)$  because the direct irradiance and diffuse irradiances are measured by the same sensor. Only diffuse radiance at scattering angles larger than  $3^\circ$  are used in MRI v2, since at the scattering angle of  $2^\circ$  abnormally large values were seen in the data. In addition, the diffuse radiances at 1627 and 2200 nm at the scattering angles higher than  $30^\circ$  were also removed because of the weak scattering of solar radiation and low sensitivity of the detector at 1627 and 2200 nm (Uchiyama et al., 2019).

150 The calibration constants at 340, 380, 400, 500, 675, 870, 940, 1020, 1627, and 2200 nm were transferred from our reference sky radiometer by side-by-side comparison. The reference sky radiometer was calibrated by the Langley method using the observation data at the NOAA Mauna Loa observatory in Hawaii, U. S. A.;  $19.54^\circ\text{N}$ ,  $155.58^\circ\text{W}$ , 3397.0 m a.s.l. (Uchiyama et al., 2014b; 2018a). The calibration constant at 315 nm was determined by accounting for the TO3 measured by the Brewer spectrophotometer at the Aerological Observatory, Japan Meteorological Agency, located next to the Meteorological Research Institute. The calibration procedure of 315 nm is described in Appendix A.

155 Completely clear sky conditions are required for accurate retrievals. Therefore, in Sect. 5.1, we selected the clear sky conditions based on the method by Kudo et al. (2010). The method judges the clear sky condition from the temporal variations of the surface solar irradiance measured by a co-located pyranometer.

160 The measurements of the surface solar irradiances at the Aerological Observatory under clear sky conditions were used for verifying the simulated surface solar irradiances using the retrieved aerosol properties, PWV, and TO3. The Aerological Observatory is a station of BSRN (Baseline Surface Radiation Network; Driemel et al., 2018). The solar direct and hemispheric diffuse irradiances are measured by pyrhelimeter (Kipp & Zonen CHP21), and pyranometer (Kipp & Zonen CMP22) with a shading eubeball in front of the sun. The global irradiances are obtained by the sum of the direct and hemispheric diffuse irradiance measurements. The pyrhelimeter and pyranometer are regularly calibrated once every 5 years

by Japan Meteorological Agency and traceable to the WRR (World Radiometric Reference). [The pyrheliometer and pyranometer used in this study were calibrated in January 2017, and July 2016, respectively.](#) The BSRN measurement errors are 2 % for global, 0.5 % for direct, and 2 % for diffuse irradiance (McArthur, 2005).

## 165 2.2 SAVEX-D

The Sunphotometer Airborne Validation Experiment in Dust (SAVEX-D) was conducted in August 2015 in the Cape Verde archipelago (Estellés et al., 2018), in conjunction with two airborne campaigns: AERosol properties – Dust (AER-D) and Ice in Clouds Experiment – Dust (ICE-D) over the eastern tropical Atlantic. The main objective of the SAVEX-D was the validation of the SKYNET and AERONET aerosol products in conditions dominated by Saharan dust, with aircraft in-situ measurements performed and integrated in the vertical. Two flights were successfully carried out under clear sky conditions on 16 and 25 August near Praia (14.948°N, 23.483°W, 128 m ASL) and Sal (16.733°N, 22.935°W, 60 m ASL) islands in the Cape Verde archipelago, respectively. The Saharan dust originating from Africa was observed during the two flights with AOD at 500 nm higher than 0.5 and 0.2, respectively. More details from the field campaigns were made available by Marengo et al. (2018) and Ryder et al. (2018).

175 A sky radiometer model POM-01 was deployed at Praia airport during SAVEX-D. We applied Skyrad MRI v2 to the sky radiometer data of the solar direct irradiances and the diffuse radiances in the ALM geometry at the wavelengths of 443, 500, 675, 870, 1020 nm (Estellés et al., 2018). Note that even measurements at a non-standard wavelength of 443 nm can be processed by our algorithm, since wavelengths used in our retrieval method can be flexibly customized to the measurements. In this study, the VSD, RRI, IRI, SSA, and ASM of the MRI v2 products were compared with those derived from the in-situ measurements (Ryder et al., 2018). The details of the aircraft in-situ measurements and methods to derive the aerosol physical and optical properties were described in Ryder et al. (2018).

## 3 Algorithms

### 3.1 Retrieval of aerosols, precipitable water vapor, and total ozone

#### 3.1.1 Inversion strategy

185 Our retrieval method is based on an optimal estimation technique similar to the one employed in the AERONET retrieval (Dubovik and King, 2000). The VSD, RRI, IRI, PWV, and TO3 are simultaneously optimized to all the measurements of the sky radiometer and all the a priori constraints. The best solution is obtained by minimizing the objective function,

$$f(\mathbf{x}) = (\mathbf{y}^{obs} - \mathbf{y}(\mathbf{x}))^T (\mathbf{W}^2)^{-1} (\mathbf{y}^{obs} - \mathbf{y}(\mathbf{x})) + \mathbf{y}_a(\mathbf{x})^T (\mathbf{W}_a^2)^{-1} \mathbf{y}_a(\mathbf{x}), \quad (4)$$

190 where  $\mathbf{x}$  is a state vector to be optimized, the vector  $\mathbf{y}^{obs}$  represents measurements, the vector  $\mathbf{y}(\mathbf{x})$  represents the simulations by the forward model corresponding to  $\mathbf{y}^{obs}$ ,  $\mathbf{W}^2$  is the covariance matrix of  $\mathbf{y}$ , the vector  $\mathbf{y}_a(\mathbf{x})$  is an a priori constraint for  $\mathbf{x}$ , and  $\mathbf{W}_a$  is an associated covariance matrix. The minimization of  $f(\mathbf{x})$  is conducted with the algorithm developed by Kudo et

al. (2016). A logarithmic transformation is applied to  $\mathbf{x}$  and  $\mathbf{y}$ . The minimum of  $f(\mathbf{x})$  in the  $\log(\mathbf{x})$ -space is searched by the iteration of  $\mathbf{x}_{i+1} = \mathbf{x}_i + \alpha \mathbf{d}$ , where vector  $\mathbf{d}$  is determined by the Gauss-Newton method, and a scalar  $\alpha$  is determined by the line search with Armijo rule. The details of the measurements ( $\mathbf{y}^{obs}$ ) and state vector ( $\mathbf{x}$ ) are described in Sect. 3.1.2. The forward model ( $\mathbf{y}(\mathbf{x})$ ) is introduced in Sect. 3.1.3. The a priori constraint ( $\mathbf{y}_a(\mathbf{x})$ ) is described in Sect. 3.1.4. Skyrad v4.2, v5, and MRI v1 also employ the optimal estimation technique using the similar cost function to Eq. (4), but a priori constraints are different. This is also described in Sect. 3.1.4. The Gauss-Newton method used for the minimization of Eq. (4) is an iterative method and requires an initial value of  $\mathbf{x}$ . We describe the initial value and final outputs in Sect. 3.1.5.

### 3.1.2 Measurement and state vectors

$\mathbf{y}^{obs}$  comprises the transmittances at the wavelengths of 315, 340, 380, 400, 500, 675, 870, 940, 1020, 1627, and 2200nm, and the normalized diffuse radiances at scattering angles larger than  $3^\circ$  in the ALM or PPL geometries. Note that the wavelengths and scattering angles used in our method can be arbitrarily selected. For example, we used the wavelengths of 443, 500, 675, 870, 1020 nm in Sect. 5.2.

Similarly to the retrieval methods of Dubovik and King (2000) and Kobayashi et al. (2010), the covariance matrix  $\mathbf{W}^2$  of Eq. (4) was assumed to be diagonal, and their values were given by the measurement errors of the transmittance and normalized diffuse radiance. The measurement error of the transmittance mainly depends on the uncertainty of the calibration constant. Uchiyama et al. (2018a) estimate the error of the calibration constant determined by the Langley method using the observation data at the NOAA Mauna Loa Observatory to be from 0.2 to 1.3 %, and the error due to the transfer of the calibration constant from the reference instrument by the side-by-side comparison was from 0.1 to 0.5 %. Therefore, we gave assumed the value of 2 % as the measurement errors of the transmittances at all the wavelengths. The measurement errors of normalized diffuse radiances are defined as 5 % in the work of Kobayashi et al. (2006). We also employed the same value, but we introduced a dynamic weight factor depending on the AOD as follows,

$$W = \min \left\{ 5\% * \max \left[ \left( \frac{0.3}{\tau_A(\lambda)} \right)^2, 1.0 \right], 100\% \right\}, \quad (5)$$

where  $\tau_A(\lambda)$  is the AOD at wavelength  $\lambda$ . This factor increases with a decrease of AOD and takes into account the fact that the absolute value of the diffuse radiance, as well as the signal-to-noise ratio, decrease with decreasing AOD. In actual measurements, the angular distribution of the diffuse radiances at 1627 and 2200 nm has unnatural oscillations with scattering angles in the cases of low AOD. This is due to the low signal-to-noise ratio of the detector at 1627 and 2200 nm (Uchiyama et al., 2019). When  $\tau_A(\lambda)$  is more than 0.3, the value of  $W$  is 5 %. The value of 0.3 was empirically determined by many trials of applying the different values of  $\tau_A(\lambda)$  to the measurements at Tsukuba.

The components of  $\mathbf{x}$  are the PWV, TO3, RRI and IRI at 315, 340, 380, 400, 500, 675, 870, 940, 1020, 1627, and 2200nm, and the parameters describing VSD. We assumed that the VSD consists of spherical and non-spherical particles and is expressed as the combination of 20 lognormal distributions in the range of the particle radius from 0.03 to 30.0  $\mu\text{m}$ :

$$\frac{dV(r)}{d\ln r} = \sum_{i=1}^{20} C_i \exp \left[ -\frac{1}{2} \left( \frac{\ln r - \ln r_{m,i}}{s_i} \right)^2 \right] \quad (6)$$

$$= \sum_{i=1}^{20} \left\{ \varepsilon_i C_i \exp \left[ -\frac{1}{2} \left( \frac{\ln r - \ln r_{m,i}}{s_i} \right)^2 \right] + (1 - \varepsilon_i) C_i \exp \left[ -\frac{1}{2} \left( \frac{\ln r - \ln r_{m,i}}{s_i} \right)^2 \right] \right\}, \quad (7)$$

$$\varepsilon_i = \begin{cases} 1, & r_i < r_{lm} \\ \varepsilon, & r_i \geq r_{lm} \end{cases}, \quad (8)$$

where  $r$  is particle radius,  $V(r)$  is volume,  $C_i$ ,  $r_{m,i}$ ,  $s_i$ , and  $\varepsilon_i$  are maximum volume, center radius, width, and volume ratio of the spherical particle to the sum of spherical and non-spherical particles for each lognormal distribution, respectively. The first term of Eq. (7) refers to spherical particles, and the second term to non-spherical particles.  $r_{lm}$  is a radius to separate  $\frac{dV(r)}{d\ln r}$  into the fine and coarse modes. It is defined as the radius at the local minimum of the  $\frac{dV(r)}{d\ln r}$  and is determined at every iterative steps of  $\mathbf{x}_{i+1} = \mathbf{x}_i + \alpha \mathbf{d}$  in the minimization process of  $f(\mathbf{x})$ . We assumed that the fine mode comprises only spherical particles, and the coarse mode is a mixture of non-spherical and spherical particles with a ratio of  $\varepsilon$ . The optimized parameters of the size distribution are  $C_i$ , and  $\varepsilon$ .  $r_{m,i}$  is fixed by the radius which separate the range of 0.03 and 30  $\mu\text{m}$  at log-spaced intervals,  $\ln \Delta r$ . The  $s_i$  is also fixed by  $\ln \Delta r / 1.65 \approx 0.21$ . The value of 1.65 is empirically selected from the range of  $s_i$ , which satisfies the following two conditions. The first condition determines the maximum value of  $s_i$ . The observed width of the fine mode of the VSD is smaller than that of the coarse mode and is about 0.4 (Dubovik et al., 2002). Since we express the VSD as the combinations of the lognormal distributions (Eq. 6), the  $s_i$  should be smaller than 0.4. The second condition is the minimum value of  $s_i$ . The  $\frac{dV(r)}{d\ln r}$  at the middle radius of two lognormal distributions,  $\ln(r) = 0.5 (\ln(r_{m,i}) + \ln(r_{m,i+1}))$ , should be larger than  $0.5(C_i + C_{i+1})$ . If not so, the shape of  $\frac{dV(r)}{d\ln r}$  has unnatural oscillations. Hence, the  $s_i$  should be larger than  $\ln \Delta r / 2.35$ , where  $2.35s_i$  is the full width at half maximum of the lognormal distribution.

The admitted radii of the VSD range from 0.03 to 30  $\mu\text{m}$  in MRI v2. However, the radius range of the previous SKYNET retrieval methods is from 0.01 to 20.0  $\mu\text{m}$ . The radius range used in the AERONET retrieval is from 0.05 to 15  $\mu\text{m}$ . We investigated the radius range which can be actually estimated from all the sky radiometer data by a similar technique as in Tonna et al. (1995). Figure A2 shows the Mie kernel functions of scattering and extinction for wavelengths from 315 to 2200 nm and scattering angles from 2° to 120°. We can see that the sky radiometer measurements carry information of the VSD in the radius range from 0.02  $\mu\text{m}$  to 30  $\mu\text{m}$  approximately. When we limit the scattering angle range from 3° to 60° and the wavelength range from 340 to 1020 nm, the radius range that can be retrieved is roughly from 0.03  $\mu\text{m}$  to 10  $\mu\text{m}$ . We might retrieve the giant particles around 20  $\mu\text{m}$  from the diffuse radiances at the wavelengths of 1627 and 2200 nm at a scattering angle of 2°. In practice, the measurement errors of the diffuse radiances at the scattering angle of 2° is too large for almost all wavelengths. ~~However, we can use the measurements at 1627 and 2200 nm at a scattering angle of 3°. Therefore, compared with the previous retrieval methods, we extended the retrieval range of the size distribution to the radius of 30  $\mu\text{m}$ .~~ However, we extended the retrieval range of the size distribution to the radius of 30  $\mu\text{m}$  by the following reason. The size distribution up to 20  $\mu\text{m}$  can be retrieved using the measurements at 1627 and 2200 nm at the scattering angle of 3°. Since we

constrain the size distribution at both ends of the radius range to low values by the smoothness constraint of Eq. 10, the size distribution at radii larger than 20  $\mu\text{m}$  is necessary. In addition, we might be able to use the measurements at a scattering angle of 2° in the future.

### 3.1.3 Forward modeling

The forward model  $\mathbf{y}(\mathbf{x})$  calculates the transmittances and the normalized diffuse radiances from  $\mathbf{x}$ . The aerosol extinction and scattering coefficients, and phase function for the spherical particles are calculated by the Mie theory. For the non-spherical particles, we employed the optical properties of the randomly oriented spheroids with a fixed aspect ratio distribution, which is optimized to the laboratory measurement of mineral dust (feldspar sample) phase matrices (Dubovik et al., 2006). The vertical profile of aerosols can be customized, but at this first stage it is assumed to be constant from the surface to the altitude of 2 km.

The gaseous absorption coefficients for water vapor and ozone are calculated by the correlated k-distribution (CKD) method according to the inputs of the PWV and TO3. The data table of the CKD method is developed by Sekiguchi and Nakajima (2008) using the HITRAN 2004 database. The vertical profile of ozone is given from the 1976 version of the U.S. standard atmosphere. The vertical profiles of water vapor, temperature, and pressure are also given from the U.S. 1976 standard atmosphere, but optionally we can select other auxiliary data. For example, ~~we used the daily measurements data~~ of the radiosonde launched at 00 UTC in the Aerological Observatory were used in Sect. 5.1, while the U.S. 1976 standard atmosphere was used in Sect. 5.2. Other than the water vapor and ozone, the gaseous absorption of  $\text{CO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{CO}$ ,  $\text{CH}_4$ , and  $\text{O}_2$  are considered in the forward model. Their vertical profiles were given from the standard atmosphere, and their absorption coefficients were calculated by the CKD method.

The solar direct irradiances and the diffuse radiances in the ALM and PPL geometries are calculated by the radiative transfer model, RSTAR (Nakajima and Tanaka, 1986; 1988). The diffuse radiances were calculated using the IMS method (Nakajima and Tanaka, 1988), which is an approximation method to simulate the diffuse radiances near the sun. For only the calculation at wavelengths of 315, 940, and 2200 nm, the response function of the interference filter of the sky radiometer was taken into account because the spectral changes in the absorption of ozone and water vapor within the filter band width cannot be ignored. We divided the 315 and 940 nm bands into five sub-bands, and the 2200 nm band into three sub-bands. For other wavelengths, the monochromatic calculation was assumed. We also incorporated the vector radiative transfer model, PSTAR (Ota et al., 2010) as an alternative to the scalar model RSTAR. The two radiative transfer codes can be easily switched. The option of the PSTAR will be useful if polarization measurements, such as in AERONET (Holben et al., 1998), are introduced to the sky radiometer in the future. Furthermore, we parallelized the codes of RSTAR and PSTAR using “OpenMP” because radiative transfer calculations at the wavelengths from 315 to 2200 nm are time-consuming.

### 3.1.4 A priori constraints

A smoothness constraint for the refractive index and size distribution is necessary for a stable retrieval (Dubovik and King, 2000). We constraint the spectral dependencies of the RRI and IRI by limiting the values of the following first derivatives of the refractive index with the wavelength,

$$\mathbf{y}_a(\mathbf{x}) = \left( \dots \frac{\ln(n(\lambda_i)) - \ln(n(\lambda_{i+1}))}{\ln(\lambda_i) - \ln(\lambda_{i+1})} \dots \frac{\ln(k(\lambda_i)) - \ln(k(\lambda_{i+1}))}{\ln(\lambda_i) - \ln(\lambda_{i+1})} \dots \right), \quad (9)$$

$$(i = 1, \dots, N_\lambda - 1),$$

where  $n$  and  $k$  are the RRI and IRI at the wavelength  $\lambda$ , and  $N_\lambda$  is the number of wavelengths. For the VSD, the second derivatives of  $C_i$  (Eq. 6) with respect to the particle radius is introduced by,

$$\mathbf{y}_a(\mathbf{x}) = (\dots \ln(C_{i-1}) - 2\ln(C_i) + \ln(C_{i+1}) \dots), \quad (10)$$

$$(i = 1, \dots, 20), C_0 = 0.1 \times C_1^0, C_{21} = 0.1 \times C_{20}^0,$$

where  $C_0$  and  $C_{21}$  are the volumes outside the radius range from 0.03 to 30.0  $\mu\text{m}$ , and  $C_1^0$  and  $C_{20}^0$  are the initial values of  $C_i$  in the iteration of the Gauss-Newton method (Sect. 3.1.5). The small values of  $C_0$  and  $C_{21}$  prevent  $C_1$  and  $C_{20}$  from being abnormal values. The denominator of the second derivative was ignored because the  $r_{m,i}$  has an equal interval.

Skyrad v4.2, v5, and MRI v1 use the similar cost function to Eq. (4), but a priori constraints are different. Skyrad v4.2 and MRI v1 employ similar smoothness constraints for the RRI, IRI, and VSD, but Skyrad v5 does not use them. MRI v1 and Skyrad v5 employ a priori estimates for the RRI, IRI, and VSD. This restricts the range of the solution but is useful to eliminate the unrealistic values. MRI v2 does not use a priori estimates, similarly to the AERONET algorithm, which successfully retrieves the RRI, IRI, and VSD without a priori estimates (Dubovik and King, 2000).

The covariance matrix  $\mathbf{W}_a^2$  in Eq. (4) determines the strength of the smoothness constraints. We assumed that the matrix is diagonal, and the values of each element corresponding to the RRI, IRI, and VSD are set empirically. The typical ranges of the RRI and IRI for the tropospheric aerosols are from 1.4 to 1.6, and from 0.005 to 0.05, respectively, at the visible and near infrared wavelengths (Dubovik and King, 2000). We therefore defined the values of  $\mathbf{W}_a^2$  as,

$$W_a = \frac{\ln(1.6) - \ln(1.4)}{\ln(2200) - \ln(315)} \cong 0.07 \text{ for RRI}, \quad (11)$$

$$W_a = \frac{\ln(0.05) - \ln(0.005)}{\ln(2200) - \ln(315)} \cong 1.2 \text{ for IRI}. \quad (12)$$

The typical VSD is expressed by a bi-modal lognormal distribution. The AERONET retrievals obtained in different aerosol conditions in the world (Dubovik et al., 2002) show that the width of the lognormal distribution for the fine mode is about half of that for the coarse mode. This suggests that the second derivative of the fine mode with respect to the particle radius is also larger than that of the coarse mode. Therefore, different values of  $W_a$  were given to the fine and coarse modes:

$$W_a = \begin{cases} 1.6, & r_i < r_{im} \\ 0.6, & r_i \geq r_{im} \end{cases}. \quad (13)$$

These values were empirically determined based on the work of Dubovik and King (2000) and by numerous trial and error using the measurements of the SAVEX-D campaign.

### 3.1.5 Initial values and outputs

315 The objective function (Eq. 4) is minimized by the iteration of the Gauss-Newton method. The iterative method requires the  
initial value of  $\mathbf{x}$ . The initial values of the RRI and IRI ~~index is are~~ given as 1.50-0.005 $\lambda$  at all the wavelengths. The ratio of the  
spherical particles in the coarse mode,  $\varepsilon$ , is 0.1. The volume of each lognormal distribution,  $C_i$ , is given from the size  
distribution created by the following procedure,

- 320 (1) AOD at weak gas absorption wavelengths, 340, 380, 400, 500, 675, 870, and 1020 nm are directly calculated from the  
direct irradiances.
- (2) Consider a bi-modal size distribution with fixed mode radii, 0.1 and 1.0  $\mu\text{m}$ , and widths, 0.4 and 0.8, for the fine and coarse  
modes, respectively.
- (3) Volume ratio between fine and coarse modes is fitted to Ångström exponent obtained from the AOD of (1).
- (4) Total volume of the size distribution is fitted to the AOD at 500 nm.

325 After finding the best solution of  $\mathbf{x}$ , the VSD, RRI, IRI, AOD, SSA, ASM, and phase function are provided as an  
output. In addition, we calculate the LIR and DEP because these are important optical properties in synergistic analyses using  
both the sky radiometer and lidar observations.

The objective function of Eq. (4) is a measure how much the  $\mathbf{x}$  is optimized to the  $\mathbf{y}^{obs}$ . However, the objective  
function includes the terms of the a priori constraints and does not imply a fitting to only  $\mathbf{y}^{obs}$ . Therefore, we output another  
330 measure of the fitness,

$$f_{obs}(\mathbf{x}) = \sqrt{\frac{(\mathbf{y}^{obs} - \mathbf{y}(\mathbf{x}))^T (\mathbf{W}^2)^{-1} (\mathbf{y}^{obs} - \mathbf{y}(\mathbf{x}))}{N_y}}, \quad (14)$$

where  $N_y$  is the number of the elements in the vector  $\mathbf{y}^{obs}$ . Eq. (14) is the mean of the differences between the sky radiometer  
measurements and ones calculated from the  $\mathbf{x}$  by the forward model, weighted by their respective experimental uncertainties.  
We can filter out the retrievals, which are not well optimized to the measurements, by giving a threshold to  $f_{obs}(\mathbf{x})$ . We used  
335 the threshold of 1.0, and the retrieval results, which did not satisfy the condition of  $f_{obs}(\mathbf{x}) > 1.0$ , were discarded in this study.  
This means that almost all the elements of the vector  $\mathbf{y}(\mathbf{x})$  lies in the range of  $\mathbf{y}^{obs} \pm \mathbf{W}$ .

### 3.2 Surface solar irradiance

In the study of the aerosol-radiation interaction, it is important to ensure the consistency between the observed and simulated  
surface solar irradiances. For this radiative closure study, the global, direct, and diffuse components of the surface solar  
340 irradiance in the wavelength region from 300 to 3000 nm were calculated from the retrieved aerosol optical properties, PWV,  
and TO3, and we compared them with those observed at the Aerological Observatory in Sect. 5.1.

The surface solar irradiances were calculated by our developed radiative transfer model (Asano and Shiobara, 1989;  
Nishizawa et al. 2004; Kudo et al. 2011). Note that this model is different from RSTAR and PSTAR used in the forward model  
of MRI v2. The solar spectrum between 300 and 3000 nm was divided into 54 intervals. Gaseous absorption by water vapor,

345 carbon dioxide, oxygen, and ozone were calculated by the CKD method. The inputs to the radiative transfer model are AOD, SSA, and phase function at 54 wavelengths from 300 to 3000 nm. These were calculated from the retrieved VSD, RRI, and IRI. The RRI and IRI at wavelengths between 315 and 2200 nm were interpolated from the retrieved RRI and IRI in the log-log space. For the wavelengths less than 315 nm and more than 2200 nm, the retrieved RRI and IRI at 315 and 2200 nm were used. A main advantage of MRI v2 is that the aerosol optical properties are retrieved in a wavelength range almost covering  
350 the whole short-wave band.

## 4 Uncertainties in retrieval products

### 4.1 Radiometric uncertainties

The uncertainties of the MRI v2 retrieval products were evaluated using the simulations of the sky radiometer measurements. The simulation was conducted for the three aerosol models of water-soluble, dust, and biomass burning (Table 1) used in the accuracy assessment of the AERONET retrieval (Dubovik et al., 2000). In the simulation, normally distributed random errors were added to direct irradiances, diffuse radiances, and surface albedo. The standard deviations used in generating the random errors are described in Table 2. The AOD, solar zenith angle, PWV, and TO3 used in the simulation were randomly selected from the ranges in Table 1. We conducted 200 simulations for each of three aerosol models and two scanning patterns of the ALM and PPL geometries, respectively. Our retrieval method was applied to total 1200 simulation data sets. In 98 out of the  
355 1200 results,  $f_{obs}(\mathbf{x})$  was more than the threshold of 1.0. When the perturbations in the simulation data were too large, our retrieval method was not able to optimize the parameters to the simulation data. The 98 retrievals were not included in the following results.

Figure 1 shows the dependencies of the retrieval errors of SSA on the solar zenith angle and AOD. In this study, we define the retrieval error as a deviation of the retrieved value from the simulated value for each individual simulation. When  
365 the solar zenith angle is small, the range of scattering angle for the diffuse radiance measurements is small, and the available information of the phase function from the diffuse radiances becomes smaller. We expected that this would affect the retrieval of aerosols, but no clear dependency of the retrieval errors of the SSA on the solar zenith angle was seen in Fig. 1. The retrieval errors of the other aerosol physical and optical properties, PWV, and TO3 also did not show any apparent dependencies on the solar zenith angle.

370 Small AODs make it difficult to retrieve the refractive index, because the diffuse radiances are less sensitive to the refractive index in this case (Dubovik et al., 2000). The retrieval errors of the SSA were obviously greater when the AOD was smaller than 0.2 (Fig. 1). This dependence on AOD was also seen in the retrieval errors of the other aerosol physical and optical properties.

The means (bias) and standard deviations (uncertainty) for the retrieval errors of the aerosol physical and optical  
375 properties, PWV, and TO3 were summarized in Table 3. Note that the AOD in Table 3 is calculated from the retrieved VSD, RRI, and IRI and is not directly obtained from the direct solar irradiance. Overall, both the biases and uncertainties of the

retrieval errors were large in the case that the AOD is less than 0.2. In particular, we note a positive bias in the IRI, and an uncertainty of more than 100 %. This bias affected the SSA and LIR, which depend on the IRI. The SSA showed a negative bias and the LIR a positive one. Even if the AOD at 500 nm was more than 0.2, the retrievals at the near infrared wavelengths were biased in the results of the IRI, SSA, and LIR of the water-soluble and biomass burning models (bias +179 % and +59 %, respectively, with an uncertainty of  $\pm 400$ –450 %). This is because the AOD of the two aerosol models is low at near infrared wavelengths. Conversely, the retrieval errors at the near infrared wavelengths for the dust model were smaller (bias +3 %, uncertainty 30 %). The retrieval errors of the DEP for the biomass burning also were more than 100 %. The reason of the large retrieval error is that the simulated value of the DEP is near zero.

Figure 2 illustrates the retrieved VSD for three aerosol models. The VSD is normalized to the total volume. The shaded area shows the radius range around the fine and coarse mode peaks, (mode radius  $\pm$  one standard deviation). The bias and uncertainty of the VSD in Table 3 is calculated from the results in the shaded areas. The biases of the retrieval errors around the fine and coarse mode peaks were less than 22 % (Table 3), but the uncertainties were not small (Fig. 2). The retrieval errors were also large in the outside of the shaded areas (Fig. 2). The retrieval error at a radius larger than the coarse mode radius + one standard deviation was more than 100 % for water-soluble and biomass burning models. However, the retrieval error of the dust model was small,  $-6\pm 57$  % for  $AOD \leq 0.2$  and  $-9\pm 24$  % for  $AOD > 0.2$ . The VSD at radii up to 30  $\mu\text{m}$  was retrieved well in the dust case. In the result of the ALM geometry for dust model, there is a single subset with the high fine mode and low coarse mode. Since the AOD at 500 nm used in this simulation was too small,  $0.26\text{E-}4$ , the retrieval failed.

Overall, the retrieval results at the near ultraviolet and visible wavelengths were good in the case that the AOD at 500 nm was larger than 0.2: the absolute values of biases + uncertainties in the retrieval products were less than 0.04 for AOD, less than 0.05 for RRI, less than 130 % for IRI, less than 50 % for VSD, less than 0.05 for SSA, less than 0.02 for ASM, less than 20 for LIR, and less than 60 % for DEP. Regardless of the AOD, the retrieval errors of the PWV and TO3 were less than 8 mm and 42 m atm-cm, respectively.

#### 4.2 Uncertainty in the aerosol vertical profile

In the previous numerical experiments, we investigated the differences of the retrieval errors between the ALM and PPL geometries without finding clear differences. One reason is that, so far, we did not consider the error from the aerosol vertical profile in the retrieval. The aerosol vertical profile affects the diffuse radiances in the PPL geometry (Torres et al., 2013; Momoi et al., 2020). Therefore, we now investigate the impacts of the aerosol vertical profile on the retrievals for the ALM and PPL geometries. To this purpose, we simulated the sky radiometer data for the dust and biomass burning models with different aerosol vertical profiles and conducted the retrieval with a fixed aerosol vertical profile from 0 to 2 km. Three patterns of the aerosol vertical profiles, constant from 0 to 2 km (P1), from 2 to 4 km (P2), and from 4 to 6 km (P3), were used in the simulation. The constant profile makes it easy to understand the influences of the aerosol layer altitude. Other parameters were

set as follows: the aerosol optical depth at 500 nm was 0.5, the PWV was 30 mm, the TO3 was 350 m atm-cm, and the solar zenith angle was 45°.

410 Table 4 summarizes the means for the retrieval errors of all the parameters, and Figure 3 shows the retrieval errors  
of SSA and ASM. ~~The impact of the aerosol vertical profile on the retrieval errors of the aerosol properties, PWV, and TO3  
for the PPL geometry was larger than those for the ALM geometry. The retrieval errors for the PPL geometry obviously  
depends on the aerosol vertical profile. The impacts of the aerosol vertical profile on the retrieval errors for the ALM geometry  
were small, but the retrieval error for the PPL geometry obviously depended on the aerosol vertical profile, even for the PWV  
and TO3.~~ The retrieval errors of SSA for both the dust and biomass burning models were positive at the wavelengths smaller  
415 than 870 nm and negative at the wavelengths larger than 870 nm (Fig. 3). These positive and negative errors were related to  
the diffuse radiances. Figure 4 shows the mean ratio of the simulated diffuse radiances to those of P1 over the scattering angles.  
The mean ratios of P2 and P3 for the PPL geometry were more than 1.0 at the wavelengths smaller than 870 nm. Only the  
mean ratios at 940 and 2200 nm, which have strong water vapor absorption, were less than 1.0. The mean ratios at 1020 and  
420 1627 nm were about 1.0. The strong diffuse radiances of P2 and P3 at the wavelengths smaller than 870 nm for the PPL  
geometry caused the underestimation of the IRI (Table 4) and the overestimation of the SSA (Fig. 3 and Table 4). The weak  
diffuse radiances of P2 and P3 at 940 and 2200 nm for the PPL geometry increased the IRI and decreased the SSA. The changes  
in the diffuse radiances at 1020 and 1627 nm is negligible but the SSA at these wavelengths were underestimated (Fig. 3). This  
is because the combined effect of the increased IRI at 940 and 2200 nm and the smoothness constraint of the spectral change  
425 for the IRI increased the IRI at 1020 and 1627 nm. Consequently, the IRI at all near infrared wavelengths were overestimated  
and the SSA was underestimated (Table 4). Figure 5 plots the ratio of the diffuse radiance to that of P1 at 340 and 940 nm.  
The strong diffuse radiances at the wavelengths smaller than 870 nm for the PPL geometry in Fig. 4 were due to the large  
diffuse radiance at the scattering angles more than 90°. This increase of the diffuse radiances at backward angles became small  
at the longer wavelengths and was negligible at 1020 and 2200 nm. The increase of the backward scattering of P2 and P3 for  
430 the PPL geometry affects the balance of the forward and backward scattering and leads to the decrease of the ASM and the  
increase of the RRI, because, as predicted by the Mie theory, the ASM decreases with an increase of the RRI (Hansen and  
Travis, 1974). On the other hand, the ratio of the diffuse radiances at 940 nm was large at scattering angles smaller than 90°  
and was small at scattering angles larger than 90°. This was also seen at 2200 nm. This feature and the smoothness constraint  
for the RRI caused the overestimation of the ASM and underestimation of the RRI at the near infrared wavelengths (Fig. 3 and  
435 Table 4).

The above experiment suggests that the influence of the aerosol vertical profile cannot be ignored in the retrieval  
using the data for the PPL geometry. In practice, the aerosol vertical profile has large variability. The synergistic approach  
with lidar is a reasonable solution for this problem (e.g., Kudo et al., 2016).

## 5 Application to real measurements

### 440 5.1 Application to the measurements at Tsukuba

The sky radiometer data collected from February to October 2018 in Tsukuba were processed by MRI v2 and Skyrad v4.2 and v5 using the following five configurations:

- 1) ALM-SW: Aerosol physical and optical properties were retrieved from the measurements in the ALM geometry. To assess the sensitivity of the retrievals to the available measurements, a subset of the measuring wavelengths (i.e., only 340, 380, 400, 445 500, 675, 870, and 1020 nm) was chosen. The PWV and TO3 were not retrieved but were given from the measurements of the radiosonde at 00 UTC and the daily mean of the Brewer spectrophotometer observation.
- 2) PPL-SW: measurements in the PPL geometry with the same wavelength subset as in ALM-SW.
- 3) ALM-LW: Aerosol physical and optical properties, PWV, and TO3 were retrieved from the measurements in the ALM geometry. The complete set of data at all the wavelengths from 315 to 2200 nm were used.
- 450 4) PPL-LW: measurements in the PPL geometry using the full range of wavelengths.
- 5) V42: the same dataset as in ALM-SW was employed, but the retrieval method was Skyrad v4.2.
- 6) V5: the same dataset as in ALM-SW was employed, but the retrieval method was Skyrad v5.

The aerosol physical and optical properties, PWV, and TO3 of the five patterns were compared. In addition, the surface solar irradiance simulated using the retrieved quantities from MRI v2 were compared with the measurements.

455 We rejected 8.2 % of the data by the quality control of Eq. (14) in the retrieval using the simulation data (Sect. 4.1), but the rejected data in the measurements under the clear sky conditions in Tsukuba were 0.07 % for ALM-SW, 0.61 % for PPL-SW, 3.12 % for ALM-LW, and 4.37 % for PPL-LW, respectively.

#### 5.1.1 Aerosols

Figure 6 illustrates the daily means of AOD, Ångström exponent, RRI, IRI, SSA, ASM, LIR, and DEP. The wavelength is 500 460 nm. The AOD is calculated from the retrieved VSD, RRI, and IRI, therefore it can be considered as a metrics of the degree of “internal closure” of the model itself. The Ångström exponent is calculated from a logarithmic fit from the AOD at the wavelengths of 340, 380, 400, 500, 675, 870, 1020 nm. The AOD was from 0.047 to 0.53 was large in spring, from March to May, ~~and~~ †The Ångström exponent was from 0.49 to 1.86 and was low in spring. The large AOD and small Ångström exponent in spring. This can be explained by transport of dust from China and Mongolia (e.g., Kudo et al., 2010; Kudo et al., 2018). The 465 AOD and Ångström exponent with all configurations agreed well.

The RRI at 500 nm for all the retrievals was large in spring, ranging from 1.45 to 1.55. According to the database of the Hess et al. (1999) and Aoki et al. (2005), the RRI of the dust is about 1.53 at visible wavelengths and larger than that of other aerosols except for the black carbon. The RRI of ALM-SW and PPL-SW were consistent with those of the V42 and V5 through the observation period. However, the RRI of ALM-LW and PPL-LW were lower in February and larger from June to 470 October. The AOD at 500 nm was generally smaller than 0.2 during these periods, and the differences of the RRI are within

the retrieval uncertainties of the RRI (Table 3). As mentioned in Sect. 4.1, the refractive index is less sensitive to the diffuse radiances for the low AOD. In particular, the AOD at 1627 and 2200 nm was less than 0.1 in February and June to October. It is difficult to retrieve the refractive index at 1627 and 2200 nm in this condition. The retrieval errors at 1627 and 2200 nm might affect the RRI at the short wavelengths through the smoothness constraint for the spectral dependency of the RRI.

475 The IRI at 500 nm of MRI v2 (ALM-SW, PPL-SW, ALM-LW, and PPL-LW) was from 0.002 to 0.1 and was large  
in February and March. Hence, the SSA of MRI v2 was from 0.74 to 0.97 and was small in February and March. In winter,  
the local emission of black carbon is increased by the combustion of fuels, and Uchiyama et al. (2014a) shows the SSA derived  
from the measurements of the integrating nephelometer and absorption photometer in Tsukuba decreases in winter. The IRI of  
MRI v2 was larger than those of V42 and V5 in the whole period. Therefore, the SSA of MRI v2 were also smaller than V42  
480 and V5 in the whole period, and the difference was more than 0.05. The previous studies show that Skyrad v4.2 tends to underestimate the IRI and overestimate the SSA by 0.02 to 0.1, compared with AERONET (Che et al., 2008; Estellés et al., 2012; Khatri et al., 2016). Hence, the IRI and SSA of MRI v2 may be closer to AERONET retrievals.

Although the ASM of MRI v2 and V5 at 500 nm were slightly larger than V42, the ASM of all the retrieval patterns had similar values from 0.6 to 0.7. These are within the typical values of the tropospheric aerosols (Dubovik et al., 2002).

485 The LIR of MRI v2 ranged from 40 to 100 sr and was larger than those of V42 and V5, i.e. 20 to 40 sr. Observations from the HSRL at Tsukuba in two years shows that the LIR at 532 nm is  $68 \pm 39.8$  sr for spherical particles and  $48 \pm 27.1$  sr for non-spherical particles (Tatarov et al., 2006). Tsukuba is a rural city near Tokyo, and the typical LIR observed in the polluted or urban air are from 40 to 80 sr (Burton et al., 2012; Groß et al., 2015). The LIR of MRI v2 lied within the ranges of the HSRL  
490 observation at Tsukuba and typical polluted air, while those of V42 and V5 were too small. The LIR increases as the SSA decreases. In addition, the non-spherical particles are incorporated in MRI v2 but not in the Skyrad v4.2 and v5. Generally, for the same refractive index and particle size, the phase function of the non-spherical particles at the scattering angle  $180^\circ$  is smaller than that of spherical particles, and the LIR of non-spherical particles is larger than that of spherical particles (e.g., Dubovik et al., 2006; Kudo et al. 2016). Both the SSA and the particle shape contribute to the difference of the LIR between MRI v2, and Skyrad v4.2 and v5.

495 The DEP was large, up to 0.2, in spring because of the transported dust. The difference among the ALM-SW, PPL-SW, ALM-LW, and PPL-LW retrievals was small. The V42 and V5 do not consider non-spherical particles and cannot derive the DEP. Two years observations of the Raman lidar at Tsukuba show the DEP of the dust layer to be about  $0.2 \pm 0.07$  (Sakai et al., 2003). Considering that our retrieval is a columnar property and includes spherical particles at low altitudes in addition to the dust layer, it is natural that our retrieved DEP is slightly smaller than that of the dust layer directly observed by the lidar.

500 Figure 7 shows the spectral dependencies of AOD, VSD normalized by the total volume, RRI, IRI, SSA, ASM, LIR, and DEP. They are represented as means over the whole observation period. The spectral dependencies of the AOD of all the retrievals showed good agreement. The difference of the RRI, ASM, and DEP among all the retrievals were also small.

The spectral changes in the IRI and SSA of MRI v2 was small. However, the IRI of V42 and V5 drastically decreased by about one order of magnitude from the near ultraviolet wavelength to the visible wavelength. Hence, the SSA was small at

505 the near ultraviolet wavelengths and was large at the visible and near infrared wavelengths. The differences of the SSA at the visible wavelengths between MRI v2 and Skyrad v4.2 and v5 could come from the [smoothness-a priori](#) constraint of the spectral dependency for the IRI. It should be considered that the constraint of MRI v2 are stronger than those of the Skyrad v4.2 and v5.

510 The LIR of V42 and V5 retrievals were smaller than that from MRI v2 at all the wavelengths. This could be due to the differences of the particle shape and SSA. The lidar ratio of the retrieval for the almucantar geometry (ALM-SW and ALM-LW) at the near ultraviolet and visible wavelengths was about 10 sr smaller than that of the retrieval for the principal plane geometry (PPL-SW and PPL-LW). However, this value is within the retrieval uncertainties (Tables 3 and 4).

515 Figure 7b is the VSD normalized to the total volume. The normalized VSD from MRI v2 had a similar bi-modal shape. However, the normalized VSD of V42 had a tri-modal shape. The normalized VSD of V5 had a shape like a mixture of MRI v2 and V42. Although there are no desert regions in Tsukuba, the third mode of V42 appeared in the whole observation period, regardless of seasons. It is unrealistic that almost all the data was contaminated by cirrus clouds. The third mode of the Skyrad v4.2 was also found during other comparisons with the AERONET retrievals (Che et al., 2008; Estellés et al., 2012). If the third mode is real, the microplastics might be a cause because our observational site is neighboring the highway. The wear and tear from tyres are major source of microplastics, and the particle size range is from 1 nm to 100  $\mu\text{m}$  (Kole et al., 520 2017; Evangelidou et al. 2020). However, we could not find any data and investigations which relate our results to microplastics. If the third mode is not real, we have to consider the measurement errors of the diffuse radiances at scattering angles near the sun. According to Fig. A2, it is considered that the third mode at radius around 10  $\mu\text{m}$  is created by the diffuse radiances at the scattering angles around 3° and at the wavelengths of around 1020 nm. Indeed, the third mode does not appear if we do not use the diffuse radiances at scattering angles less than 4° (Fig. 8a). We need to investigate the measurement accuracies of the diffuse radiances at scattering angles near the sun. In the MRI v2 retrieval, the dynamic weight factor depending on the AOD (Eq. 5) weakens the contribution of the diffuse radiances at the near infrared wavelengths to the objective function (Eq. 4). This has the effect to suppress the third mode of the VSD. [Figure 8b shows the influences of the dynamic weight factor. If the dynamic weight factor is removed, the third mode appears in the MRI v2 retrievals.](#) 525

530 We further examined the differences of the ALM-SW, V42, and V5 retrievals because their wavelength subset is the standard in SKYNET. Figure 9 shows the comparison of AOD from the ALM-SW, V42, and V5 retrievals with the AOD obtained from the direct irradiance (DAOD). The DAOD was calculated by the Skyrad v4.2 software. The AOD of ALM-SW, V42, and V5 are calculated from the retrieved VSD, RRI, and IRI. The AOD of V42 and V5 agreed with the DAOD but the AOD of ALM-SW was slightly larger than the DAOD. The mean differences of the AOD of ALM-SW from the DAOD were less than about 0.02 for all the wavelengths (Table 5). The large AOD of ALM-SW comes from the reason that MRI v2 535 optimizes the parameters to the transmittances, but the Skyrad v4.2 and v5 optimizes the parameters to the DAOD. In the optimal estimation, the parameters are preferentially optimized to the measurements, which significantly contribute the objective function (Eq. 4). The contributions of the measurements depend on the value of  $W$  in Eq. 4. The value of  $W$  for the DAOD is 0.01/DAOD in the Skyrad v5. This means that the algorithm tries to optimize the parameters to the range of DAOD

$\pm 0.01$ . In MRI v2, the value of 2 % is given to the transmittance. ~~The relation of the perturbation between the transmittance~~

540 ~~( $T$ ) and AOD ( $\tau$ ) is described as follows:~~

$$T + \Delta T = \exp\{-m(\tau + \Delta\tau)\}, \quad (15)$$

$$\tau + \Delta\tau = -\frac{1}{m} \ln(T + \Delta T) = -\frac{1}{m} \ln T - \frac{1}{m} \ln\left(1 + \frac{\Delta T}{T}\right) = \tau - \frac{1}{m} \ln\left(1 + \frac{\Delta T}{T}\right), \quad (16)$$

$$\frac{\Delta\tau}{\tau} = -\frac{1}{m\tau} \ln\left(1 + \frac{\Delta T}{T}\right) \approx -\frac{1}{m\tau} \frac{\Delta T}{T}, \quad (17)$$

The aerosol optical depth ( $\tau$ ) is related to the transmittance ( $T$ ) by

545 
$$\tau = -\frac{\ln T}{m}, \quad (15)$$

where  $m$  is optical air mass. For the simplicity, the optical depths for the Rayleigh scattering and gaseous absorption are ignored. The relation of the perturbation between  $\tau$  and  $T$  is given from the partial differential of Eq. (15) with respect to  $T$  as follows:

$$\Delta\tau = \frac{\partial\tau}{\partial T} \Delta T = -\frac{1}{m} \frac{\Delta T}{T} \quad (16)$$

550 where  $\Delta\tau$  and  $\Delta T$  are the perturbations for  $\tau$  and  $T$ .  ~~$m$  is optical air mass. For the simplicity, the optical depths for the Rayleigh scattering and gaseous absorption are ignored.  $\Delta T/T$  is 0.02 in MRI v2. In the case that  $\tau$  is 0.4 and  $m$  is 1.2,  $\Delta\tau/\tau$  is 0.042 in MRI v2, and 0.025 in the Skyrad v5. The value of  $\Delta\tau/\tau$  of MRI v2 is always larger than that of the Skyrad v5 in the range of  $m$  from 1 to 2. Therefore, the fitness of the parameters to the DAOD in MRI v2 is weaker than the Skyrad v5. Since  $\Delta T/T$  is 0.02 in MRI v2,  $\Delta\tau$  ranges between 0.01 and 0.02 in the range of  $m$  from 1 to 2. On the other hand,  $\Delta\tau$  is 0.01 in the Skyrad v5. Therefore, the fitness of the parameters to the DAOD in MRI v2 is weaker than in Skyrad v5.~~

560 Figure 10 is the comparison of SSA between ALM-SW, V42, and V5. ~~The SSA of ALM-SW at 340, 380, and 400 nm agreed with that of V5 and was slightly smaller than that of V42. The SSA of ALM-SW at wavelengths more than 500 nm was smaller than those of V42 and V5, and the differences between ALM-SW, V42, and V5 became larger at the longer wavelengths. The uncertainty of the retrieved SSA is large in the low AOD because the diffuse radiances become insensitive to the SSA. Therefore, the differences of the SSA between ALM-SW, V42, and V5 were large at longer wavelengths. Overall, the SSA approached to similar values when the AOD at 500 nm is more than 0.3. Furthermore, the coefficients of the determination between the ALM-SW and V5 were higher than the V42. Overall, these-These features were also seen in the scatter plots of the RRI, IRI, ASM, and LIR (Figs. S1 to S4). Figure 11 illustrates the normalized VSD of ALM-SW, V42, and V5 for the different values of AOD at 500 nm. The third mode of the V42 retrieval decreases when the AOD is more than 0.3. The third mode of the SKYRAD v4.2 is a common feature in the case of low AODs. The normalized VSD of V5 had a closer shape to that of ALM-SW in the case of the high AOD.~~

Table 6 is a summary of the differences between the ALM-SW, V42, and V5 retrievals for the different grades of the AOD at 500 nm. The AOD, RRI, and ASM of ALM-SW, V42, and V5 agreed. Conversely, the differences of IRI, SSA, and LIR between the ALM-SW, V42 and V52 were larger than the expected uncertainty, however the differences decrease in

570 the case that the AOD was more than 0.3. These differences were caused by the smoothness constraint for the refractive index and size distribution, and the particle shape, and the assumption of measurement errors in the retrieval algorithm.

### 5.1.2 Water vapor and ozone

Figure 12 shows the PWV of the ALM-LW and PPL-LW retrieval results, and radiosonde observation at 00 UTC (09 Japan Standard Time). Note that Skyrad v4.2 and v5 cannot use the measurements at 315 and 940 nm and cannot estimate PWV and TO3. All the radiosonde data in the whole observation period is plotted in Fig 12a but the ALM-LW and PPL-LW are the retrieval results under the clear sky conditions. Therefore, the ALM-LW and PPL-LW retrieval results in Fig 12a follow the lower envelope of the radiosonde data. Their seasonal changes of the ALM-LW and PPL-LW results agreed well with the radiosonde data (Fig. 12a). This is also visible from the scatter plot between the ALM-LW and PPL-LW (Fig. 12b). The means and standard deviations of the differences between the retrievals and the radiosonde observation were  $0.1 \pm 2.7$  mm for the ALM-LW and  $0.1 \pm 3.9$  mm for the PPL-LW and were within the expected retrieval uncertainty of PWV (Table 3). The previous works of the PWV retrieval from the sky radiometer shows that the bias and root mean square deviation of retrieval error are from -0.01 to -0.2 mm and from 1.35 to 1.97 mm (Campanelli et al. 2018), and from 0.33 to 0.90 mm and from 1.79 to 1.98 mm (Uchiyama et al. 2014b), respectively. Our result has slightly large deviations but is comparable to the previous works.

Figure 13 shows the comparison of the TO3 between the ALM-LW and PPL-LW retrievals, and Brewer spectrophotometer observation. The seasonal changes were consistent among the different techniques (Fig. 13a), and the coefficient of determination was good, more than 0.7 (Fig. 13b). However, the TO3 of the ALM-LW and PPL-LW were slightly large. The means and standard deviations of the differences between the retrievals and the Brewer spectrophotometer were  $24 \pm 25$  m atm-cm for the ALM-LW and  $23 \pm 24$  m atm-cm for the PPL-LW.

In both PWV and TO3 retrievals, the difference between the ALM-LW and PPL-LW were small. It should be considered that the influence of the aerosol vertical profile was small. The PWV could be stably provided from the sky radiometer. However, further investigation is necessary for the calibration of the measurements at 315 nm and the retrieval of the TO3.

### 5.1.3 Surface solar radiation

The global, direct, and diffuse components of the surface solar irradiance calculated from the retrieved aerosol optical properties, PWV and TO3 of the ALM-SW, PPL-SW, ALM-LW, and PPL-LW, V42, and V5 were compared with the measurements at the Aerological Observatory, an observational station of BSRN (Fig. 14). Considering the measurement errors of the surface solar irradiance (Sect. 2.1), all the calculated irradiances from the retrievals showed good agreements with the measurements. In the MRI v2 results, the mean differences between the calculated irradiances from the retrievals and the measurements were about from 2 to 247 Wm<sup>-2</sup> (from 30.4 to 1.2 %) for the global irradiance, less than from 224 to 109 Wm<sup>-2</sup> (from 3-0.6 to 1.2 %) for the direct irradiance, and from -2 to -1 less than 4 Wm<sup>-2</sup> (from 2-3.8 to -1.9 %) for the diffuse irradiance, respectively. The ALM-LW and PPL-LW results for the global and direct irradiances were obviously slightly better than the

ALM-SW and PPL-SW, i.e. the use of all the wavelengths and the retrieval of water vapor and ozone turns out to be effective. The mean differences of the global irradiances of V42 and V5 were 14 and 12 Wm<sup>-2</sup> (2.2 and 1.9 %), slightly worse than that of MRI v2. The differences of the direct irradiances between V42, V5, and MRI v2 were small, but the differences of the diffuse irradiances were large. The mean differences of the diffuse irradiance for V42 and V5 were positive, and those for MRI v2 were negative. This means that the SSA of V42 and V5 is overestimated, and the SSA of MRI v2 is underestimated.

Figure 15 shows the deviations of the calculated global, direct, and diffuse irradiances from the measurements, as a function of the AOD at 500 nm. Note that there are no data around the AOD of 0.6 in the V5 results because Skyrad v5 failed to retrieve the aerosol optical properties. In the MRI v2 results, the direct irradiance deviations were increased with a decrease of AOD. They were from -5 to 5 % around the AOD of 0.6 but were increased up to 10 % at the AOD less than 0.2. The diffuse irradiance deviations were decreased with a decrease of the AOD. The most of the diffuse irradiance deviations were positive, from 0 to 10 %, around the AOD of 0.6 but were from -20 to 10 % at the AOD less than 0.2. The negative mean differences of the diffuse irradiances in the MRI v2 results of Fig. 14 were due to the underestimation of the diffuse irradiances at the low AOD. The overestimation of the direct irradiances at the low AOD means the underestimation the retrieved AOD, and the underestimated AOD results in the underestimation of the diffuse irradiances. Furthermore, the uncertainty of the SSA retrieved by MRI v2 was large in the case of the AOD less than 0.2, and the SSA was underestimated (Table 3). The underestimations of the retrieved AOD and SSA would be the causes of the underestimated diffuse irradiances at the AOD less than 0.2. However, the contribution of the diffuse irradiance to the global irradiance is small in the case of low AOD. Consequently, the global irradiance deviations of the MRI v2 results were from -5 to 5 %, and their dependencies on the AOD was smaller than the direct and diffuse irradiance deviations.

Similar to the MRI v2 results, the direct irradiance deviations of the V42 and V5 results were from -5 to 5 % and were increased with a decrease of the AOD. The diffuse irradiance deviations of the V42 and V5 results were decreased with a decrease of the AOD. The most of the diffuse irradiance deviations were from -10 to 10 % in the AOD less than 0.2 and were better than the MRI v2 results. In the AOD more than 0.2, the most of the diffuse irradiance deviations were from 0 to 15 % and were larger than the MRI v2 results. The positive mean differences of the diffuse irradiances in the V42 and V5 results of Fig. 14 were due to the overestimation of the diffuse irradiances at the high AOD. Since the most of the direct irradiance deviations were from -3 to 5 % and were biased to be positive at the AOD more than 0.2, the retrieved AOD is considered to be slightly underestimated. However, the diffuse irradiance deviations were positive. Therefore, the overestimation of the retrieved SSA would be a cause of the overestimation of the diffuse irradiances at the high AOD. This supports the fact that the SSA retrieved by the MRI v2 is better than that of V42 and V5 at the high AOD. The contribution of the diffuse irradiance to the global irradiance increases with an increase of the AOD. As a result, the global irradiance deviations of the V42 and V5 results were positive, from 0 to 5 %, in the AOD more than 0.2. This results in the positive mean differences of the global irradiances in the V42 and V5 results of Fig. 14.

Overall, the calculated global, direct, and diffuse irradiances from the MRI v2 retrievals agreed well with the measurements. However, the differences between the calculated and measured irradiances depended on the AOD and SSA. The underestimation of the SSA retrieved by MRI v2 in the low AOD is an issue to be solved in the future.

## 5.2 Comparison with the aircraft in-situ measurement of the SAVEX-D

The MRI v2 was applied to POM\_01 sky radiometer measurements during the SAVEX-D campaign that took place at Praia in the Cape Verde archipelago in August 2015 (Estellés et al., 2018). The retrieval results were compared with the in-situ measurements from the Facility for Airborne Atmospheric Measurements (FAAM) atmospheric research aircraft (Ryder et al., 2018). Table 7 shows the aerosol optical properties retrieved from the sky radiometer in the two flights performed. The AOD observed by the sky radiometer at 500 nm was about  $0.64 \pm 0.10$  on 16 August and  $0.25 \pm 0.04$  on 25 August. In both days, the Saharan dust originating from Africa was observed at altitudes from 1 km to 6 km by an airborne lidar (Marengo et al., 2018). Maritime aerosols were also observed in the boundary layer, but the dust particles were dominant (Ryder et al., 2018). Therefore, the Saharan dust is a major contributor of the retrieved columnar aerosol optical properties from the sky radiometer. The RRI, IRI, SSA, and ASM of MRI v2 showed good agreements with those derived from the aircraft in-situ measurements (Table 7). The sky radiometer reports the optical properties at 500 nm, whereas reports those same properties at 550 nm. Given the short wavelength difference, we think that these quantities are comparable, because the spectral changes in these quantities are small between 500 and 550 nm (e.g., Hess et al. 1998).

Figure 15-16 shows the comparison of the VSD in the two flights. In addition to MRI v2, the retrievals of the Skyrad v4.2 and v5 were compared with the in-situ measurement. In the result on 16 August, all the retrievals revealed a good performance for the coarse mode (radius  $> 0.5 \mu\text{m}$ ). The fine mode (radius  $< 0.2 \mu\text{m}$ ) of Skyrad v5 was overestimated. The fine mode of Skyrad v4.2 was slightly overestimated but agreed to the in-situ measurement within the mean  $\pm$  one standard deviation. All the retrievals failed to reproduce the peak of the ~~giant particles-VSD~~ at the radius around  $10 \mu\text{m}$ , because the sky radiometer data at wavelengths from 443 to 1020 nm (1627 nm and 2200 nm are not available in the POM\_01 model) and at scattering angles more than  $3^\circ$  do not have information on the ~~giant particles-VSD~~ at radius around  $10 \mu\text{m}$  (Sect. 3.1 and Fig. A2). In the result on 25 August 2015, all the retrievals underestimated the VSD at radii larger than  $1.0 \mu\text{m}$ , in particular the v4.2. For the radius  $< 0.2 \mu\text{m}$ , all distributions displayed the same behavior as for 16 August. During the 25 August experiment, the sky radiometer, which was deployed at the ground site of Praia, measured the direct and diffuse radiation in the southern direction. However, the flight was conducted close to the island of Sal, which is located northeast of Praia, at Santiago island. This spatial difference ~~of the observations and the horizontal heterogeneity of the transported dust may be a cause~~ of the underestimation of the coarse mode. Overall, the MRI v2 showed good performances for both the fine and coarse modes of the VSD.

The LIR and DEP were not obtained from the aircraft in-situ measurements. Therefore, the retrieved LIR and DEP were compared with the lidar measurements of the Saharan dust during AER-D and SAMUM 2 (Table 7). The LIR of MRI v2

was  $45\pm 9$  sr and  $52\pm 10$  sr at 500 nm, and  $46\pm 10$  sr and  $55\pm 10$  sr at 443 nm, respectively for 16 and 25 August. The LIR derived from the airborne elastic backscatter lidar during AER-D was  $54\pm 8$  at 355 nm (Marenco et al. 2018). Although the wavelengths are different, the LIR of MRI v2 was close to that of the airborne lidar. It is shown that Saharan dust has similar values of LIR between 355 and 532 nm (e.g., Groß et al. 2015; Shin et al., 2018). The DEP of MRI v2 was  $0.25\pm 0.08$  and  $0.25\pm 0.01$  at 500 nm, respectively. The DEP was not obtained from the airborne lidar during AER-D. Therefore, the DEP of MRI v2 was compared with the ground-based Raman lidar measurements during the second field campaign of the Saharan Mineral Dust Experiment (SAMUM 2) in the literature. Groß et al. (2011) investigated the LIR and DEP of the Saharan dust over Praia during SAMUM 2. The Raman lidar observations from 28 to 30 January 2008 showed that the LIR was  $63\pm 6$  sr at both 355 and 532 nm, and the DEP was about 0.3 at 532 nm. The LIR and DEP of MRI v2 were slightly smaller than the Raman lidar measurements. The MRI v2 retrieval is the columnar property including the maritime aerosols in the boundary layer. Since the LIR of the sea salt is around 20 sr, and the DEP is near zero (e.g., Groß et al., 2015), the sea salt contributes to decrease both the LIR and DEP. Furthermore, Ryder et al. (2018) described that the aspect ratio of the sampled particles in the flights during the AER-D campaign flights was slightly smaller than the typical value of the Saharan dust. These would be the reason that the LIR and DEP of the sky radiometer retrievals were smaller than the lidar observations during SAMUM 2.

In summary, under dusty conditions, the physical and optical properties of the Saharan dust retrieved by MRI v2 were broadly consistent with those of the aircraft in-situ and lidar measurements. For further evaluation, in-situ validations of the different species for other case studies, such as biomass burning aerosols, is necessary.

## 6 Summary and conclusion

We developed a new method, Skyrad MRI v2, to retrieve aerosols columnar properties (volume size distribution, real and imaginary parts of the refractive index, single-scattering albedo, asymmetry factor, lidar ratio and linear depolarization ratio), water vapor, and ozone from the sky radiometer measurements. The advantages of MRI v2 are a full use of all the sky radiometer wavelengths from 315 to 2200 nm, and the application to two scanning patterns of the measurements in the ALM and PPL geometries. The use of all the wavelengths provides the aerosol properties covering the full short-wave band and enables the more accurate evaluation of the aerosol impacts on the atmospheric radiative budget. The Skyrad v4.2, v5, and MRI v1 were applicable to only the measurement in the ALM geometry, but we can analyse the measurements in the PPL geometry by MRI v2. This increases the amount of the observation available particularly at the observation sites at the low latitudes.

We have estimated the retrieval uncertainties of MRI v2 using simulated data with perturbations comparable to the uncertainties of the measured solar direct irradiance, diffuse radiance, and surface albedo. The resulting retrieval errors showed a dependency on the AOD and were small in the case of AODs larger than 0.2. The absolute values of biases  $\pm$  uncertainties in the retrieval products at the near ultraviolet, visible, and near infrared wavelengths were less than 0.04 for the AOD, less than 0.05 for the RRI, less than 130 % for the IRI, less than 50 % for the VSD, less than 0.05 for the SSA, less than 0.02 for the ASM, less than 20 for the LIR, and less than 60 % for the DEP. The retrieval errors of the PWV and TO3 were less than 8

700 mm and 42 m atm-cm, respectively. Furthermore, the influence of the aerosol vertical profile to the retrieval was investigated. The impact of the aerosol vertical profile on the retrieval from the diffuse radiances in the ALM geometry were small. However, the aerosol vertical profile cannot be ignored in the retrieval from the diffuse radiances in the PPL geometry. The largest impacts of the aerosol vertical profile were observed in the diffuse radiances at the backscattering angles. The increase of the diffuse radiances resulted in the overestimation of the SSA. The increase of the backward scattering relative to the forward scattering resulted in the underestimation of the ASM. The best solution of this problem is the co-located observations of sky radiometer and lidar, and a synergistic analysis (e.g., Kudo et al. 2016). Another solution may be a synergistic use of the measurements in both the ALM and PPL geometries. The aerosol vertical profile affects the measurements in the PPL geometry, particularly at 940 nm. This implies that the aerosol vertical profile may be estimated from the measurements in the PPL geometry. In this aspect, the scanning in both the ALM and PPL geometries should be conducted every time regardless the solar zenith angle although the standard schedule of the scanning in the ALM and PPL geometry depends on the solar zenith angle.

710 The MRI v2 was applied to the measurements at Tsukuba, Japan. The results of aerosol physical and optical properties are compared with the Skyrad v4.2 and v5. The AOD, RRI, ASM showed good agreements. The IRI of MRI v2 was larger than those of the Skyrad v4.2 and v5. Hence, the SSA of MRI v2 was smaller than the Skyrad v4.2 and v5. In previous studies, it has been pointed out that the Skyrad v4.2 tends to overestimate the SSA compared to the AERONET (Che et al., 2008; Estellés et al., 2012; Khatri et al., 2016). The MRI v2 overcomes this problem. The LIR of MRI v2 was larger than the one from Skyrad v4.2 and was closer to the HSRL measurements. This is because the MRI v2 considers non-spherical particles. The DEP of MRI v2 increased to about 0.2 in the dust cases in spring. The results were close to the Raman lidar measurements of the dust layers. The VSD of MRI v2 had a typical bi-modal shape but the Skyrad v4.2 had a tri-modal shape. This behaviour in Skyrad v4.2 is also pointed out by the works of Che et al. (2008) and Estellés et al. (2012). There is a possibility that the tri-modal shape was due to the too large diffuse radiances at the scattering angles around  $3^\circ$ . The problem also was improved in the MRI v2 retrieval. The PWV of MRI v2 agreed with the radiosonde measurements. The TO3 of MRI v2 was larger, about 25 m atm-cm, than the Brewer spectrophotometer measurements, but the seasonal change was consistent. The overestimation would be due to the calibration constant at 315 nm. Furthermore, we investigated the radiative closure of the surface solar irradiance between the measurements of BSRN and simulations using the retrieved aerosol optical properties, PWV, and TO3. The simulated surface solar irradiances agreed to the measurement, and the mean errors for the global irradiances were about  $+24 \text{ Wm}^{-2}$  (+13 %).

725 The MRI v2 were compared with the data in two flight periods during the SAVEX-D 2015. The aerosol physical and optical properties retrieved in two events of the transported Saharan dust were compared with those derived from the aircraft in-situ measurements of the Saharan dust (Ryder et al., 2018; Marengo et al., 2018). The RRI, IRI, SSA, ASM, VSD, and LIR of MRI v2 agreed well with the aircraft in-situ measurements. Furthermore, the LIR and DEP of MRI v2 were consistent with those of the Saharan dust observed by the Raman lidar (Groß et al., 2011). The MRI v2 showed good performances for dust. Recently, it is shown that dust is substantially coarser than represented in current global climate models (Kok et al., 2017;

Adebiyi and Kok, 2020). Theoretically, we showed that the size distribution at radius greater than 10  $\mu\text{m}$  can be retrieved by using the sky radiometer measurements at 1627 and 2200 nm. Since the MRI v2 can utilize the measurements at 1627 and 2200 nm but the Skyrad v4.2, v5, and MRI v1 cannot, the remote sensing of SKYNET with MRI v2 would be useful to investigate the dust particles.

MRI v2 brought out the performance of the sky radiometer more than ever, and the radiative closure experiment showed the consistency between the surface solar radiation and the retrieved aerosol, water vapor, and ozone. MRI v2 would be useful for monitoring aerosols, water vapor, and ozone, evaluating their impacts on the surface solar radiation, and validating the satellite products and the aerosol prediction models. For the further development, the co-located observation with lidar is useful. The aerosol vertical profile is assumed in MRI v2, but the lidar improves it. The depolarization ratio from the lidar and the refractive index and size distribution from the sky radiometer would be useful to improve the scattering model of non-spherical particles, such as dust, soot, and volcanic ash particles. MRI v2 uses the same randomly oriented spheroid model with a fixed aspect ratio distribution as the AERONET, but it is shown that the inconsistencies in the spectral variabilities of the lidar ratio and depolarization ratio of dust particles between the lidar and AERONET sun photometer data, in particular, in the near ultraviolet wavelength range (Müller et al., 2010). Recently, the various realistic particle models are developed for dust (e.g., Ishimoto et al., 2010; Gasteiger et al., 2011), soot (e.g., Kahnert et al., 2013; Ishimoto et al., 2019), and volcanic ash (e.g., Lindqvist et al., 2011). The application of these models to the sky radiometer and lidar data would improve the remote sensing of aerosols. The sky radiometer covers the major three wavelengths of the lidar, 355, 532, and 1064 nm. This may be an advantage, compared to the AERONET sun photometer. Moreover, the introducing the polarization measurements to the sky radiometer may help to retrieve the non-spherical particles. MRI v2 is useful to this future study because the vector radiative transfer model is already incorporated into MRI v2.

## Appendices

### Appendix A. Calibration of 315 nm

The sky radiometer data at 315 nm was calibrated with reference to the daily mean of TO3 observed by the Brewer spectrophotometer at the Aerological Observatory. The calibration procedure is:

- (1) The AOD at wavelengths other than 315 nm are calculated from the solar direct irradiances.
- (2) The AOD at 315 nm is calculated by the extrapolation in the log-log plane of wavelength and AOD.
- (3) Select a day in the condition that the daily change in the AOD is small. This is a condition required in the Langley method.
- (4) An initial value of the calibration constant at 315 nm is estimated by the Langley method.
- (5) Transmittance at 315 nm is calculated using the calibration constant at 315 nm.
- (6) The TO3 is estimated by minimizing the following objective function:

$$f(\text{TO3}) = (T^{obs} - T(\text{TO3}))^T (T^{obs} - T(\text{TO3})), \quad (\text{A1})$$

765 where  $T^{obs}$  is the observed transmittance of (5), and  $T(TO3)$  is the calculated transmittance by the same forward model described in Sect. 2.3. That is, the response function of the interference filter, the vertical profiles of pressure, temperature, and ozone concentration are taken into account. This non-linear least square problem is solved by the Gauss-Newton method. (7) The daily mean of TO3 is calculated.

(8) The daily mean TO3 is compared with that observed by the Brewer spectrophotometer. If the difference is large, the calibration constant is changed manually, and go back to (5). If the difference is small, the process is stopped. The threshold for the difference is defined as 3 m atm-cm, which is about 1 % of the climate value of the TO3, 310 m atm-cm at Tsukuba.

This procedure is not automated now. We subjectively selected 15 days during the observation period at Tsukuba and estimated the calibration constants at 315 nm. Figure A1 shows the result of the calibration constant at 315 nm and the fitting line by the polynomial regression. The calibration constant drastically changed in a year. This feature is also pointed out by Khatri et al. (2014). We were not able to find the cause of this change in this study. Further investigation is necessary. The calibration constant obtained by the polynomial approximation was used in the analysis of Sect. 5.1.

## Appendix B. Relation of the size distribution to the sky radiometer measurements

Tonna et al. (1995) investigated the relation of the size distribution to the sun/sky photometer measurements, based on the Mie theory. The kernel functions for scattering and extinction relating to the phase function and optical depth were described as follows:

$$K(x) = \frac{3}{8\pi} \frac{[i_1(\theta, x, \tilde{m}) + i_2(\theta, x, \tilde{m})]}{x^3}, \quad (\text{A2})$$

$$K_e(x) = \frac{3}{4x} Q_e(x, \tilde{m}), \quad (\text{A3})$$

where  $x$  is size parameter,  $i_1$  and  $i_2$  are the Mie intensity functions,  $Q_e$  is the extinction coefficient,  $\theta$  is scattering angle, and  $\tilde{m}$  is the complex refractive index. These functions are normalized to their integral over  $x$  and are investigated in Tonna et al. (1995). We also used the same functions but plotted the kernel functions as a function of the particle radius, taking the wavelength and the scattering angle as parameters (Fig. A21). Although Tonna et al. (1995) plotted the kernel functions at the scattering angles of 3, 10, 30, 60, and 120°, we added the kernel functions at the scattering angle of 2° because the sky radiometer measures the diffuse radiances at the scattering angle of 2°. From the behavior of the kernel functions in Fig. A1A2, we can see that the sky radiometer model POM-01 measurements, of which wavelength is from 315 to 1020 nm, have the information of the size distribution at the radius from 0.02 to 20  $\mu\text{m}$ . Since the model POM-02 have the measurements at the wavelengths of 1627 and 2200 nm, the radius range is broader, from 0.02 to 30  $\mu\text{m}$ .

### **Code availability**

The Skyrad pack MRI version 2 software is available on request by contacting the first author of the paper. The software program is coded in Fortran and is compiled on both Intel and GNU Fortran platforms.

### 795 **Data availability**

The sky radiometer data is available on request by contacting the first author of the paper.

### **Author contribution**

RK developed the Skyrad MRI v2 code and performed the sky radiometer retrieval experiments. MC and HD intensively tested the Skyrad MRI v2 code on the SKYNET/Europe data. HD, and MM improved the Skyrad MRI v2 code. RK, AU, AY, RN, 800 NO, and HI carried out the observation at Tsukuba. VE, MC, FM, and CR proposed the SAVEX-D experiment. VE, FM, and CR worked in the AER-D and SAVEX-D mission science team implementing the airborne sampling strategy. OI and KN worked in the BSRN observation at Tsukuba, Japan. RK prepared the manuscript with contributions from all co-authors.

### **Competing interests**

The authors declare that they have no conflict on interests.

### 805 **Acknowledgements**

The authors are grateful to the OpenCLASTR project for allowing us to use the SKYRAD.PACK, RSTAR, and PSTAR in this research. The SAVEX-D campaign airborne data was obtained using the BAe-146-301 Atmospheric Research Aircraft operated by Airtask Ltd and managed by the Facility for Airborne Atmospheric Measurements (FAAM). It was a success thanks to many staff at the Met Office, the University of Leeds, University of Manchester, University of Hertsfordshire, FAAM, 810 Directflight Ltd, Avalon Engineering and BAE Systems.

**Table 1: Configuration of the simulation in the assessment of retrieval uncertainties**

Aerosol	Water-soluble	Dust	Biomass burning
Radius ( $\mu\text{m}$ )/width of fine and coarse modes	0.118/0.6, 1.17/0.6	0.1/0.6, 3.4/0.8	0.132/0.4, 4.5/0.6
Volume ratio of fine mode to coarse mode	2	0.066	4
Real and imaginary parts of refractive index at all the wavelengths	1.45—0.0035 <i>i</i>	1.53—0.008 <i>i</i>	1.52—0.01 <i>i</i>
Single-scattering albedo at 340/500/1020 nm	0.97/0.97/0.96	0.83/0.83/0.87	0.88/0.86/0.73
Asymmetry factor at 340/500/1020 nm	0.68/0.64/0.63	0.75/0.75/0.75	0.69/0.60/0.40
Lidar ratio at 340/500/1020 nm	62/53/45	78/69/57	95/75/31
Linear depolarization ratio at 340/500/1020 nm	0.03/0.05/0.09	0.09/0.15/0.25	0.00/0.00/0.00
Aerosol optical depth at 500 nm	Random in the range from 0.0 to 1.0		
Vertical profile	Constant from 0 to 2 km		
Surface albedo	0.1 for near ultraviolet and visible wavelengths 0.2 for near infrared wavelengths		
Solar zenith angle	Random in the range from 10 to 70 degree		
Precipitable water vapor	Random in the range from 0 to 100 mm		
Total ozone	Random in the range from 250 to 550 m atm-cm		

\* Size distribution, and refractive index of water-soluble, dust, and biomass burning is cited from Dubovik et al. (2000).

Depolarization ratios of the biomass burning model are not zero but less than 0.001.

**Table 2: Random errors of the simulation in the assessment of retrieval uncertainties**

Surface albedo	Normally distributed random deviations with the standard deviation of 0.05.
Measurement error	
Direct irradiance	Normally distributed random errors with the standard deviation of 2 %
Diffuse radiance	Normally distributed random errors with the standard deviation of 5 %

\* The standard deviations for direct irradiance, and diffuse radiances were determined from the works of Uchiyama et al. (2018a), and Kobayashi et al. (2006), respectively.

**Table 3: Means and standard deviations of the retrieval errors**

\*<sup>1</sup> Aircraft in-situ measurements over the Cape Verde Islands during AER-D in 2015 (Ryder et al. 2018)

\*<sup>2</sup> Elastic backscatter lidar measurements over the Cape Verde Islands during AER-D in 2015 (Marenco et al. 2018)

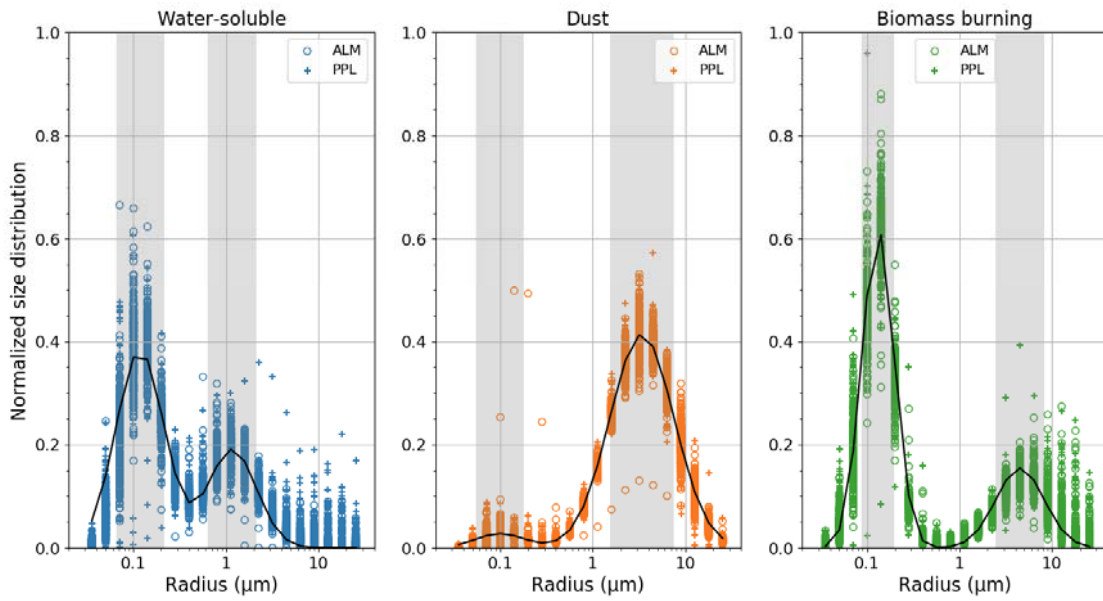

1030 \*<sup>3</sup> Raman lidar measurements over the Cape Verde Islands during SAMUM 2 in 2008 (Groß et al. 2011)

1035

Figure 1: Dependencies of the retrieval errors of the single-scattering albedo at 500 nm on the solar zenith angle (left) and the aerosol optical depth at 500 nm (right). WS, DS, and BB denote the water-soluble (blue), dust (orange), and biomass burning (green) models, respectively. ALM and PPL denote the scanning patterns of the almucantar (circle) and principal plane (plus) geometries, respectively.

1040

Figure 2: The retrieved (circle and plus) and simulated (solid line) volume size distributions for water-soluble (left, blue), dust (center, orange), and biomass burning (right, green). The size distribution is normalized to the total volume. Circle and plus symbols indicate that the scanning pattern of simulated data are the almucantar (ALM) and principal plane (PPL) geometries, respectively. The shaded area is the range of the radius around the peak of fine and coarse modes. The range of radius around the peak is defined as mode radius  $\pm$  one standard deviation (see Table 1).

1045

1050 **Figure 3: Retrieval error of the single-scattering albedo (upper) and asymmetry factor (lower) for the simulation data of the dust (left) and biomass burning models (right) with different aerosol vertical profiles of 0 to 2 km (blue), 2 to 4 km (green), and 4 to 6 km (orange). The solid and dashed lines are the retrieval errors for the simulation data in the almucantar (ALM) and principal plane (PPL) geometries, respectively. Note that the y-axis ranges for dust and biomass burning differ in the plots.**

1055 **Figure 4: Mean ratio of the simulated diffuse radiances over the scattering angle with the aerosol vertical profiles of 0 to 2 km (blue), 2 to 4 km (green), and 4 to 6 km (orange) to those with the aerosol vertical profile of 0 to 2 km. Left and right figures are the simulations for the dust and biomass burning models, respectively. The solid and dashed lines are the simulation for the almucantar (ALM) and principal plane (PPL), respectively.**

Figure 5: Ratio of the simulated diffuse radiances at 340 nm (upper) and 940 nm (lower) with different aerosol vertical profiles of 0 to 2 km (blue), 2 to 4 km (green), and 4 to 6 km (orange) to those with an aerosol vertical profile of 0 to 2 km. Left and right figures are the simulations for the dust and biomass burning models, respectively. The solid and dashed lines are the simulation for the principal plane (PPL) and almucantar (ALM) geometries, respectively.

1060

ALM-SW ALM-LW PPL-SW PPL-LW V42 V5

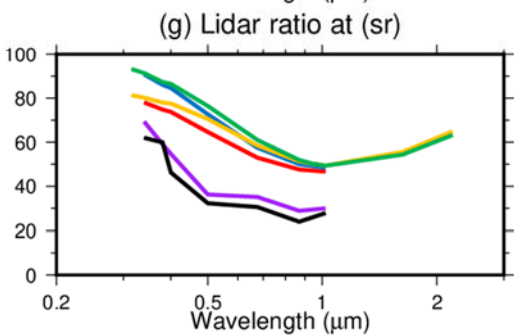

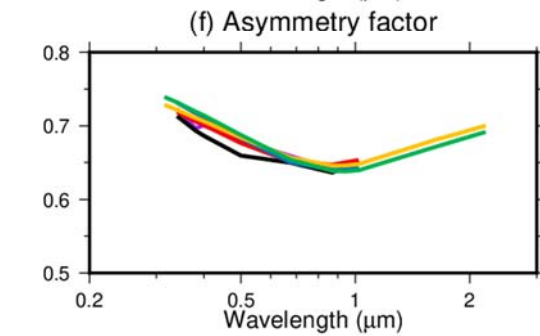

Figure 6: Daily means of aerosol optical depth (a), Ångström exponent (b), real (c) and imaginary (d) parts of refractive index, single-scattering albedo (e), asymmetry factor (f), lidar ratio (g), and linear depolarization ratio (h). Colors indicate the ALM-SW (red), ALM-LW (yellow), PPL-SW (blue), PPL-LW (green), V42 (black) and V5 (purple) retrieval patterns.

1065

ALM-SW ALM-LW PPL-SW PPL-LW V42 V5

Figure 7: Means during the whole observation period for aerosol optical depth (a), normalized volume size distribution to total volume (b), real (c) and imaginary (d) parts of refractive index, single-scattering albedo (e), asymmetry factor (f), lidar ratio (g), and

1070 **linear depolarization ratio (h). Colors indicate the ALM-SW (red), ALM-LW (yellow), PPL-SW (blue), PPL-LW (green), V42 (black) and V5 (purple) retrieval patterns.**

(a) V42

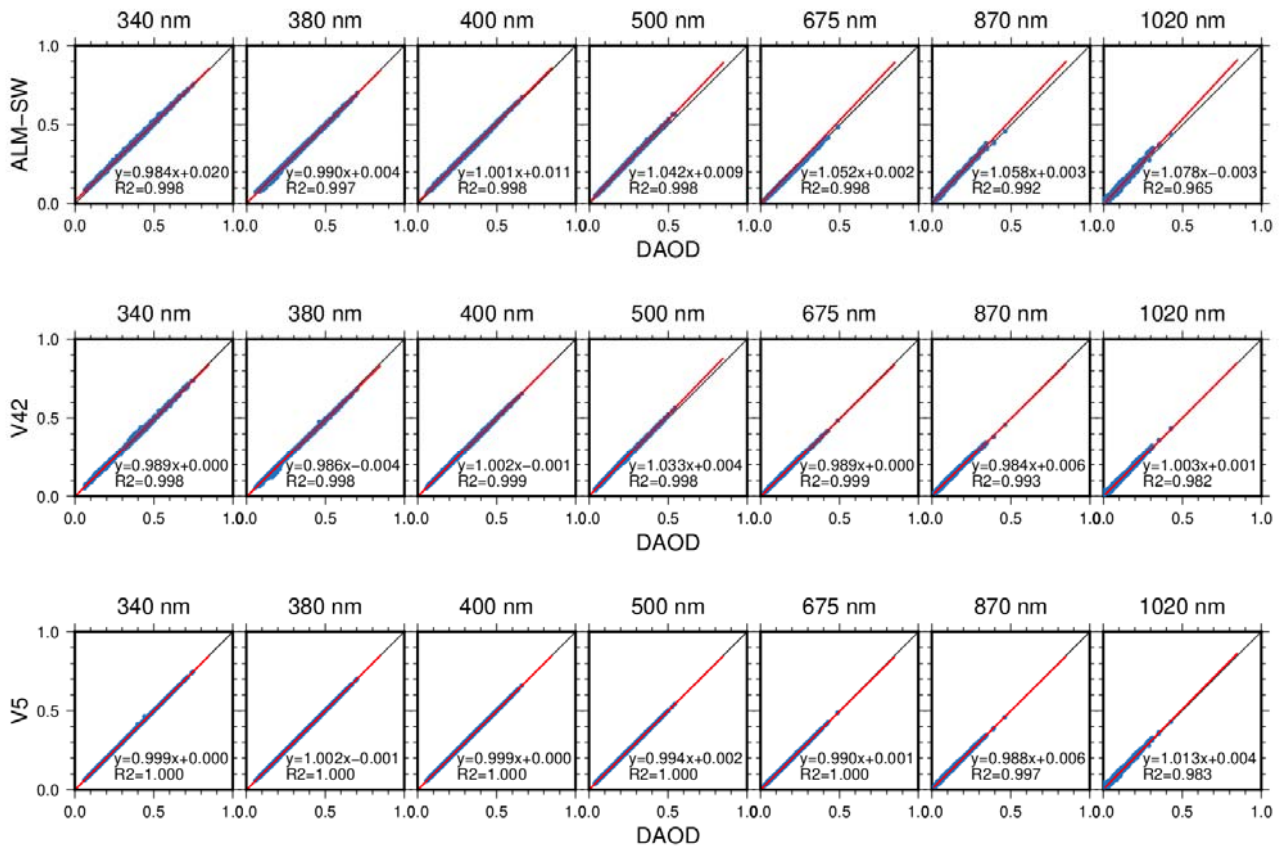

(b) ALM\_SW

**Figure 8:** Volume size distributions retrieved from the diffuse radiances at scattering angles more than 3° (orange) and 5° (gray and black) by the SKYRAD v4.2 in Tsukuba on 14 March 2018. Thick lines are daily means. Retrieved volume size distribution in Tsukuba on 14 March 2018. (a) The results of the Skyrad v4.2 using the diffuse radiances at scattering angles more than 3° (orange) and 5° (gray and black). (b) The results of MRI v2 using the diffuse radiances at scattering angle more than 3°, and with (gray and black) and without (orange) the dynamic weight factor of Eq. (5). The thick lines are daily means.

**Figure 9:** Comparisons of aerosol optical depth of ALM-SW, V42, and V5 with the aerosol optical depth derived from the direct irradiance (DAOD). The aerosol optical depth of ALM-SW, V42, and V5 are calculated from the retrieved size distribution and refractive index. “ $y=ax+b$ ” and “R<sup>2</sup>” are the linear fitting and the coefficient of the determination for all the data.

1085 **Figure 10: Comparisons of the single-scattering albedo between ALM-SW, V42, and V5. Colors indicate the aerosol optical depth at 500 nm. “ $y=ax+b$ ” and “ $R^2$ ” are the linear fitting and the coefficient of the determination for the data of the aerosol optical depth more than 0.3.**

1090 **Figure 11: Means of normalized volume size distributions of the ALM-SW (red), V42 (blue), and V5 (green) for the data of aerosol optical depth at 500 nm more than 0.3 (thick lines) and less than 0.3 (broken lines).**

Figure 12: Seasonal changes (a) and scatter plots (b) of the precipitable water vapor of the ALM-LW (red) and PPL-LW (blue), and radiosonde observation (black). “ $y=ax+b$ ” and “ $R^2$ ” are the linear fitting and coefficient of determination.

1095 Figure 13: Seasonal changes (a) and scatter plots (b) of the total ozone of the ALM-LW (red) and PPL-LW (blue), and Brewer spectrophotometer observation (black). “ $y=ax+b$ ” and “ $R^2$ ” are the linear fitting and coefficient of determination.

# Surface solar irradiance ( $\text{Wm}^{-2}$ )

### Surface solar irradiance

**Figure 14: Comparison of global, direct, and diffuse solar irradiances between the simulations using ALM-SW, ALM-LW, PPL-SW, PPL-LW, V42, and V5 retrieval results, and the measurements. “dif” indicates the mean and standard deviation of the differences. “ $y=ax+b$ ” and “ $R^2$ ” are the linear fitting and coefficient of determination.**

Figure 154: Differences of global (red), direct (blue), and diffuse (green) solar irradiances between the simulations using ALM-SW, ALM-LW, PPL-SW, and PPL-LW, V42, and V5 retrieval results, and the measurements, as a function of the aerosol optical depth at 500 nm.

Figure 165: Volume size distributions of the MRI v2 (red), Skyrad v4.2 (blue), and v5 (green) retrievals and in-situ measurements (black) on 16th (upper) and 25th (lower) August 2015 during the SAVEX-D. Closed circle, error bar, and shaded area of the in-situ measurement indicate mean, measurement uncertainty, and uncertainty due to vertical integration. Solid line and shaded area of MRI v2 indicate the mean, minimum, and maximum. Solid lines and shaded areas of Skyrad v4.2 and v5 indicate the means and standard deviations.

Figure A1: Estimated calibration constant at 315 nm and the fitting line by the polynomial regression. “R2” is the coefficient of determination.

1115

Figure A2: Normalized kernel functions for extinction and scattering at six scattering angles and at eleven wavelengths. The complex refractive index is assumed to be  $1.45 - 0.0035 \times 10^{-3}i$ .
