12

13 **Abstract**

14 Since May 2017 and August 2018, two ground-based MAX-DOAS (Multi AXis Differential
15 Optical Absorption Spectroscopy) instruments have been continuously recording daytime spectral
16 UV-visible measurements in the north-west (University of Natural Resources and Life Sciences
17 (BOKU) site) and south (Arsenal site), respectively, of the Vienna city centre (Austria). In this
18 study, vertical aerosol extinction (AE) profiles, aerosol optical depth (AOD), and near-surface AE
19 are retrieved from MAX-DOAS measurements recorded on cloud-free days applying the Bremen
20 Optimal estimation REtrieval for Aerosols and trace gaseS (BOREAS) algorithm. Measurements
21 of atmospheric profiles of pressure and temperature obtained from routinely performed sonde
22 ascents are used to calculate box-air-mass-factors and weighting functions for different seasons.
23 The performance of BOREAS was evaluated against co-located ceilometer, sun photometer, and
24 in situ instrument observations covering all four seasons. The results show that the vertical AE
25 profiles retrieved from the BOKU UV-visible MAX-DOAS observations are in very good
26 agreement with data from the co-located ceilometer, reaching correlation coefficients (R) of 0.936-

1 0.996 (UV) and 0.918-0.999 (visible) during fall, winter, and spring seasons. Moreover, AE
2 extracted using the lowest part of MAX-DOAS vertical profiles (up to 100 m above ground) are
3 highly consistent with near-surface ceilometer AE ($R > 0.865$ and linear regression slopes of 0.815-
4 1.21) during the fall, winter, and spring seasons. A strong correlation is also found for the
5 BOREAS-based AODs when compared to the AERONET ones. Notably, the highest correlation
6 coefficients ($R = 0.953$ and $R = 0.939$ for UV and visible, respectively) were identified for the fall
7 season. While high correlation coefficients are generally found for the fall, winter, and spring
8 seasons, the results are less reliable for measurements taken during summer. For the first time, the
9 spatial variability of AOD and near-surface AE over the urban environment of Vienna is assessed
10 by analyzing the retrieved and evaluated BOREAS aerosol profiling products in terms of different
11 azimuth angles of the two MAX-DOAS instruments and for different seasons. We found that the
12 relative differences of averaged AOD between different azimuth angles are 7-13%, depending on
13 the season. Larger relative differences of up to 32% are found for near-surface AE in the different
14 azimuthal directions. This study revealed the strong capability of BOREAS to retrieve AE profiles,
15 AOD, and near-surface AE over urban environments and demonstrated its use for identifying the
16 spatial variability of aerosols, in addition to the temporal variation.

17

18 **1 Introduction**

19 Atmospheric aerosols are defined as particles (liquid or solid) suspended in the air, with particle
20 diameters in the range of 10^{-9} to 10^{-4} m (0.001 μm to 100 μm) and various shapes, chemical
21 compositions, and hygroscopic and optical properties (Seinfeld and Pandis, 2006). Aerosols are an
22 important component of the Earth's atmosphere and play a crucial role in atmospheric chemistry,
23 cloud formation and lifetime, Earth's radiation budget, and climate (IPCC, 2013). It has also been
24 widely documented that enhanced atmospheric aerosol loading has adverse effects on human health
25 (Cohen et al., 2005; Liu et al., 2009; Russell and Brunekreef, 2009; Fann et al., 2012; Lelieveld et
26 al., 2015).

27 Sources of aerosols include natural emissions from the sea surface, soils, terrestrial vegetation,
28 volcanoes, and wildfires, as well as anthropogenic emissions from agricultural and industrial
29 activities, combustion processes, abrasion, and solvent use (Kanakidou et al., 2018).

1 A number of instruments for ground-based observations have been developed in the last decades
2 to obtain aerosol optical properties and vertical profiles in the troposphere. In situ instruments (e.g.
3 optical particle counters) are often designed to measure particulate matter (PM) concentrations (e.g.
4 PM_{2.5} and PM₁₀, whose size is defined as less than 2.5 and 10 μm in diameter, respectively) in
5 ambient air.

6 In addition to in situ measurement techniques, ground-based remote sensing instruments such as
7 sun photometers, LIght Detection And Ranging (LIDAR), ceilometers, and Multi AXis Differential
8 Optical Absorption Spectrometers (MAX-DOAS) as well as corresponding retrieval approaches
9 have been developed to obtain aerosol optical properties and vertical profiles (Holben et al., 1998;
10 Ansmann et al., 2011; Madonna et al., 2018; Frieß et al., 2016).

11 From sun photometer measurements, precise information on the total aerosol extinction (AE) and
12 scattering phase function can be derived and column-averaged aerosol size distribution, single
13 scattering albedo, and refractive index can be extracted (Holben et al., 1998). A large part of such
14 sun photometer measurement efforts is done in the framework of the AERONET (AErosol RObotic
15 NETwork) network (<https://aeronet.gsfc.nasa.gov/>).

16 Research grade LIDARs provide vertical profiles of aerosol backscattering and other information
17 at high vertical resolution (e.g. Madonna et al., 2018). In contrast, the retrieval of attenuated
18 backscatter and aerosol backscattering coefficient from ceilometer observations is limited by
19 instrument accuracy and highly dependent on the availability of data from co-located ancillary
20 instruments (e.g. sun photometer and/or Raman multi-wavelength LIDAR). However, the lower
21 costs and lower maintenance requirements associated with commercial ceilometers make these
22 instruments attractive for ground-based observations of aerosol optical properties and vertical
23 profiles in global scale networks (Madonna et al., 2018; Lotteraner and Piringer, 2016; Baumann-
24 Stanzer et al., 2019).

25 More than 15 years ago, a method to derive aerosol optical properties and vertical profiles from
26 MAX-DOAS observations was presented (Wagner et al., 2004), and since then has received
27 increasing attention (e.g. Frieß et al., 2006; Clémer et al., 2010; Yilmaz, 2012; Wang et al., 2013;
28 Vlemmix et al., 2015; Chan et al., 2017; Bösch et al., 2018; Beirle et al., 2019; Friedrich et al.,
29 2019). The derived aerosol information has been used for environmental studies as well as for the

1 validation of satellite observations and model simulations (e.g. Ma et al., 2013). State-of-the-art
2 MAX-DOAS retrieval algorithms (Tirpitz et al., 2021 and references therein) can be used to
3 quantify horizontal inhomogeneities in aerosol loading over urban and rural areas, in addition to
4 the aerosol vertical distribution. Further research efforts are needed to better retrieve aerosol optical
5 properties and vertical profiles by using the above mentioned algorithms and to compare and
6 validate the resulting aerosol products against independent co-located measurements.

7 In this study, we evaluate and analyze AE profiles, aerosol optical depth (AOD), and near-surface
8 (e.g. the lowest extinction point representing the altitude range between the surface and up to 100
9 m) AE retrieved from UV-visible spectral measurements collected with two MAX-DOAS
10 instruments in Vienna, Austria, located in the north-west and south of the city center. The retrieval
11 of UV-visible aerosol profiling products is based on the BOREAS algorithm (Bremen Optimal
12 estimation REtrieval for Aerosols and trace gaseS) (Bösch et al., 2018), which has been developed
13 by the Institute of Environmental Physics of University of Bremen (IUP-B) to improve an earlier
14 profile retrieval algorithm (Wittrock, 2006). The retrieval performance of BOREAS was recently
15 assessed from synthetic data computed with SCIATRAN (Rozanov et al., 2014) as well as using
16 real-world measurements taken in September 2016 during the Second Cabauw Intercomparison
17 campaign for Nitrogen Dioxide measuring Instruments (CINDI-2) in a rural environment (Frieß et
18 al., 2019; Tirpitz et al., 2021). From spectral measurements collected during CINDI-2, AE profiles
19 and AOD retrieved with BOREAS were validated with ancillary data. Overall, the results show a
20 satisfactory performance of BOREAS when the retrieved synthetic profile is close to the a priori.
21 However, due to the coarse vertical resolution (100 m), a comparison with surface in situ
22 measurements remains challenging. More recently, Gratsea et al. (2020) reported on the BOREAS
23 retrieval of AE profiles from ground-based MAX-DOAS measurements taken over the urban
24 environment of Athens, Greece. For validation purposes, they selected four case studies covering
25 different seasons and origins of aerosol loads and assessed the performance of BOREAS through
26 comparison with ground-based lidar AE profiles and sun photometer AOD measurements.

27 This study aims to evaluate UV-visible aerosol profiling products retrieved with BOREAS, in this
28 case over the urban environment of Vienna, Austria, through comparison with co-located
29 instruments. In a first step, AE profiles, AOD, and near-surface AE are retrieved from MAX-DOAS
30 UV and visible spectral measurements conducted on the roof of a campus building of the University

1 of Natural Resources and Life Sciences (BOKU) on cloud-free days in the period between
2 September 2017 and August 2019. The BOREAS aerosol profiling products are then compared
3 with data from co-located ceilometer, sun photometer, and in situ instruments. In the second step,
4 additional insights into the spatio-temporal variability of AOD and near-surface AE over the urban
5 environment of Vienna are provided by analyzing BOREAS aerosol profiling products retrieved
6 from measurements collected with two MAX-DOAS instruments (BOKU and Arsenal). By
7 plotting AOD and near-surface AE against simultaneous BOREAS retrievals of tropospheric
8 nitrogen dioxide vertical column densities (NO_2 VCDs) and near-surface NO_2 , respectively, the
9 origin of the aerosol is discussed.

10 The paper is structured as follows: in section 2, the instruments used in this study and the respective
11 data retrievals/data products are presented. As the study is based on cloud-free days, the
12 methodology to select such days is also introduced in this section. Results and insights into the
13 spatial and temporal patterns and the origin of aerosols over the urban environment of Vienna are
14 presented in section 3, followed by a summary and conclusions (section 4).

15

16 **2 Methodology**

17 **2.1 Instrumentation**

18 **2.1.1 MAX-DOAS**

19 Within the framework of the VINDOBONA (VIenna horizontal aNd vertical Distribution
20 OBServations Of Nitrogen dioxide and Aerosols) project, three ground-based MAX-DOAS
21 instruments have been assembled and put in continuous operation since December 2016, May
22 2017, and August 2018 at three different locations in Vienna (www.doas-vindobona.at). As the
23 lowest elevation angles which are essential for the retrieval of AE profiles are partially blocked by
24 trees and buildings at the University of Veterinary Medicine (VETMED) site, measurements of the
25 third MAX-DOAS instrument are not considered in this study.

26 Briefly, MAX-DOAS is a ground-based remote sensing technique for retrieving tropospheric trace
27 gases and aerosols by measuring scattered sunlight at different azimuthal and elevation angles (e.g.

1 Wagner et al., 2004). The MAX-DOAS systems measuring in Vienna were developed at the
2 Institute of Environmental Physics of the University of Bremen (IUP-B) in Bremen, Germany (e.g.
3 Peters, 2013) and continuously improved during international measurement campaigns such as
4 CINDI, TransBrom, SHIVA, MAD-CAT, and CINDI-2 (Roscoe et al., 2010; Peters et al., 2012;
5 Schreier et al., 2015; Wang et al., 2017; Donner et al., 2019). After the assembly, characterization
6 and testing phases in the laboratory of IUP-B, these instruments were transferred to the locations
7 in Vienna, where they continuously measure scattered sunlight at selected azimuthal and elevation
8 angles to cover air masses over large parts of the urban environment (Schreier et al., 2020).

9 In this study, UV-visible spectral measurements are taken from the BOKU and Arsenal MAX-
10 DOAS instruments located in the north-west (48.2379°N, 16.3317°E, 267 m a.s.l.) and south
11 (48.1818°N, 16.3908°E, 333 m a.s.l.) of the city center, respectively (see Fig. 1 and Table 1). The
12 two instruments are operating in two configurations: (1) elevation scans at fixed azimuthal
13 directions and (2) azimuthal scans at fixed elevation angles. The former configuration, which is
14 considered in this study, is based on five azimuthal viewing directions between 74° and 144°
15 (BOKU MAX-DOAS) and six azimuthal viewing directions between 324° and 20° (Arsenal MAX-
16 DOAS) (see Fig. 1), which were selected to capture the city center as well as point into the direction
17 of the other MAX-DOAS instruments. Elevation sequences consisting of $\alpha = 0^\circ, 1^\circ, 2^\circ, 3^\circ, 4^\circ, 5^\circ,$
18 $10^\circ, 15^\circ, 30^\circ,$ and 90° (zenith) are continuously performed at these azimuthal directions.
19 Measurements taken at $\alpha = 0^\circ$ elevation angle are however not considered for the MAX-DOAS
20 profile retrieval. Further technical details about the spectrometers of the BOKU (Shamrock SR-
21 193i-A) and Arsenal (AvaSpec-ULS2048x64) MAX-DOAS instruments can be found in Schreier
22 et al. (2020) and Behrens et al. (2019), respectively.

23

24 **2.1.2 Ceilometer**

25 The national weather service in Austria, “Zentralanstalt für Meteorologie und Geodynamik”
26 (ZAMG), operates a commercial ceilometer of the type Vaisala CL51 at the site “Hohe Warte”
27 (48.2483°N, 16.3564°E, 198 m a.s.l.) of ZAMG (see Fig. 1 and Table 1), performing routine
28 measurements since July 2012 (Lotteraner and Piringer, 2016). Briefly, the Vaisala CL51
29 ceilometer (hereinafter referred to as ceilometer) uses diode-laser lidar technology that emits

1 powerful laser pulses with wavelengths of 910 ± 10 nm in a vertical direction. Backscatter signals
2 are collected from about 50 m above ground up to an altitude of 15 km with a vertical resolution
3 of 10 m (Wagner and Schäfer, 2015). Recently, a method to obtain time series of mixing-heights
4 from ceilometer measurements was developed at ZAMG (Lotteraner and Piringer, 2016). In our
5 study, backscatter profiles with a temporal resolution of about half a minute are converted into AE
6 profiles (see section 2.2.3), which are used to evaluate AE profiles retrieved with BOREAS (see
7 section 3.1.1).

8

9 **2.1.3 Sun photometer**

10 Since May 2016, the Institute of Meteorology and Climatology of BOKU (BOKU-Met) operates a
11 sun photometer (Cimel CE318) within the AERONET project. Briefly, the ground-based Cimel
12 CE318 sun photometer (hereinafter referred to as sun photometer) measures direct sunlight at
13 different selected wavelength ranges. The extinction measurements are used to calculate column-
14 integrated AODs and Angstrom exponents (Holben et al., 1998). Additionally, column-integrated
15 aerosol parameters such as size distribution, refractive index, single scattering albedo, and phase
16 function can be retrieved by applying AERONET Version 3 inversion algorithms. The sun
17 photometer is located on the BOKU-Met measurement platform at a distance of about 2.5 m from
18 the BOKU MAX-DOAS instrument (see Fig. 1 and Table 1). In this study, AOD at 340, 380, 440,
19 500, 870, and 1020 nm are used for the scaling of ceilometer backscatter profiles (see section 2.2.3)
20 as well as for the comparison with AOD retrieved from BOKU MAX-DOAS UV-visible spectral
21 measurements (see section 3.1.2).

22

23 **2.1.4 In situ aerosol measurements**

24 The Vienna air quality monitoring network, which is maintained by the “Wiener
25 Umweltschutzabteilung (Magistratsabteilung 22)”, provides continuous half-hourly values of
26 PM_{2.5} and PM₁₀ from six and thirteen, respectively, in situ instruments (e.g. Grimm EDM180)
27 within the boundaries of Vienna (<https://www.wien.gv.at/ma22-lgb/luftgi.htm>). In this study,
28 PM₁₀ data are obtained from the station “Gerichtsgasse” (48.2611°N, 16.3969°E, 164 m a.s.l.)

1 located in Vienna's 21st district "Floridsdorf" (see Fig. 1), which is a site characteristic for the
2 urban background and located close to the 74° azimuthal viewing direction of the BOKU MAX-
3 DOAS. These measurements, which have been continuously performed since January 2017 using
4 a Grimm EDM180 (Spangl, 2019), are used for the comparison of MAX-DOAS retrieved near-
5 surface AE (see section 3.1.3).

6

7 **2.1.5 Pyranometer**

8 The measured global radiation, which is used for the selection of cloud-free days (see section 2.2.4),
9 is obtained from star pyranometer (Schenk) observations, which are performed since the year 2005
10 at the BOKU-Met measurement platform. Briefly, the Schenk star pyranometer has six black and
11 six white painted sectors, whereby the temperature difference between the black and white
12 segments is proportional to the incident solar radiation.

13

14 **2.2 Data retrieval and analysis**

15 **2.2.1 Vertical sensitivity, information content, and sources of errors**

16 The vertical sensitivity of MAX-DOAS measurements, which is highest close to the surface,
17 strongly decreases with altitude up to about 2 km, in particular for the UV channel and albeit in
18 weaker form also for the Vis channel (e.g. Rodgers and Connor, 2003; Bösch et al., 2018; Tirpitz
19 et al., 2021). Above that altitude, BOREAS and, in general, MAX-DOAS optimal estimation
20 retrieval results converge with the a priori profile. Consequently, an accurate quantification of
21 aerosols is not possible at these atmospheric layers. In contrast to ceilometer observations, the
22 vertical resolution of MAX-DOAS is limited at the surface (~100 m) and increases with altitude,
23 affecting both the profile shape and the near-surface concentrations of aerosols.

24 In order to make the two profiles comparable in a quantitative way, the ceilometer profiles are
25 convoluted with BOREAS averaging kernels (AVKs), by applying the following formula
26 introduced in Rodgers and Connor (2003): $x_{\text{new}} = x_{\text{apri}} + A(x_{\text{ceilo}} - x_{\text{apri}})$, where x_{new} is the smoothed
27 ceilometer AE profile, x_{apri} and x_{ceilo} denote the BOREAS a priori and ceilometer AE profile,

1 respectively, and A is the AVK matrix obtained from BOREAS calculations. AVKs characterize
2 the sensitivity of the solution to the true state, and thus, the gain of information for each retrieved
3 MAX-DOAS profile is represented by A . Degrees of freedom (DOFs), which can be quantified by
4 the trace of A , refers to the number of individual pieces of information that can be retrieved.

5 In Figures 2 and 3, examples of averaging kernels and associated DOFs for AE profiles retrieved
6 with BOREAS in the UV and Vis channels, respectively, are shown for 10 October 2018. The left
7 two panels represent the morning (06:50 UTC), the middle two panels show the noon (11:44 UTC),
8 and the right two panels feature AVKs and associated vertical profiles for the afternoon (13:34
9 UTC). Overall, the vertical sensitivity is limited to about 2 km (UV) and 2.5 km (Vis) on this day,
10 meaning that more information is obtained for the Vis channel due to longer effective light path
11 lengths and thus, higher sensitivity. It should be noted that negative AVK values, particularly
12 observed during noon and afternoon between 1 and 2.5 km altitude, indicate that additional aerosol
13 loads can decrease the retrieved solution close to the surface.

14 In two recent studies (Friess et al., 2019; Tirpitz et al., 2021) it was found that the averaging kernels
15 and associated DOFs of BOREAS aerosol retrievals show much smaller information content than
16 AVKs from other retrievals developed by other groups. Nevertheless, good agreement of BOREAS
17 vertical aerosol profiles with products of the other algorithms was found in those two studies. Low
18 information content of AVKs is also found in our study. However, we underline that this might be
19 related to additional regularisation terms and generally less straightforward interpretation of
20 BOREAS AVKs. More details on BOREAS retrieved AVKs and DOFs can be found in Bösch et
21 al. (2018) and Tirpitz et al. (2021).

22 In addition to the AVKs, the MAX-DOAS retrieved (black lines) and a priori (gray lines) as well
23 as the ceilometer unsmoothed (orange lines) and convoluted (brown lines) AE profiles are depicted
24 in Figs. 2 and 3. The error bars of the MAX-DOAS retrieved profile represent the total error of the
25 aerosol retrieval. The total error (S_{tot}) can be represented in the following equation: $S_{\text{tot}} = S_{\text{sm}} + S_{\text{fw}}$
26 $+ S_{\text{ns}}$, where S_{sm} denotes the smoothing error, S_{fw} is the forward model error, and S_{ns} describes the
27 retrieval noise (Rodgers, 2004). As can be clearly seen in the two figures, aerosol profiles retrieved
28 in the Vis channel are less error-prone than the UV ones. More details on BOREAS errors can be
29 found in Bösch et al. (2018).

1 With respect to the Vaisala CL51 ceilometer data, some uncertainties are linked with background
2 and dark current effects. However, most of these noise aspects have been analyzed in great detail
3 and are mostly overcome when using the most recent firmware (e.g. Kotthaus et al., 2016). Another
4 feature found for aerosol detection by using ceilometer instruments is the effect of water vapor on
5 the ceilometer emission wavelength. Wiegner and Gasteiger (2015), for example, found that the
6 error in the backscatter retrieval can be in the order of 20% for mid-latitudes when water vapor
7 absorption is ignored. It should be noted that in our study, no water vapor correction is applied.

8 AOD errors from AERONET sun photometers are in the range of 0.02 and 0.01 for the UV and Vis
9 channels, respectively (Sayer et al., 2013).

10

11 **2.2.2 Vertical AE profiles, AOD, and near-surface AE from MAX-DOAS** 12 **measurements**

13 The retrieval of AE profiles, AOD, and near-surface AE on cloud-free days is performed with the
14 BOREAS algorithm (Bösch et al., 2018). The abundance of the oxygen molecule (O_2) only depends
15 on pressure and temperature and decreases exponentially with altitude. The concentration of the
16 O_2 - O_2 collision complex (O_4) is proportional to the squared O_2 concentration and thus also
17 decreases exponentially with altitude. The column amounts of the latter (O_4) can be retrieved from
18 DOAS measurements in the UV and visible wavelength range because of its spectral absorption
19 features (Wagner et al., 2004). In general, the BOREAS aerosol retrieval algorithm uses the
20 difference between modelled and measured O_4 differential slant optical thicknesses around the O_4
21 absorption bands at 360 and 477 nm to retrieve AE profiles in an iterative Tikhonov regularization
22 scheme (Rodgers, 2004). In more detail, the radiative transfer model (RTM) SCIATRAN is used
23 for the computation of weighting functions, which are needed for the profile inversion of aerosols
24 (Bösch et al., 2018). BOREAS and SCIATRAN (Rozanov et al., 2014) are linked in several ways:
25 For the aerosol retrieval part, BOREAS uses an inversion function implemented in SCIATRAN.
26 For the trace gas retrieval part, BOREAS calls SCIATRAN only for the RTM calculations, but not
27 for the inversion. In addition to the O_4 differential slant column densities (DSCDs) retrieved using
28 the retrieval settings given in Schreier et al. (2020), atmospheric sondes profiles of pressure and
29 temperature are used as input. In this study, aerosol profiling products are retrieved with BOREAS

1 using measured atmospheric profiles of pressure and temperature from a co-located site, instead of
2 using profiles from a U.S. Standard Atmosphere (Bösch et al., 2018; Gratsea et al., 2020) or
3 averaged profiles of O₃ sonde measurements (Tirpitz et al., 2021). Atmospheric profiles of pressure
4 and temperature used in this study are measured twice a day at the “Hohe Warte” site of ZAMG
5 (see Fig. 1), e.g. at 12 UTC and 0 UTC. For the BOREAS retrieval, pressure and temperature
6 profiles taken at 12 UTC, which are downloaded from a global data base
7 (<http://weather.uwyo.edu/uperair/sounding.html>), are used as input.

8 The radiative transfer calculations with SCIATRAN are performed using the aerosol phase function
9 and single scattering albedo of AERONET Version 3 (Almucantar Level 1.5 Inversion) data from
10 the instrument located at BOKU, selecting the data closest in time to the MAX-DOAS
11 measurement. The general configuration of BOREAS was used to retrieve AE values on a vertical
12 grid ranging from the station altitude up to 4 km, with a 100 m grid step. The a priori profile was
13 chosen to be exponentially decreasing (AE surface value: 0.18, scale height: 1.25 km) with the pre-
14 scaling option introduced in Bösch et al. (2018) to cope with highly varying aerosol loads. The
15 value for the scale height was determined from preliminary tests performed on measurements taken
16 from the IUP Bremen MAX-DOAS instrument.

17 The period between AE profiles, AOD, and near-surface AE retrieved at recurring azimuth viewing
18 directions was about 35-45 min until March 2019; and 50-75 minutes since then because of the
19 added azimuthal viewing directions for the first configuration and full implementation of the
20 second configuration (see section 2.1.1).

21 Although BOREAS NO₂ profiling products are briefly addressed to investigate the origin of
22 aerosols over the urban environment of Vienna (see section 3.2), the main focus of this study is on
23 aerosol profiles. Accordingly, details on the NO₂ retrieval are omitted and the reader is referred to
24 Bösch et al. (2018) and Schreier et al. (2020).

25

26 **2.2.3 Vertical AE profiles from ceilometer measurements**

27 Range-corrected backscatter profiles (hereinafter referred to as backscatter profiles) from
28 ceilometer observations can be converted into AE profiles as recently reported in the context of the

1 validation of AE profiles retrieved from MAX-DOAS measurements (Bösch et al., 2018; Wagner
2 et al., 2020). In this study, we follow the approach described in Wagner et al. (2020) to obtain AE
3 profiles using the following procedure: In a first step, backscatter profiles are extracted from the
4 original (daily) data files, which are made available by ZAMG. Second, extremely high values ($>$
5 100000), which appear at altitudes well above the mixing-height, are replaced with NaNs. Third,
6 the ceilometer profiles with higher temporal and vertical resolution are aggregated to match both
7 the time and altitude range of the MAX-DOAS AE profiles. On the one hand, gridding the data in
8 time is achieved by finding the ceilometer measurements closest in time with the first MAX-DOAS
9 measurements of individual vertical scans and then averaging the backscatter signals. In order to
10 cover the duration of the MAX-DOAS vertical scan and adding a few additional ceilometer
11 measurements before and after the individual scans, the averaging is realized over a range of five
12 values before the start time of MAX-DOAS vertical scan and ending ten values after that time. The
13 motivation of adding a few more ceilometer measurements before and after is to achieve better
14 smoothing of the backscatter signals. In fact, the ceilometer averaging interval is about 9.5 minutes,
15 while the duration of one MAX-DOAS vertical scan is about 4.5 minutes. On the other hand,
16 gridding the data in space is achieved by averaging over intervals of ten backscatter signals
17 (because of 10 m vertical resolution) to match the 100 m vertical sampling of MAX-DOAS
18 measurements. Because of missing ceilometer measurements below 50 m above surface and in
19 order to match the lowermost MAX-DOAS measurement (e.g. 260 ± 50 m), the single 50 m above
20 ground ceilometer measurement is used instead of averaging for the lowermost layer. The
21 averaging is performed starting from the 360 ± 50 m MAX-DOAS layer and up to the last layer (e.g.
22 3960 ± 50 m). Effects of missing ceilometer data below 50 m on the comparisons presented below
23 are expected to be negligibly small in our study as the location of the ceilometer instrument is 69
24 m below the BOKU MAX-DOAS instrument (see Sect. 2.1). Once the ceilometer measurements
25 are gridded to the time and vertical resolution of MAX-DOAS measurements, backscatter profiles
26 are vertically integrated between the lowest (50 m above surface) and highest altitude (4 km). The
27 vertically integrated backscatter profiles are scaled in an intermediate step by the AERONET AOD
28 at 910 nm (average of AOD at 870 nm and 1020 nm) in order to match the operating wavelength
29 range of the ceilometer. The profiles are then scaled by the AOD at 360 nm (average of AOD at
30 340 nm and 380 nm) and 470 nm (average of AOD at 440 nm and 500 nm), which is in accordance
31 with MAX-DOAS AE profiles retrieved in the UV (Arsenal and BOKU MAX-DOAS) and visible

1 (BOKU MAX-DOAS only) spectral ranges (see Sect. 2.2.2), respectively. We note that, in contrast
2 to Wagner et al. (2020), an extinction correction is not performed in our study because the effect
3 of this correction was found to be negligibly small. Finally, converted ceilometer AE profiles are
4 convoluted with BOREAS AVKs (see Sect. 2.2.1).

5

6 **2.2.4 Selection of days with cloud-free conditions**

7 The evaluation of UV-visible MAX-DOAS aerosol profiling products in this study is based on days
8 with cloud-free conditions. To select cloud-free days in Vienna, the following procedure is applied:

9 First, clear sky global radiation for the period September 2017 to August 2019 is simulated using
10 the RTM solver DISORT2 (Stamnes et al., 1988) of the radiative transfer software package
11 libRadtran (Mayer and Kylling, 2005). Mean vertical atmospheric profiles (mid-latitude summer
12 and winter as a function of the season) of atmospheric pressure and air, ozone, oxygen, water vapor,
13 carbon dioxide and nitrogen dioxide densities are used as input parameters for the RTM
14 calculations. The vertical profile of ozone is scaled according to the column ozone measurements
15 taken from the WOUDC satellite database (woudc.org). Solar zenith angle (SZA) is taken at the
16 time of MAX-DOAS measurement and AOD is taken from AERONET. The temporal resolution
17 of the simulated global radiation matches the MAX-DOAS measurements.

18 Second, measured global radiation from the site of the BOKU-Met weather station
19 (<https://meteo.boku.ac.at/wetter/aktuell/>) is temporally resampled to the MAX-DOAS time series.
20 This data is compared with the simulated data of the first step in order to select cloud-free days
21 automatically.

22 In the third step – the comparison – the following criteria are used to select cloud-free days: (i) data
23 points are defined as “low error” if the difference between measured and simulated global radiation,
24 relative to the simulated global radiation, is below or equal to 20%, (ii) for a day to be considered
25 as clear or partially clear sky at least 60% of the data points must be classified as “low error”, and
26 (iii) the daily sum of the second-order differences (second derivative) of the radiation time-series
27 is used as a measure of sky condition variability. The daily sum of second-order differences of the
28 measured data must be less than 2.5 times the simulated data (see Fig. 4). The empirical value of

1 2.5 was found to work best for the separation between clear and cloudy skies in our case. The above
2 criteria were found by trial-and-error. Due to the annual variation of radiation there can not be a
3 single empirically determined criteria. After applying these criteria, a total number of 119 days
4 from September 2017 to August 2019 remains. However, the final number of cloud-free days used
5 in this study is further reduced due to missing MAX-DOAS and/or ceilometer and/or sun
6 photometer and/or atmospheric sounding observations. Thus, total numbers of 102 cloud-free days
7 (40 days in fall, 14 days in winter, 22 days in spring, and 28 days in summer) for the BOKU UV,
8 74 cloud-free days (27 days in fall, 10 days in winter, 9 days in spring, and 28 days in summer) for
9 the BOKU visible, and 81 cloud-free days (27 days in fall, 10 days in winter, 16 days in spring,
10 and 28 days in summer) for the Arsenal MAX-DOAS instruments are selected for the retrieval of
11 vertical AE profiles, AOD, and near-surface AE. It should be noted that the total number of days
12 with cloud-free conditions is lower for the BOKU visible and Arsenal MAX-DOAS because their
13 operation started later in time and also because of technical problems with the BOKU visible MAX-
14 DOAS in spring 2019, which resulted in the loss of a couple of days.

15

16 **3 Results and discussion**

17 **3.1 Evaluation of BOREAS aerosol profiling products**

18 The performance of BOREAS in this study is evaluated by considering AE profiles, AOD, and
19 near-surface AE retrievals in the UV and visible channels that fulfill the following criteria: (1) the
20 absolute and relative difference between measured and simulated O_4 DSCDs at all individual
21 elevation angles is less than $1000 \times 10^{40} \text{ molec}^2 \text{ cm}^{-5}$ and less than 10%, respectively, (2) the
22 maximum AOD is less than 1.0, and (3) no more than 50 iterations were needed in the retrieval. It
23 should be noted that in some cases, the absolute and relative difference criteria can be reached
24 although no convergence of BOREAS is found. In general, convergence is not reached if the a
25 priori is not appropriate, for example, when the shape of the vertical profile and/or the assumed
26 AOD are wrong. Moreover, temporal changes in pressure and temperature can affect the BOREAS
27 retrieval. The latter is related to the fact that a single daily pressure/temperature vertical profile
28 taken from sonde measurements performed at noon is used in our study (see section 2.2.2). Bösch
29 (2019), for example, analyzed temperatures larger than the U.S. standard temperature profile

1 measured by sondes, which were taken at different daytimes on 15 September 2016 during the
2 CINDI-2 campaign, and their implication for BOREAS profiling results. These increased
3 temperatures are directly linked to smaller O_4 values, which lead to an increase in extinction for
4 the aerosol profiles within the BOREAS retrieval. In this study, relative differences with values up
5 to +12% were found for near-surface AE when using pressure/temperature from sondes instead of
6 using profiles from a U.S. Standard Atmosphere.

7

8 **3.1.1 Comparison of MAX-DOAS AE profiles with ceilometer AE profiles**

9 BOREAS AE profiles retrieved from the UV and visible BOKU MAX-DOAS measurements taken
10 at an azimuth angle of 74° (represented as a solid blue line in Fig. 1) are compared against AE
11 profiles obtained from the ceilometer, which is about 2.25 km away and close to the selected
12 viewing direction (see Fig. 1). The comparison is performed for all available cloud-free days falling
13 into the period September 2017 to August 2019 (see section 2.2.4) and presented for the different
14 seasons.

15 Overall, the MAX-DOAS AE profiles retrieved in the UV and visible range are consistent with the
16 convoluted ceilometer AE profiles in terms of linear relationship, in particular during the fall,
17 winter, and spring seasons with correlation coefficients of $R = 0.935-0.996$ (UV) and $R = 0.757-$
18 0.999 (visible) (see Fig. 5 and 6, respectively). In the left panels of that figures, seasonal averages
19 of all extinction points of MAX-DOAS and ceilometer extracted from a number (N) of profiles
20 available from cloud-free days within selected time intervals are correlated with each other, where
21 extinction profile points at all altitudes have equal weight. Overall, higher correlation coefficients
22 are observed for the Vis profiles, except for profile comparisons performed for the afternoon.
23 Increases of BOREAS AE between 2 and 3 km altitude, which could be related to clouds in the
24 field of view of lower MAX-DOAS viewing directions, seems to cause these lower correlation
25 coefficients. Smallest R values are found for summer, with $R = 0.888$ (UV) and $R = 0.757$ (visible).
26 The largest correlation coefficients during summer are found in the early morning (6-8 UTC),
27 which could be related to the lower mixing-heights (< 1 km).

1 The number of UV retrievals differs from the number of visible retrievals, which can be explained
2 by the different length of time series (see section 2.2.4) and, at the same time, higher numbers of
3 flagged retrievals for the UV measurements (see section 3.1). The fact that the same number of
4 cloud-free summer days (28 days) are evaluated for the UV and visible BOREAS retrievals, but
5 more BOREAS retrievals are considered for the visible channel implies that more AE profile
6 retrievals are flagged as invalid in the UV channel. Quantitatively speaking, 66.6% (fall), 64.9%
7 (winter), 61.5% (spring), and 67.2% (summer) BOREAS retrievals fulfill the criteria (see Sect. 3.1)
8 in the UV channel, whereas 87.1% (fall), 78.7% (winter), 81.5% (spring), and 78.3% (summer)
9 successful BOREAS retrievals are obtained for the Vis channel.

10 The right panels of Figs. 5 and 6 depict the comparison between MAX-DOAS and ceilometer near-
11 surface AE data, which are representative for the lowest level of the troposphere (e.g. from the
12 instrument's altitude up to 100 m above). In this case, the lowest extinction points from all daytime
13 measurements of available cloud-free days are correlated with each other. Consequently, the
14 number of data points is the sum of N of the five selected time spans given in the left panels plus
15 data points from time spans before and after the selected ones. The highest set of correlation
16 coefficients of $R > 0.85$ and linear regression slopes (S) of $S > 0.815$ & $S < 1.121$ are encountered
17 in the fall, winter, and spring seasons, for both spectral channels. This finding implies that the
18 BOREAS retrieval of near-surface AE delivers the best results during that time of the year. These
19 plots underline the difficulties that BOREAS has in retrieving AE profiles and near-surface AE
20 during summer, most probably due to (i) well-mixed air masses as indicated by maximum mixing-
21 heights, (ii) decreasing sensitivity of MAX-DOAS with increasing altitudes, (iii) significant lower
22 AODs than the AERONET ones, and (iv) profiles with box-like shapes, which are not well
23 retrieved with the exponential a priori used.

24 In Figures 7 and 8, absolute ($AE_{\text{MAX-DOAS}} - AE_{\text{ceilometer}}$) and relative differences ($(AE_{\text{MAX-DOAS}} -$
25 $AE_{\text{ceilometer}}) / AE_{\text{ceilometer}} * 100$) are presented for the vertical profile retrievals in the UV and Vis
26 channels, respectively. In the left panels of these figures, absolute (solid black lines) and relative
27 (color-coded lines) differences are shown for different altitude ranges and time intervals. For the
28 vertical AE profiles retrieved in the UV channel it is obvious that AE values at most altitude levels
29 are lower for the MAX-DOAS than for the ceilometer. However, there are two exceptions where
30 both the absolute and relative differences are positive, namely near-surface in winter and very

1 slightly between 2 and 3 km altitude, in particular found in the afternoon, but for all seasons. As
2 the positive differences of the latter are also observed for the Vis retrievals at these altitudes, with
3 even higher amounts of more than 100%, we again speculate that clouds in the field of view of the
4 lower MAX-DOAS viewing directions could be the reason. Another cause for these large
5 deviations between MAX-DOAS and ceilometer could be related to increases in temperature at
6 these altitude levels in the afternoon. The use of only a single temperature profile from noon time
7 sonde measurements in the BOREAS retrievals could in principle cause differences. However, as
8 these differences are also seen before noon, in particular for the Vis retrievals in summer, we rather
9 relate these features to clouds. The lowest absolute and relative differences are found for the
10 vertical AE profiles retrieved in the Vis channel for the fall and spring season.

11 The right panels of Figs. 7 and 8 show the distribution and mean of absolute differences obtained
12 for the UV and Vis channels, respectively, for the near-surface level. Overall, the best agreement
13 of near-surface AE is achieved for the spring and winter seasons, with slightly lower differences
14 found for the Vis retrievals. It should be noted that with the exception of winter, mean absolute
15 differences in near-surface AE are negative for all seasons.

16

17 **3.1.2 Comparison of MAX-DOAS AOD with sun photometer AOD**

18 The retrieved BOREAS AOD using UV (360 nm) and visible (477 nm) BOKU MAX-DOAS
19 measurements taken at an azimuth angle of 74° is evaluated against the AOD (average of
20 AERONET AOD at 340 and 380 nm for the UV as well as average of AERONET AOD at 440 and
21 500 nm for the visible channel) obtained from co-located sun photometer observations (see Fig. 9).
22 As already found for the comparison of AE profiles, the best agreement between the two
23 independent AOD measurements is found in fall ($R = 0.953$ and $R = 0.934$ for the UV and visible
24 channel, respectively). While BOREAS generally underestimates AOD in the UV channel, AOD
25 obtained in the visible channel is slightly overestimated during fall and spring. Lower BOREAS
26 AODs are expected because of the limited sensitivity of MAX-DOAS profiling for higher altitudes,
27 e.g. above 4 km (Bösch et al., 2018; Tirpitz et al., 2021), whereas AERONET AODs might better
28 represent elevated aerosol in the free troposphere and stratosphere. The slopes of the linear
29 relationship are generally higher for the comparison of AODs retrieved in the Vis channel.

1 Interestingly, correlation coefficients and slopes for the UV and Vis retrievals are in best agreement
2 for the winter season. This could be an indication that aerosols are accumulated in the lowest layers,
3 where the sensitivity of MAX-DOAS is highest for both the UV and Vis channels. In contrast, the
4 largest discrepancy of slopes is found for spring, which could arise from elevated aerosols that are
5 better retrieved due to better sensitivity in the Vis channel. One explanation for the overestimations
6 noticed in the visible channel of the BOREAS retrievals in fall and spring (with slopes larger than
7 1) could be linked to spatial variations of AOD over the urban environment of Vienna, which will
8 be discussed later in section 3.2. As a consequence of different viewing geometries (e.g. 74°
9 azimuthal pointing with the MAX-DOAS vs. direct sun observations with the sun photometer), the
10 two measurements do not always sample the same air masses.

11

12 **3.1.3 Comparison of MAX-DOAS near-surface AE with in situ surface PM10**

13 In addition to the evaluation of BOREAS near-surface AE against ceilometer observations (see
14 Sect. 3.1.1), AE is compared against surface in situ measurements of particulate matter. Near-
15 surface AE can be extracted from both ceilometer AE profiles and MAX-DOAS/BOREAS
16 retrievals. The evaluation is performed through comparison with surface PM10 concentrations
17 obtained from the air quality monitoring station “Gerichtsgasse (Floridsdorf)”, which is about 5.5
18 and 3.25 kilometers away from the BOKU MAX-DOAS and ceilometer, respectively (see Fig. 1).
19 It should be noted that AE and PM10 are two different physical quantities and thus, a perfect
20 correlation is not expected. In agreement with the previous findings, the BOREAS AE retrievals in
21 the UV and visible channels are qualitatively most consistent with ambient surface PM10
22 concentrations during the fall, winter, and spring seasons (see Fig. 10 and Fig. 11). For the near-
23 surface AE retrieved in the UV (Vis) channel, the strongest correlation with $R = 0.782$ ($R = 0.825$)
24 is found for the fall (spring) season. The slopes and intercepts of the linear regression characterizing
25 the BOREAS AE and the PM10 datasets are in very good agreement with those obtained from the
26 linear regression between the ceilometer AE and surface PM10 concentrations in that season of the
27 year, but also in winter and spring. This result highlights the strong performance of BOREAS, in
28 particular for the lowest 100 m. It should be noted that BOKU and ZAMG sites are located in
29 suburban areas, whereas the location of the in situ station “Gerichtsgasse” is characterized as urban

1 (Spangl, 2019). This could explain the larger scatter observed during winter, which might be the
2 result of a combination of spatial differences in emission strength, different measuring heights, and
3 rather stable meteorological conditions, thus favoring less mixing of aerosols.

4

5 **3.2 Spatial variability of AOD and near-surface AE**

6 To better understand the spatial variabilities of AOD and near-surface AE and the origin of aerosols
7 over the urban environment of Vienna, combined MAX-DOAS aerosol and NO₂ profiling products
8 were used. Towards this direction, the MAX DOAS UV data for the five (BOKU) and six (Arsenal)
9 azimuthal angles (see Fig. 1) were analyzed in more detail. Because of the rather weaker
10 performance of BOREAS during summer, the results of the following analysis are presented for
11 the fall, winter, and spring seasons only. In order to make the MAX-DOAS measurements of all
12 viewing directions comparable, the retrieved AOD and near-surface AE together with the NO₂
13 retrieval products of tropospheric NO₂ vertical column density (VCD NO₂) and near-surface NO₂
14 concentrations, are interpolated to half-hour intervals. In a second step, only those time intervals
15 with available aerosol and NO₂ columns at all eleven azimuth angles are considered.

16 Consequently, half-hour intervals with missing observations for at least one azimuth angle are
17 discarded from the data sets. Inevitably, this filtering procedure further reduces the number of
18 aerosol profiles obtained during cloud-free conditions ($N = 52$ in fall, $N = 24$ in winter, and $N = 30$
19 in spring). After removing half-hour intervals with missing observations, the remaining data points
20 are averaged per azimuth angle and per season, excluding summer as mentioned before.

21 The relationship between the spatial variability of averaged AODs and averaged VCD NO₂ is
22 presented in Fig. 12. The results reveal that higher AOD values (e.g. the vertically integrated AE)
23 are detected by the Arsenal MAX-DOAS, whereas higher VCD NO₂ (e.g. the vertically integrated
24 NO₂ concentration) is found by the BOKU MAX-DOAS. The reason for the lower VCD NO₂
25 values observed by the Arsenal MAX-DOAS could be that the instrument is installed on a tower
26 platform at 131 m above ground. Thus, NO₂ in the lowest layers close to the surface is not captured
27 by the instrument. Higher AOD amounts at the Arsenal site could be related to industrial emission
28 sources nearby. The highest amounts of both AOD and VCD NO₂, which includes observations

1 from only a couple of cloud-free days, are detected by both instruments during fall. A closer look
2 at the averaged BOKU MAX-DOAS retrieval results reveals that the ratio of the maximum AOD
3 (74°) over the minimum AOD (144°) was 1.07 (fall), 1.13 (winter), and 1.08 (spring). For the VCD
4 NO_2 , the opposite trend is observed with the highest values towards the urban core and the lowest
5 in the suburban areas in the north-east. Greater irregularities from this pattern, but still significant
6 spatial differences are found for the Arsenal MAX-DOAS with the averaged AOD maximum
7 (348°) in spring, being also $\sim 10\%$ higher than the minimum (324°).

8 Similarly, the spatial patterns of averaged near-surface AE, in relation to averaged near-surface
9 NO_2 concentrations, are illustrated in Fig. 13. Overall, near-surface AE increases with increasing
10 NO_2 concentrations, suggesting that both aerosols and nitrogen oxides (NO_x) are released from
11 anthropogenic emission sources. The highest values for both near-surface AE and NO_2 are found
12 in winter, followed by fall and spring. Interestingly, the highest winter amounts of both near-
13 surface AE and NO_2 are observed when the BOKU MAX-DOAS instrument is measuring at an
14 azimuth angle of 88° . Along the respective light path of this viewing direction, heavy-traffic roads
15 and a heat-generating power-station (waste incineration plant in Spittelau, 48.2344° N, 16.3594°
16 E) can be found. In contrast, AE and NO_2 near-surface amounts are second-lowest at this viewing
17 direction during fall and spring, which could be interpreted as an indication of a significant
18 contribution of the heat-generating power-station to local air pollution in winter. As expected,
19 higher spatial differences are found for the near-surface aerosol and NO_2 profiling products than
20 for column-integrated retrieval results. While average BOKU MAX-DOAS retrieval results reveal
21 that maximum near-surface AE (144°) is higher than minimum near-surface AE (74°) by a factor
22 of 1.32 in spring, the largest relative difference between maximum (324°) and minimum (10°)
23 averages of 25% is observed for the Arsenal MAX-DOAS retrievals in winter.

24

25 **4 Summary and outlook**

26 In this study, an evaluation of BOREAS aerosol profiling products is presented by comparing AE
27 profiles, AOD, and near-surface AE retrieved from UV and visible MAX-DOAS measurements
28 with data from co-located ceilometer, sun photometer, and in situ instruments. It is the first time

1 that AE profiles are reported for different seasons and daytimes over the urban environment of
2 Vienna.

3 Both the location and viewing direction of the BOKU MAX-DOAS are arranged in a way to cover
4 as much as possible of the vertical extent of the measurements taken by the ceilometer, resulting
5 in an overlap of an altitude up to 4 km. The rather short distance of 2.25 km between the BOKU
6 MAX-DOAS and ceilometer further reduces effects that could arise from spatial variations. In
7 addition to the evaluation of the vertical AE profiles, measurements of co-located sun photometer
8 (a few meters away) and in situ instruments are obtained to assess the quality of vertically-
9 integrated and near-surface BOREAS retrieval results.

10 In contrast to the recent BOREAS-based profile studies (Bösch et al., 2018; Gratsea et al., 2020;
11 Tirpitz et al., 2021), this study takes into account measured atmospheric profiles of pressure and
12 temperature taken at a co-located site of the Austrian official weather service (e.g. the same site
13 where the ceilometer is operated). To systematically evaluate the retrieved BOREAS aerosol
14 profiling products in Vienna, MAX-DOAS measurements from more than a hundred cloud-free
15 days covering all seasons of the 2017-2019 period are considered.

16 The results of this study show that the retrieved BOREAS AE profiles from the BOKU MAX-
17 DOAS measurements are consistent with AE profiles from the co-located ceilometer. The highest
18 correlation coefficients of 0.936-0.996 (UV) and 0.918-0.999 (visible) are found for the fall, winter,
19 and spring seasons. The largest discrepancies between the two independent measurements, also in
20 terms of absolute and relative differences, arise during summer, most probably as a result of
21 elevated mixing-heights leading to pronounced vertical mixing of air masses. The good
22 performance of BOREAS is underlined by the agreement found when AOD and near-surface AE
23 are compared with AERONET AOD and in situ PM10 measurements, again with the exception of
24 summer. A summary of correlation coefficients obtained in this study is given in Table 2.

25 After resampling BOREAS aerosol profiling products, the spatial variability of vertically-
26 integrated and near-surface aerosol amounts was investigated. While relative differences of the
27 mean AOD retrieved from MAX-DOAS measurements taken at different azimuth angles are on
28 the order of 7-13%, larger relative differences of up to 32% between averaged values obtained for
29 the different viewing directions are found for near-surface AE. The high correlation of the near-

1 surface AE and near-surface NO₂ suggests that the aerosol layer close to the ground is mainly of
2 anthropogenic origin. However, cases of high AOD are sometimes also found at low NO₂ VCDs,
3 most probably as a consequence of trans-boundary pollution and/or dust events that temporally
4 affect air masses above the urban environment of Vienna.

5 In conclusion, good agreement between MAX-DOAS aerosol profiling products and data from co-
6 located instruments is found, highlighting the strong performance of BOREAS for the retrieval of
7 tropospheric vertical aerosol profiles covering the range between the instrument's altitude up to 4
8 km as well as its capability to detect spatial variations of aerosol amounts over urban environments.

9

10 **Data availability.** Data can be requested from the corresponding author
11 (stefan.schreier@boku.ac.at).

12

13 **Author contributions.** SFS, TB, and AR formulated the overarching goals of this study. TB
14 performed calculations with the MAX-DOAS profile retrieval algorithm BOREAS. SFS applied
15 the method to convert ceilometer backscatter profiles into aerosol extinction profiles. PW applied
16 a RTM to simulate global radiation and MR developed the procedure to select cloud-free days. SFS
17 performed the analyses and prepared the manuscript. SFS and AR are responsible for the
18 continuous operation of the BOKU MAX-DOAS instrument. SFS, AR, KL, and MV are
19 responsible for the continuous operation of the Arsenal MAX-DOAS instrument. PW as the
20 principal investigator of the AERONET Vienna_BOKU site provided the sun photometer
21 measurements. CL is responsible for the continuous operation of the ZAMG ceilometer and
22 provided both range-corrected backscatter and mixing-height data. All authors contributed to the
23 writing of this manuscript.

24

25 **Competing interests.** Andreas Richter is a member of the editorial board of the journal.

26

1 **Acknowledgements.** This study was funded by the Austrian Science Fund (FWF): I 2296-N29,
2 the German Science Foundation (DFG): Ri 1800/6-1, and A1 Telekom Austria. Special thanks go
3 to Werner Sagmeister and Helmut Kropf from A1 Telekom for their organizational and technical
4 support. Our thanks go to the University of Wyoming for making available the atmospheric
5 sounding data. We would like to thank “Amt der Wiener Landesregierung” and
6 “Umweltbundesamt” for making the air quality (e.g. PM10) data freely available. Many thanks go
7 to the (extended) VINDOBONA team for helping to establish a MAX-DOAS measurement
8 network in Vienna. Finally, we would like to thank the BOKU-Met weather station team for
9 helping to maintain meteorological instruments and making freely available its data.

 2 Figure 1. Geographical location of co-located instruments considered in this study: Arsenal (A)
 3 and BOKU (B) MAX-DOAS with their associated azimuthal viewing directions (in clockwise
 4 direction): 324° (cyan), 336° (red), 348° (yellow), 0° (green), 10° (blue), and 20° (magenta)
 5 (Arsenal MAX-DOAS) as well as 74° (blue), 88° (green), 129° (yellow), 137° (red), and 144°
 6 (cyan) (BOKU MAX-DOAS). The white symbols at the end of azimuthal viewing directions are
 7 shown to better interpret the results of Figs. 12 and 13. Ceilometer (Z), sun photometer (B), and in
 8 situ (F) instruments are located close to the 74° azimuthal viewing direction of the BOKU MAX-
 9 DOAS. The linear distance between the two MAX-DOAS instruments is ~7.5 kilometers. The cross
 10 in circle symbol indicates the location of the waste incineration plant. Image © Google Earth.

 2 Figure 2. Exemplary averaging kernels for the retrieved aerosol extinction in the UV channel
 3 (MAX-DOAS: 338-370 nm, ceilometer: 360 nm) for the morning (06:50 UTC), noon (11:44 UTC),
 4 and afternoon (13:34 UTC) of 10 October 2018. Altitudes and corresponding AVK lines are
 5 associated with a color. Also shown are the respective MAX-DOAS a priori (gray lines), MAX-
 6 DOAS retrieved (black lines), ceilometer unsmoothed (orange lines), and ceilometer AVK
 7 smoothed (brown lines) vertical AE profiles. The error bars of the MAX-DOAS retrieved vertical
 8 AE profiles represent the total error of the BOREAS aerosol retrieval. Degrees of freedom (DOFs)
 9 are given for each individual AVKs. The respective AOD values are obtained from AERONET
 10 measurements.

 2 Figure 4. Criteria and process for selecting cloud-free days: (i) data points are defined as “low
 3 error” if the difference between measured and simulated global radiation, relative to the simulated
 4 global radiation, is below or equal to 20%, (ii) for a day to be considered as clear, or partially clear
 5 sky at least 60% of the data points must be classified as “low error”, and (iii) the daily sum of the
 6 second-order difference is used as a measure of sky condition variability. The daily sum of the
 7 second-order difference of the measured data must be less than 2.5 times than the simulated data.

5 Figure 5. Averaged vertical AE [1/km] profiles retrieved from BOKU MAX-DOAS (B, see Fig. 1)
 6 at 74° azimuth angle (black solid lines) and ceilometer (Z, see Fig. 1) (color-coded solid lines)
 7 observations (left panels) for selected time periods and the four seasons fall (SON), winter (DJF),
 8 spring (MAM), and summer (JJA). The dashed black and color-coded lines represent the standard
 9 deviation of MAX-DOAS and ceilometer averaged vertical AE profiles, respectively. The gray
 10 horizontal lines illustrate corresponding averages of mixing-heights from ceilometer
 11 measurements. Scatter plots of MAX-DOAS and ceilometer near-surface AE for the different

1 seasons are shown in the right panels. Data of cloud-free days as defined in Sect. 2.2.4 between 1
2 September 2017 and 31 August 2019 are included. The measurements shown here are
3 representative for the UV channel (MAX-DOAS: 338-370 nm, ceilometer: 360 nm).
