Abstract Observations collected during the 25-February-2020 deployment of the Vapor In-Cloud Profiling Radar at the Stony Brook Radar Observatory clearly demonstrate the potential of G-band radars for cloud and precipitation research, something that until now was only discussed in theory. The field experiment, which coordinated an X-, Ka, W- and G-band radar, revealed that the Ka-G pairing can generate differential reflectivity signal several decibels larger than the traditional Ka-W pairing underpinning an increased sensitivity to smaller amounts of liquid and ice water mass and sizes. The observations also showed that G-band signals experience non-Rayleigh scattering in regions where Ka- and W-band signal don't, thus demonstrating the potential of G-band radars for sizing sub-millimeter ice crystals and droplets. Observed peculiar radar reflectivity patterns also suggest that G-band radars could be used to gain insight into the melting behavior of small ice crystals.

G-band signal interpretation is challenging because attenuation and non-Rayleigh effects are typically intertwined. An ideal liquid-free period allowed us to use triple frequency Ka-W-G observations to test existing ice scattering libraries and the results raise questions on their comprehensiveness.

Overall, this work reinforces the importance of deploying radars with 1) sensitivity sufficient to detect small Rayleigh scatters at cloud top in order to derive estimates of path integrated hydrometeor attenuation, a key constraint for microphysical retrievals, 2) sensitivity sufficient to overcome liquid attenuation, to reveal the larger differential signals generated from using G-band as part of a multifrequency deployment, and 3) capable of monitoring atmospheric gases to reduce related uncertainty.

1 Introduction

Over the past 20 years, millimeter-wavelength radars have become the instrument of choice for the study of cloud and precipitation. Today, radars operating at 35- and 94-GHz frequencies are routinely operated at ground-based observatories (e.g., U.S. Department of Energy Atmospheric Radiation Measurement (ARM) user facilities (Stokes

and Schwartz, 1994) and the Aerosol, Clouds and Trace gases Research Institute (ACTRIS; (Pappalardo, 2018))) and from a variety of ship-based and air-borne platforms (Kollias et al., 2007b). In space, the CloudSat 94-GHz cloud profiling radar has been operating since May 2006 (Stephens et al., 2002) and the Earth Cloud Aerosols and Radiation Explorer (EarthCARE), the first spaceborne Dopplerized cloud profiling radar, is expected to be launched in 2023 (Illingworth et al., 2015). Reasons for the popular use of millimeter-wavelength radars include that this frequency range is much more sensitive (in contrast to cm-wavelength radars) to cloud droplets and small ice crystals and that it allows for the collection of observations at excellent spatial resolution (~30m; (Kollias et al., 2020a). Although non-Rayleigh scattering signatures in the radar Doppler spectrum can be exploited for sizing large raindrops and snow (i.e., Mie notches techniques, (Kollias et al., 2002), it remains challenging to extract quantitative information about the sizes and mass of small hydrometeors using observations from stand-alone single-frequency millimeter-wave radars. For the most part, challenges arise since signal at any one frequency experiences both attenuation (related to particle mass) and scattering (related to particle habit and size) making it nearly impossible to disentangle these effects.

Fortunately, attenuation and scattering of radar signals are frequency dependent such that they can be exploited to retrieve independent information about particle mass, habit, or size, depending on the character of scattering. For instance, the observations from two (or more) radar frequencies within the same scattering regime, but different absorption regime, can be combined to isolate differential attenuation signals useful for the retrieval of liquid water content (Hogan et al., 2005;Zhu et al., 2019). Alternatively, observations collected at two (or more) radar frequencies experiencing similar signal absorption, but differential scattering, can be combined to reveal information about ice crystal habit and size (Kneifel et al., 2015). That being said, modern multi-frequency pairings are limited because i) they rely on frequencies that experience little differential attenuation in liquid clouds causing larger liquid water content retrieval uncertainty and ii) they do not produce differential scattering signals for hydrometeors smaller than 800 μm , thus leaving a noticeable gap in our understanding of the microphysical properties of drizzle and small ice particles.

In response to these limitations, the research community has expressed an interest in developing radars operating at higher frequencies in the so-called G-band (110 – 300 GHz, (Battaglia et al., 2014). Compared to a Ka-W (35-GHz-94-GHz) frequency pair, a Ka-G frequency pair should experience measurable differential attenuation at smaller water mass amounts and non-Rayleigh scattering at smaller particle sizes (e.g., (Battaglia et al., 2014;Hogan and Illingworth, 1999;Lhermitte, 1988). What is more, a Ka-G frequency pair is expected to always produce differential signals larger than that of traditional pairs, thus increasing the resilience to noise and precision of hydrometeor mass or size retrievals. Other applications of G-band and submillimeter-wavelength radars come from the presence of a water vapor absorption line at 183 GHz. By tuning the radar frequency between positions of higher and lower absorption near a water vapor line, (e.g., 183 or 325 Ghz), G-band radars can be used to profile water vapor using the Differential Absorption Radar (DAR) technique (Battaglia and Kollias, 2019;Lebsock et al., 2015;Roy et al., 2018;Cooper et al., 2018).

65 Surprisingly, the first G-band radar built for meteorological applications was only developed in the late 1980's; McIntosh et al. (1988) designed a 215-GHz non-Dopplerized high-power Extended Interaction Klystron transmitter radar system and demonstrated that it was capable of making backscatter measurements from terrain targets at ranges of several kilometers under normal atmospheric conditions. Mead et al. (1989) attempted to use the system to characterize clouds and fog and realized that it did not possess sufficient sensitivity to detect clouds and light precipitation. Thirty years past before we saw the development of the next generation of G-band radars. In 2018, thanks to significant technological advancements in radar front ends, mixers and low-power wide-bandwidth solid state G-band sources, the Jet Propulsion Laboratory (JPL) developed a highly sensitive non-Dopplerized frequency-modulated continuous-wave (FMCW) G-band radar tunable from 167 to 174.8 GHz (i.e., DAR; (Cooper et al., 2020; Roy et al., 2018). The system, named Vapor In-Cloud Profiling Radar (VIPR), was deployed during 7-days over 75 April 2019 at the ARM Southern Great Plains facility to evaluate VIPR's ability to exploit differential absorption signatures to retrieve in-cloud humidity profiles (Roy et al., 2020). VIPR's retrievals were evaluated against coincident measurements from ARM water vapor sensors, with the primary comparison coming from frequently launched radiosondes. Furthermore, VIPR's integrated water vapor measurement capabilities in clear air columns were investigated by comparing with both radiosonde and Raman lidar profiles. These comparisons highlighted VIPR's 80 ability to profile in-cloud water vapor with high resolution (< 200 m) and accuracy (RMSE < 1 g m⁻³), especially within the planetary boundary layer. This deployment also helped identify regimes where VIPR's specific DAR channel locations (i.e., 167 and 174.8 GHz) resulted in retrieval biases stemming from frequency-dependent hydrometeor scattering properties. Shortly thereafter, VIPR was deployed aboard a DHC-6-300 aircraft from Twin Otter International Ltd for its first airborne measurement campaign in November 2019 and January 2020 (Roy et al, 85 in prep).

VIPR was deployed again in February 2020 at the Stony Brook Radar Observatory (SBRO) to demonstrate the capability of G-band radars for characterizing rain, ice crystals, and snow. There, it collected observations alongside three radars operating respectively at 9.4, 35 and 94 GHz, thus providing first light multi-frequency radar observations 90 including G-band. Here, we present the results of the quadruple-frequency radar field experiment that sampled a frontal system accompanied by pre-frontal cirrus clouds followed by ice transitioning into light warm rain. The presented work demonstrates the value of using a G-band radar as part of a multi-frequency radar observatory and underlines some important lessons learned and requirements needed for taking full advantage of G-band radar observations for cloud and precipitation microphysical studies.

95

2 Sensors and operations

The SBRO is a fenced-in facility located on the edge of Stony Brook University's commuter parking lot located on Long Island, New York state, USA (40°53'50" N, 73°07'38" W). The SBRO is equipped with a W-band profiling 100 radar, a Ka-band scanning polarimetric radar and, through a partnership with Raytheon, it also hosts two X-band dual-polarization low-power phased array radars (Kollias et al., 2018). In addition to these radar systems the SBRO is also

equipped with a backscatter lidar, a long-range scanning Doppler lidar as well as a surface flux system, and three Parsivel2 disdrometers. The observatory's equipment suite is completed by a sounding system, and a small drone with integrated meteorological sensors. When combined these systems have the ability to probe the atmosphere from surface to the top of the troposphere over horizontal scales of 20-40 km.

This section provides details specific to the operation of these systems during the deployment of the G-band VIPR radar on February 25th, 2020, beginning with a picture of the instrument layout during the field deployment (Fig. 1). Like the picture illustrates, all systems were installed in very close proximity in order to facilitate multi-frequency retrievals.

2.1 Vapor In-cloud Profiling Radar (VIPR)

VIPR is a first-of-its-kind solid-state G-band differential absorption radar (DAR). It's technical specifications are described in detail in Cooper et al. (2020) and (Roy et al., 2020).

When it was deployed at the SBRO, VIPR transmitted 300 mW of power at 167 and 174.8 GHz, and was operated in frequency-modulated, continuous-wave (FMCW) mode with a chirp bandwidth of 10 MHz and corresponding range resolution of 15 m. With a single-pulse coherent integration time of 1 ms, VIPR realizes a noise-equivalent reflectivity of -40 dBZ at 1 km range. To reduce random noise from radar speckle, 2000 individual pulses are incoherently averaged to form a single reflectivity profile, resulting in a temporal resolution of about 5 seconds. All observations reported here utilize the noise floor subtraction technique detailed in Roy et al. (2018), and any observations with signal-to-noise ratio below 0 dB have been removed from this analysis. For the multi-frequency analysis in this work, we only focus on the measurements at 167 GHz since it experiences less gas absorption than VIPR's higher frequency channel.

Around noon on Feb. 24, 2020 (one day before the official field deployment) VIPR was installed near, but outside a large shipping container. That day VIPR was mostly operated off zenith for calibration purposes (details in Sect. 3.2). On the official deployment day of Feb. 25, 2020, VIPR continued operating next to the large shipping container but this time in vertically pointing mode. Following the onset of rain that day, VIPR's transmitter had to be turned off on a number of occasions to wipe water droplets off of the radar antenna (gaps seen in Fig. 8c). In some instances, we noted that strong radar returns from close-range rain caused an increase in the system noise floor of up to 20 dB stemming from broadband phase noise in the transmitted signal (Cooper et al., 2020). At 20:41 UTC, following the onset of heavier surface rain, VIPR was moved inside the adjacent container and pointed 40° off zenith. Note that off-zenith observations collected during the official deployment were not analyzed as part of the current study.

2.2 W-band Profiling Radar (ROGER)

140

ROGER, named after late radar pioneer Roger Lhermitte, is a refurbished version of the W-band (94.8 GHz) radar previously integrated on the Center for Interdisciplinary Remotely Piloted Aircraft Studies Twin Otter aircraft (Mead et al., 2003). ROGER is a single polarization 0.3° beam width Coherent Frequency Modulated Continuous Wave (CFMCW) radar with Doppler capability. Its range resolution is configurable between 5-150 m and it can detect targets up to a maximum range of up to 18.8 km. ROGER was refurbished by SBRO staff for ground-based vertically pointing operations in 2017. The effort involved building a new metal frame to hold the radar's two 24-inch parabolic dish antennas and all the CFMCW electronics as well as installing a server computer and power supplies.

145

150

During VIPR's deployment, ROGER was set to operate with a range gate spacing of 30-m and collected a full radar Doppler spectrum every 4 sec achieving a sensitivity of roughly -30 dBZ at 1 km.

2.3 Ka-band Scanning Polarimetric Radar (KASPR)

KASPR is a mechanically scanning 0.3° beamwidth Ka-band fully polarimetric radar. Further details about KASPR can be found Kollias et al. (2020b).

155

For most of the VIPR deployment, until 21 UTC to be exact, KASPR was operating vertically pointing with 15 m range resolution and 13.6 km maximum range. It only transmitted H polarized wave and collected a full co-polar and cross-polar radar Doppler spectrum every 1 sec achieving a sensitivity of roughly -42 dBZ at 1 km. Towards the end of the deployment, between 19:06-24:00 UTC, KASPR's vertically pointing observations were supplemented every 5-minutes by a 15° elevation plan point indicator scan (PPI) and a hemispheric range-height indicator scan (HS-RHI; (Kollias et al., 2014). Both scan types were designed to collect dual polarization observations at 45 m range resolution for a 30 km range. Note that the scanning observations were not analyzed as part of the current study.

160

2.4 X-band dual-pol phased array radar (SKYLER)

165

SKYLER is a dual-polarization X-band low-power phased-array radar with an antenna beamwidth of 1.98° in azimuth and 2.1° in elevation at boresight. SKYLER's full range of capabilities are described in Kollias et al. (2020b).

170

During VIPR's deployment, SKYLER was only operated between 18:00-24:00 UTC. SKYLER was mounted on a rotation table installed on a mobile truck's flatbed oriented facing upward to enable the collection of vertically pointing observations. SKYLER was set to operate with a 2 μ s pulse, 48 m range gate spacing with maximum range of 9.85 km. For collection of observations at 1-s time resolution, SKYLER was able to achieve a sensitivity of roughly +15 dBZ at 1km.

175 Because SKYLER's receiver blanking parameters were incorrectly set, its reflectivity observations collected below
1.25 km are biased low (hashed region on Fig. 8a). Knowing that this bias could be corrected for, we elected to display
these observations, but only performed quantitative retrievals using SKYLER observations collected above 1.25 km.

180 **2.5 Ancillary Measurements**

One of the SBRO Parsivel2 laser optical disdrometers was operating during the VIPR's deployment. Vendor provided
algorithms were used to classify the Parsivel2 drop observations into 32 separate size and velocity classes every 1
minute. In this work, Parsivel2 observations are mainly used for conducting power calibration of all four radars.

185 The National Weather Service (NWS) performs balloon-borne radiosonde measurements twice a day (00:00 UTC and
12:00 UTC) from the Brookhaven National Laboratory campus in Upton NY, 22 km east of the SBRO location. On
February 25, 2020, SBRO staff and Stony Brook University students also launched two GRAW DFM-90 radiosondes
at 01:46 UTC and 15:44 UTC directly from the SBRO.

190 A Stream Line XR Doppler LiDAR and a Lufft CMH 15k backscatter lidar were also operated during the field
experiment. The Doppler lidar was set to operate at 60 m range resolution and 1 sec temporal resolution, providing
estimates of air motion in the subcloud layer (not analyzed as part of the current study) while the backscatter lidar was
set to operate with a 15 m range resolution and 15 s temporal resolution for monitoring the location of liquid layers.

195 **3 Radar data post-processing**

Before they can be used to gain insight on atmospheric liquid and/or ice, high-frequency radar measurements must be
post-processed to remove signal attenuation caused by atmospheric gases. Also, and especially in the content of multi-
200 frequency analysis, radar signals should be calibrated to improve the accuracy of quantitative retrievals. This section
describes the steps used to post-process and calibrate the radar observations collected by the VIPR, ROGER, KASPR
and SKYLER radar and how these corrected observations are combined to conduct a multi-frequency analysis.

205 **3.1 Gaseous attenuation correction**

When thermodynamic information is available, radio wave propagation models can be used to estimate radar signal
attenuation by atmospheric gases. Here we use the MPM93 model, an updated version of the millimeter-wave
propagation model described by (Liebe, 1985; Liebe et al., 1993), to compute two-way gas attenuation of X-, Ka-, W-
and G-band signals for the conditions that occurred at 12:00 UTC and 15:44 UTC on February 25th, 2020 when two
210 radiosondes were launched. Figures 2a and 2b show the profiles of temperature, dew point temperature and humidity
recorded at the NWS site 22 km east of SBRO at 12:00 UTC and at the SBRO at 15:44 UTC. The two-way gas

attenuation profiles depicted in Fig. 2c confirm that millimeter radar signals, particularly at G-band, experience non-negligible gas attenuation. For this particular mid-latitude winter case, we estimate two-way gas attenuation at 11 km to reach ~0.1 dB at X-band, ~0.5 dB at Ka-band, ~2.0 dB at W-band and 10.0 dB at G-band. The large variability in gas attenuation from frequency to frequency, especially near water vapor absorption lines, is what allows DAR techniques to be used for water vapor profiling. On the upside the notable magnitude of the gas attenuation at higher-frequencies (i.e., W-band but even more so G-band) makes them ideal frequencies to use for such application. On the downside, significant gas attenuation hinders the sensitivity of high frequency radars to clouds and light precipitation.

Since the following analysis focuses on quantifying hydrometer properties, we correct all radar signals for two-way gas attenuation using the profiles derived above. The profiles estimated using the 12:00 UTC sounding are used to correct radar measurements collected before 13:52 UTC, while the ones estimated using the 15:44 UTC sounding are used to correct the rest of the radar measurements. The variability between the consecutive profiles can be used to get a sense of the uncertainty associated with using only two soundings to correct the daylong radar dataset.

225

3.2. Radar reflectivity calibration

On February 24, 2020 (one day before the official field experiment), VIPR's calibration was verified using the methodology described in Roy et al. (2020); the exercise required hanging a small calibration sphere between two light posts roughly 200 m from the SBRO. KASPR's calibration is similarly checked twice a year by SBRO staff using a corner reflector located 300 m away from the SBRO.

SKYLER, ROGER and KASPR measurements are also sporadically calibrated using Parsivel2 measurement collected during rain episodes following a standard calibration technique similar to that described in Chandrasekar et al. (2015) and Kollias et al. (2019). In short, the Parsivel2 disdrometer particle size distribution (PSD) measurements are used as input to a T-matrix scattering algorithm (Mishchenko et al., 1996) that estimates the hydrometeors radar reflectivity for radar frequencies of interest. The idea is then to compare the disdrometer-derived radar reflectivity estimates to the reflectivity observed by the radar at the same height and use their difference to calibrate the radar measurement across the entire atmospheric column. Additional steps arise from the fact that radars generally do not collect measurements down to surface level where disdrometers are located. The several hundred-meter path between these measurements results in three sources of systematic calibration error that can be addressed: 1) radar signal attenuation by atmospheric gases present in the path, 2) radar signal attenuation by the raindrops present in the path and 3) a time lag reflecting the time it takes raindrops to fall from the observed height to the surface. Changes in the particle size distribution due to processes like evaporation and collision/coalescence may also occur but since these changes are nearly impossible to quantify, they remain a source of uncertainty. The first 3 effects can be corrected for before comparing radar reflectivity observed at the lowest observation height to the disdrometer-derived radar reflectivity estimates. The technique described in the previous section can be used to correct for gas attenuation along the path. Liquid attenuation can be estimated using a T-matrix scattering algorithm and Parsivel2 PSD measurements assuming

250 that the PSD remains constant along the path between the radar’s lowest observation height and the surface (355 m
for KASPR, ROGER and VIPR is and 1,250 m for SKYLER). Then, time-series analysis can be used to correct for
the time lag between the corrected radar reflectivity (from the radar at the lowest observation height) and the
disdrometer-derived radar reflectivity estimates.

255 For this analysis, Parsivel2 measurements collected between 17:53-24:00 UTC are used to calibrate the measurements
from all four radars. Because of uncertainties in Parsivel2 PSD measurements (Tokay et al., 2014), only rain PSDs
with mean diameter greater or equal to 0.6 mm are considered for the calibration procedure (refer to Fig. 3a for details).
The median difference between the disdrometer-derived and radar-derived (corrected for gas and liquid attenuation
and time-lag) radar reflectivity over the rain episodes was used to calibrate the entire radar data record collected on
that day. The resulting calibration coefficients amount to -8.1, 0.2, -2.3, and 1.3 dB for SKYLER, KASPR, ROGER,
260 and VIPR respectively. The small calibration coefficients found for VIPR and KASPR also suggest that the target and
corner reflector calibration procedures performed for these radars were reasonably effective.

3.3 Multi-frequency analysis

265 Ideally, multi-frequency analysis would be performed using perfectly time-matched and volume matched observations
in order to be able to attribute any signal differential to the properties of the hydrometeor population. Unfortunately,
previous work has shown that perfectly matching radar observations is extremely challenging even for radars installed
on the same pedestal (Kollias et al., 2014). Observation volume differences unavoidably occur as a result of using
different radar frequencies, which require the use of different transmitting configurations such as pulse width, pulse
270 repetition frequency, and number of samples per integration. Temporal and vertical averaging of radar data on a
common grid has been used in an attempt to alleviate radar observation mismatching.

Here we co-gridded the post-processed radar observations from all four radars on a joint 15 m, 4 sec resolution grid.
The gridded observations are subsequently averaged in time in 60-s increments to reduce noise. The denoised radar
275 observations are used to estimate the dual wavelength ratio ($DWR_{A-B} = dBZ_A - dBZ_B$, in dB) for three pairs of
observed radar reflectivity (Ka-W, Ka-G and W-G).

4 Key findings from the multi-frequency radar deployment

280 On 25 February 2020, following the movement of a surface trough and associated low-pressure system, a stationary
front established itself over the SBRO. The four profiling radar systems and the two lidar systems operating at the
time observed the transition from pre-frontal cirrus to rain associated with this system. The following sections discuss
key findings attributable to the deployment of a G-band radar as part of a multi-frequency radar deployment in these
two weather regimes.

285

4.1 Using G-band for ice crystals sizing and habit characterization

290 The radar and lidar observations displayed in Fig. 4 reveal that a deck of prefrontal cirrus clouds, whose top extended near 9-10 km, advected over the observatory between 7:00 and 10:00 UTC. Observations from KASPR, ROGER and VIPR show that the thickness of the cirrus layer varied over time between ~ 2 and 6 km in depth. In the lowest part of the cloud layer, moderate lidar backscatter signals ($\sim 10^{-4.2} \text{ m}^{-1} \text{ sr}^{-1}$) suggest the presence of high number concentrations of small particles. Thin bands of high lidar backscatter signals ($\sim 10^{-3} \text{ m}^{-1} \text{ sr}^{-1}$) near 3.0 and 4.0 km support the idea that supercooled liquid layers were also present in the lowest part of this cloud system certainly in the earlier and later parts of the period, and likely over the entire period (Fig. 4e). If so, interaction with supercooled liquid could have
295 influenced the ice particle growth processes in the atmospheric column. The mean Doppler velocity recorded by KASPR offers additional insights into the complex dynamical and microphysical structure of the observed layer (Fig. 4d). The signature of a gravity wave with an air velocity of $0.3\text{-}0.4 \text{ m s}^{-1}$ and a period of 5-6 min is clearly evident throughout the hydrometeor layer. Several, higher frequency dynamical features are also identifiable in what appears like mammatus clouds features in the lowest 2 km of the system between 8:45-9:15 UTC.

300 Differences in radar reflectivity measured by the Ka- (Fig. 4a), W- (Fig. 4b) and G- (Fig. 4a) band radars are a direct result of differences in signal attenuation and scattering, which can be best visualized in dual-wavelength ratio (DWR) space. Figure 5 shows DWR estimated using the traditional Ka-W pair (panel a), the Ka-G pair (panel b) and the W-G pair (panel c). These first light DWR observations involving G-band confirm all the advantages predicted by
305 scattering theory.

Focusing below ~ 4.5 km, we observe that in contrast to the Ka-W pair (Fig. 5a), the frequency pairs with G-band (Fig. 5b-c) indeed experiences larger differential signals for the same hydrometeor population; for the case observed, the DWR profile shown in Fig. 6b allows us to estimate that this gain was as large as ~ 4 dB for the Ka-G pair in comparison
310 to the Ka-W pair. This increased dynamic range in DWRs corresponds to an increased sensitivity in the transfer function between DWRs and microphysical properties. This underpins the value of using frequency pairs farther apart in the frequency spectrum not only to mitigate the impact of possible noise when retrieving the size of smaller particles or lower water mass amounts but also to increase retrieval precision. Finally, observations collected above 4.5 km reveal the G-band's strength in small particle regimes. In this region, absence of Ka-W differential signal (i.e., DWR
315 = 0 dB) suggests the presence of Rayleigh targets (Tridon et al., 2020). At these frequencies Rayleigh targets correspond to ice populations with PSDs of mass-weighted mean diameter smaller than ~ 1 mm (Tridon et al., 2019). The absence of differential scattering signals at Ka-W band prevents us from gaining further information about such small ice crystals. On the other hand, the present of differential signal at Ka-G band and W-G band on the order of a few decibels across most the layer (see Fig 5b-c and Fig. 6b) that DWR estimates that use G-band signals can provide
320 size information about smaller ice crystals..

Interpreting and performing retrievals from DWR observations always requires considering the interplay of signal attenuation and non-Rayleigh scattering (Tridon et al., 2013). Observations collected during the period around 8:42 UTC highlight this important limitation of DWR analysis targeting the characterization of ice crystals. The lack of convergence at 0 dB in the profile extracted at 8:42 UTC suggests the presence of considerable water condensate (liquid and/or ice) mass in the atmospheric column (Fig. 6d). Backscatter lidar observations do allude to the presence of liquid layers (of unknown depth) over that period (Fig. 4e). Tridon et al. (2020) suggest that if DWR reaches a constant value with height (a.k.a. a Rayleigh plateau), the DWR of this plateau can be used to estimate integrated water condensate mass within the layer. In this particular profile, the Ka-W-band pair reached a clear Rayleigh plateau at 5 km showing a 1 dB DWR loss to hydrometeor attenuation. We argue that both the Ka-G pair and the W-G pair also reached a Rayleigh plateau near 6.8 km showing in the neighborhood of 3.5 dB DWR loss to hydrometeor attenuation. This signal could be qualified as being the first quantitative hydrometeor mass signal recorded at G-band. Because ice and snow attenuation considerably increase when moving from the W- to the G-band reaching one-way values of 0.9, 2.5, and 8.7 dB m² kg⁻¹ at 96, 140, and 225 GHz (Tridon et al., 2020; Nemerich et al., 1988), the DWR plateau for the G-band pairs is affected by both the liquid water path and the ice water path. On the other hand, the DWR plateau for the Ka-W pair is mainly driven by the liquid water path. We believe that the shallowness of the W-G band plateau results from the limited sensitivity of ROGER, which is likely insufficient to detect additional Rayleigh targets populating the top of the ice cloud. This observation supports the need for developing highly sensitive radars when targeting small (in size) hydrometeor populations. Unfortunately, because millimeter-wavelength radar signals alone cannot be used to precisely distribute the retrieved water path across the atmospheric column, non-Dopplerized DWR observations in mixed-phased clouds cannot be disentangled to isolate the non-Rayleigh signals required for sizing and identifying ice crystal habit leaving yet again a gap in our understanding.

The DWR profile shown in Fig. 6b taken from observations collected at 8:00 UTC shows a contrasting situation where G-band signals can be directly used for ice microphysical retrievals. In that profile DWR is seen to converge to 0 dB such that differential signal across the column can be interpreted from resulting exclusively from non-Rayleigh scattering. Under such conditions DWR can be related to ice crystal size given the proper ice scattering library. Kneifel et al. (2015) initially proposed using DWR_{X-Ka} versus DWR_{Ka-W} diagrams to identify ice particle types from multi-wavelength radar observations. Recently, it has become evident that details of the PSDs and unaccounted attenuation complicate the analysis of such diagrams that must be interpreted with caution (Battaglia et al., 2020). Figure 7 shows DWR_{Ka-W} versus DWR_{W-G} diagrams for two periods encompassing the profiles described above. Overlaid are DWR_{Ka-W} - DWR_{W-G} estimated using self-similar-Rayleigh-Gans approximation and different particle type models and PSD; specifically, unrimed aggregates are represented using the mass-diameter relationships from Hogan and Westbrook (2014) (hereafter HW14) and that of Leinonen and Szyrmer (2015) (hereafter LS15) particle class A. Rimmed aggregates are represented using the mass-diameter relationships of LS15 for particle type B with 2 kg m⁻² of liquid water path. Overlaid are DWR_{Ka-W} - DWR_{W-G} estimated using self-similar-Rayleigh-Gans approximation and different particle type models and PSD; specifically, unrimed aggregates are represented using the mass-diameter relationships from Hogan and Westbrook (2014) (hereafter HW14) and that of Leinonen and Szyrmer (2015)

(hereafter LS15) particle class A. Rimed aggregates are represented using the mass-diameter relationships of LS15
360 for particle type B with 2 kg m^{-2} of liquid water path. Also overlaid are $\text{DWR}_{\text{Ka-W}}-\text{DWR}_{\text{W-G}}$ estimated using Discrete
Dipole Approximation scattering calculations for different particle types following formulation prepared by Eriksson
et al., (2018) (hereafter E19); specifically: icon graupel, block column, plate, sector snowflake and flat three bullet
rosette. Since the shape of the PSD may also impact the scattering of the ice crystal population, PSDs are represented
using a gamma function with a shape parameter (μ) of either 0 or 4. We acknowledge that this does not encompass all
365 PSD shapes such as the super exponential one of aggregate populations reported by Westbrook et al. (2004). In any
case, the idea is to use overlap between the observed and estimated DWR-DWR to gain information about particle
habit.

The first period (7:45 – 8:12 UTC) depicted in Fig. 7a corresponds to the period that presented a high DWR slanted
370 feature (referring back to Fig. 5) and a thin liquid layer (referring back to the lidar backscatter observations of Fig. 4).
Plotting the radar observations in DWR-DWR space can help determine if the amount of liquid attenuation caused by
this thin liquid layer is significant thus preventing us for inferring particle habit directly from the gas attenuation
corrected and calibrated radar measurements. To be exact, a clustering of the DWR-DWR observations collected in
the upper part of the cloud (between 5.75-7.00 km) near the 0,0 point (depicted by the contours on Fig. 7a) would
375 indicate an absence of signal attenuation. For this particular period, a 0.5 dB offset is seen suggesting that a slight
adjustment should be made to the observed DWR before they can be interpreted in terms of differential scattering and
used to infer particle habit. Even with this slight adjustment, we find that the scattering calculation results only partially
match the DWR-DWR signatures observed leaving a noticeable gap in the high ($> 7 \text{ dB}$) $\text{DWR}_{\text{Ka-W}}$ and low ($< 5 \text{ dB}$)
 $\text{DWR}_{\text{W-G}}$ region. This gap could result from outstanding radar calibration bias or from a misrepresentation of the
380 particle size distribution and/or shape of naturally occurring ice crystal in existing scattering libraries. In any case, it
calls for further research. We note that the scattering models that are closest to the observed values are those for
unrimed aggregates (yellow and magenta lines) and plates (cyan line). Attempting to further characterize these ice
crystals, we note that the sounding reported a temperature in the region of roughly -15°C and relative humidity of
roughly 80 % (referring to Fig. 2). Under such thermodynamic conditions, high $\text{DWR}_{\text{Ka-W}}$ are typically associated
385 with the presence of dendritic crystals and aggregates (e.g., (Bechini et al., 2013; Andrić et al., 2013)). Based on the
velocity of the primary peak in the KASPR Doppler spectra over the period, we estimate the fall speed of the ice
particles to be roughly 0.8 m s^{-1} . These slow fall speeds would be consistent with the presence of unrimed particles;
something that is also in line with our conclusion that this period did not present significant amounts of supercooled
liquid. Altogether the large DWR values and the low terminal velocity suggest the presence of large and fluffy,
390 unrimed particles (Locatelli and Hobbs, 1974).

The second period (8:12-9:12 UTC) depicted in Fig. 7b corresponds to the period containing non-negligible
attenuation by water condensates. This period also presents a broad high DWR area between 2 and 5.5 km altitude
(referring back to Fig. 5). The offset from 0,0 $\text{DWR}_{\text{Ka-W}}-\text{DWR}_{\text{W-G}}$ of observations collected between 5.75-7.00km can
395 also be used to confirm the presence of water condensates (depicted by the contours on Fig. 7b). Although tempting,

it is not possible to directly interpret this DWR-DWR diagram since details about the vertical distribution of the liquid and ice water content is not known and as such attenuation cannot be accurately corrected for. Based on the velocity of the primary peak in the KASPR Doppler spectra over the period, we estimate the fall speed of the ice particles to be roughly 1.3 m s^{-1} . Such faster fall speeds would be consistent with the presence of rimed particles; something that is also in line with our conclusion that this period presented significant amounts of supercooled liquid.

4.2 Using G-band for characterizing melting and sizing submillimeter drizzle droplets

The radar observations displayed in Fig. 8 show the light surface rain episode that occurred following the frontal passage between 18:00 and 18:30 UTC. Observations from KASPR allow us to establish that the cloud sustaining the rain extended up to 8 km. The bright band observed by all radars, although notably different, is suggestive of a transition from ice particle to liquid water near 2 km. This idea is substantiated by radiosonde reports that place the 0-degree isotherm near 2 km (Fig. 2a). Surface disdrometer measurements indicate that rainfall rate at the surface varied reaching up to 2.1 mm hr^{-1} during the period (Fig. 2a within the limits of period 3). From time-lag estimates performed as part of the calibration procedure, we estimate that the rain drop fall speeds ranged from 3 to 6 m s^{-1} . These estimates are consistent with KASPR mean Doppler velocity measurement made during the period (not shown).

Difference in radar reflectivity measured by the X- (Fig. 8a), Ka- (Fig. 8b), W- (Fig. 8c) and G- (Fig. 8d) band radars during the period and specifically at 18:07 UTC (Fig. 9a) are a direct result of difference in signal attenuation and scattering.

Differential signal scattering explains the progressive reduction in the overall radar reflectivity factor measured by the X-band SKYLER, Ka-band KASPR, W-band ROGER and G-band VIPR. For raindrop sizes typical of such light precipitating systems (see Fig. 2a for estimates from the disdrometer), it can be safely assumed that X-band waves with their 3.2 cm wavelength (λ) experience Rayleigh scattering. In the Rayleigh scattering regime, radar backscattering cross section (σ_b) is proportional to D^6/λ^4 where D is particle diameter. Because wavelength is much larger than particle diameter σ_b tends to be very small in that regime. That being said, the radar reflectivity factor (Z), which was designed to compensate for the wavelength dependency, can acquire very high values in that scattering regime ($Z \sim D^6$). In contrast to X-band signals, Ka-, W- and G-band signals are expected to experience both Rayleigh scattering (for drops smaller in size relative to the wavelength) and non-Rayleigh scattering (for drops larger in size relative to the wavelength). In the non-Rayleigh scattering regime, σ_b does not monotonically increase with D^6 but rather follows a lower power resonance pattern with damping of the oscillation (Fig. 4 of Kollias et al., (2007a)). As a result, although in non-Rayleigh scattering σ_b acquires much higher values than those in Rayleigh scattering, the reported radar reflectivity factor during non-Rayleigh conditions is lower. Variations in each of the radars' "dominant" drop population (i.e., the largest drop size behaving as a Rayleigh scatterer), also explains variations in the observed radar bright band. SKYLER, like a typical centimeter wavelength radar, observed a bright band marked by clear boundaries at both the top and the bottom. Inferring information about the ice melting process from the properties of

the radar-detected bright band is still an active area of research (e.g., Heymsfield et al., 2015; Li et al., 2020). The early work of Fabry and Zawadzki (1995) suggested that the magnitude and vertical extent of the radar reflectivity enhancement at cm-wavelength are influenced by precipitation rate, phase transitions (i.e., liquid coating ice), change in fall speed throughout melting, precipitation growth and changes in the particle size distribution linked to aggregation and breakup. More recent studies using cm-wavelength radars suggested that the depth of the radar bright band, at cm-wavelengths, may be linked to the presence of rimed particles (e.g., Kumjian et al., 2016; Wolfensberger et al., 2016). In contrast, at mm-wavelength radars, non-Rayleigh scattering reduces the influence of large melting snowflakes in determining the magnitude and vertical extent of the melting layer radar signature (Kollias and Albrecht, 2005). In addition, due to their increased relative sensitivity to small melting ice crystals, mm-wavelength radars like KASPR and ROGER observe a higher top boundary of their bright band. While not observed here, it has been suggested that W-band radars can provide insight into the activity of the aggregation process because this process is believed to cause of a dip, as opposed to the enhancement that is the bright band, in the radar reflectivity profile (a.k.a. dark band; (Sassen et al., 2005; Sassen et al., 2007; Heymsfield et al., 2008)). Interestingly, observations collected by the VIPR reveal a well-defined bright band at G-band frequency. VIPR's bright band differs from that of the other radars in two main ways: 1- its top boundary is slightly higher compared to that of the W-band, 2- its bottom boundary is higher than that of the X-band. These discrepancies are in line with our interpretation that VIPR's signal is controlled by the melting of even smaller ice crystals. This agrees with Li and Moisseev (2020) interpretation that the radar bright band properties depend on the radar wavelength since the radar wavelength effectively dictates the ice population size "in focus". We should also note that part of this discrepancy could be explained by the fact that our X-band SKYLER has a much larger range resolution than our G-band VIPR (300 m vs. 15 m).

Although G-band signals should allow for sizing smaller raindrops because they experience non-Rayleigh scattering at smaller droplets sizes (compared to longer wavelengths), one must remember that G-band signals also experience non-negligible liquid attenuation. Theoretical calculations suggest that extinction coefficients at 94- and 220-GHz rapidly increase for particles with size up to $D_m \approx 1$ mm and 0.4 mm, respectively, and then steadily decrease as a function of D_m (Lhermitte, 1990). For the duration of the observed rain event, we estimate (from disdrometer PSD measurements) that two-way liquid attenuation of the G-band signal varied from 0 to 10 dB (Fig 3 c). While non-negligible, this value is only about 2.2 times (in linear scale) higher than that experienced by a W-band radar like ROGER or the CloudSat-CPR (Fig. 3c; (Battaglia et al., 2014)). As seen in Fig 8 both ROGER and VIPR were both equally able to penetrate through the 2 km thick rain layer and detect a large portion of the cloud aloft (Fig. 8c and d respectively). The fact that VIPR and ROGER could not observe the cloud top speaks to the importance of operating highly sensitive G-band and W-band radars especially if they are meant to document the properties of liquid precipitating clouds. The other fact that SKYLER could also not observe the cloud top also speaks to the importance of operating sensitive X-band radars for cloud studies (liquid attenuation not being an issue at cm wavelengths).

Like we saw in ice clouds, large DWR_{Ka-G} and DWR_{W-G} were measured during the rain event (Fig 9b); in this example profile collected at 18:07 UTC DWR_{Ka-G} reached values as high as 30 dB. Interpreting these signals requires separating

470 the contributions of liquid attenuation and non-Rayleigh scattering. In regimes with large $D_m (> 1 \text{ mm})$, similar liquid
attenuation at W- and G-band should allow for the interpretation of DWR_{W-G} signals in terms of differential scattering
caused by liquid drops (that is when gas attenuation has been corrected for). Such interpretation is arguably more
challenging using the Ka-W or the Ka-G frequency pair (Matrosov, 2005).

475 5 Conclusions

Several observational gaps in cloud and precipitation remote sensing observations still exist especially at the mid and
high latitudes (Battaglia et al., 2020). Radars at frequency above 100 GHz are now technologically feasible as proved
by the VIPR system, recently built by JPL. This work presents multi-frequency (X-, Ka-, W- and G-band) radar
480 observations from a field experiment at the Stony Brook Radar Observatory (SBRO). Albeit short, the field experiment
provided a long-sought-after first light demonstration of the potential of multiwavelength radar observations that
include G-band for the characterization of ice crystals, snow and rain. Besides confirming expectations derived from
scattering theory, the field experiment revealed a number of considerations relevant to the deployment of G-band
systems.

485 1) The observations clearly demonstrate that G-band radars can be made sensitive enough to probe clouds and light
precipitation and that in spite of the strong water vapor attenuation occurring at this frequency. The large
sensitivity of G-band radars can in part be explained by improvements in radar gain with increased frequency; all
else equal, for a fixed aperture size, radar sensitivity improves by 24 dB going from 10 to 170 GHz.

490 2) Since G-band signals are especially prone to attenuation by water vapor, we recommend that G-band radars
targeting the characterization of clouds and precipitation should have differential absorption capabilities in order
to avoid confounding effects due to water vapor attenuation. This could be achieved through the use of interlaced
pulses whose frequency would range around a water vapor absorption line. The exact frequency range should
495 ideally be tuned to the specific water vapor condition like proposed in Roy et al. (2020), Cooper et al. (2020) and
Battaglia and Kollias (2019).

The observations presented here reinforce the idea that the sensitivity of all the radar systems involved in future
multi-wavelength radar studies should be sufficient to allow the detection of the Rayleigh plateau near the top of
500 ice clouds (or near the base if using an airborne system); that is necessary to ensure that we have a robust
estimation of the differential (dual-wavelength) path integrated liquid attenuation (Tridon et al., 2020). For rain
studies as well, G-band radar sensitivity should be large enough to allow signals to penetrate through the rain
shaft and that despite attenuation by liquid water reaching several dBs. Nominally radar systems should be capable
of detecting unattenuated reflectivity as weak as -40 dBZ at 1 km after 1-s signal integration (i.e., -20 dBZ at 10
505 km altitude). In the present study, the radars deployed generally meet this sensitivity criteria. It follows that
deployments in humid environments would drive higher sensitivity requirements because of enhanced signal

attenuation by water vapor. The same can be said about deployments in liquid containing clouds where enhanced signal attenuation by liquid water is to be expected.

510

- 3) The observation collected during this experiment confirm that the Ka-G pair generates the strongest differential reflectivity signal, with observed values of DWR reaching up to 13 dB in ice regions; 4 dB larger than traditionally Ka-W pairs. The increased differential signal should allow for increased retrieval confidence, especially in low liquid water content regions and/or for small particle sizes.

515

- 4) The steep DWR_{Ka-G} gradients observed support the idea that Ka-G differential signals are more sensitive to incremental changes in particle size thus allowing for more precise quantitative retrievals compared to those achievable using a Ka-W pair.

520

- 5) In the absence of Ka-W differential signals, observations of non-Rayleigh scattering differential signals at Ka-G and W-G demonstrates the potential of G-band radars for sizing smaller ice particles.

525

- 6) An ideal case observed during the field experiment allowed us to investigate ice crystal habit. DWR-DWR observed by the Ka-W-G trio were compared to estimates made using several scattering libraries. The scattering libraries tested could only provide a partial explanation of the scattering properties of the ice crystals observed with gaps in the high ($> 7\text{dB}$) DWR_{Ka-W} and low ($< 5\text{ dB}$) DWR_{W-G} region. This gap could result from outstanding radar calibration bias, or from a misrepresentation of the particle size distribution and/or shape of naturally occurring ice crystal; in any case additional triple frequency observations including G-band would help confirm this finding, which, if correct, should motivate further research into the scattering properties of naturally occurring ice crystal populations.

530

- 7) The observations collected during a melting event suggest that G-band radars can detect radar bright bands. The character of this bright band is likely indicative of the melting behavior of smaller ice crystals.

535

- 8) In rain, the G-band radar reflectivity values are several orders of magnitude lower than those measured by the W-band, Ka-band and X-band radar systems creating measurable DWR signal. Interpreting these differential signals may be challenging because they result from both differential scattering and attenuation. In large particle regimes where W- and G-band signals experience similar attenuation by liquid attenuation, DWR_{W-G} should provide information more closely related to the mass-weighted diameter of the particle size distribution. Ideally full Doppler spectrum capabilities should be added to G-band radars. Especially for applications in rain and mixed-phase clouds, Doppler capability would allow for application of spectral ratio techniques like proposed in (Tridon et al., 2013).

540

545 Longer datasets with similar measurement capabilities are needed to fully assess the potential and challenges
associated with using non-Dopplerized G-band radar observations for the study of clouds and precipitation systems.
Such observations can in turn be used to raise the technology and science readiness levels of space-borne G-band
systems. Because of their reversed observation geometry, G-band radar signals from an above-cloud vantage point
should suffer from less signal attenuation than ground-based systems thus requiring a lower sensitivity to collect
550 similar observations; that is because water vapor and rain are typically concentrated in the lowest part of the
atmosphere, which spaceborne G-band radar signals will encounter last. The reduced signal attenuation should drive
a less stringent sensitivity requirement (-20 dBZ in the troposphere after signal integration of ½ of the radar footprint).

Data availability. The datasets collected at the SBRO during the field experiment will be made publicly available.
The NWS sounding data is available at <https://www.spc.noaa.gov/exper/soundings/>.

555 *Author contribution.* K. Lamer, M. Oue, A. Battaglia, R. Roy, K. Cooper and P. Kollias were actively involved in the
field experiment; K. Lamer operated the Doppler lidar, M. Oue operated the KASPR, and R. Roy and K. Cooper
together operated VIPR. M. Oue and R. Dhillon performed initial data exploration work. P. Kollias finalized the data
analysis. A. Battaglia and P. Kollias's input were instrumental in interpreting the radar signatures observed. K. Lamer
560 lead the writing of the final version of this manuscript. All members of the team reviewed and added to this final
version.

Acknowledgements. K. Lamer was supported by Brookhaven National Laboratory LDRD #20-002 EE/EBNN. M. Oue
and P. Kollias were supported by the National Science Foundation award #1841246 entitled:
565 "Collaborative proposal: Studies of the microphysical processes in ice and mixed-phase clouds and precipitation using
multiparameter radar observations combined with cloud modeling". A. Battaglia was supported by UK-CEOI under
the Grace project. The research by R. Roy and K. Cooper was carried out at the Jet Propulsion Laboratory, California
Institute of Technology, under a contract with the National Aeronautics and Space Administration
(80NM0018D0004). This research also used the Advanced Leicester Information and Computational Environment
570 (ALICE) High Performance Computing Facility at the University of Leicester, UK. We would like to thank the
Brookhaven National Laboratory staff and Stony Brook University students who assisted during the field experiment;
special thanks go to Edward Luke for operating SKYLER and to Zeen Zhu, Samantha Nebylitsa, Jacob Segall, and
Kristofer Tuftedal for launching radiosondes from the SBRO.

Figure 1: a) Picture of the VIPR G-band radar system when it was deployed at the Stony Brook Radar Observatory. Also deployed at the observatory was a truck-mounted X-band phased-array named SKYLER (visible in a), the container-mounted parabolic-dish Ka-band radar named KASPR (visible in a and b), the FMCW W-band radar named ROGER (visible in b) and a Parsivel2 disdrometer (visible b).

715

720

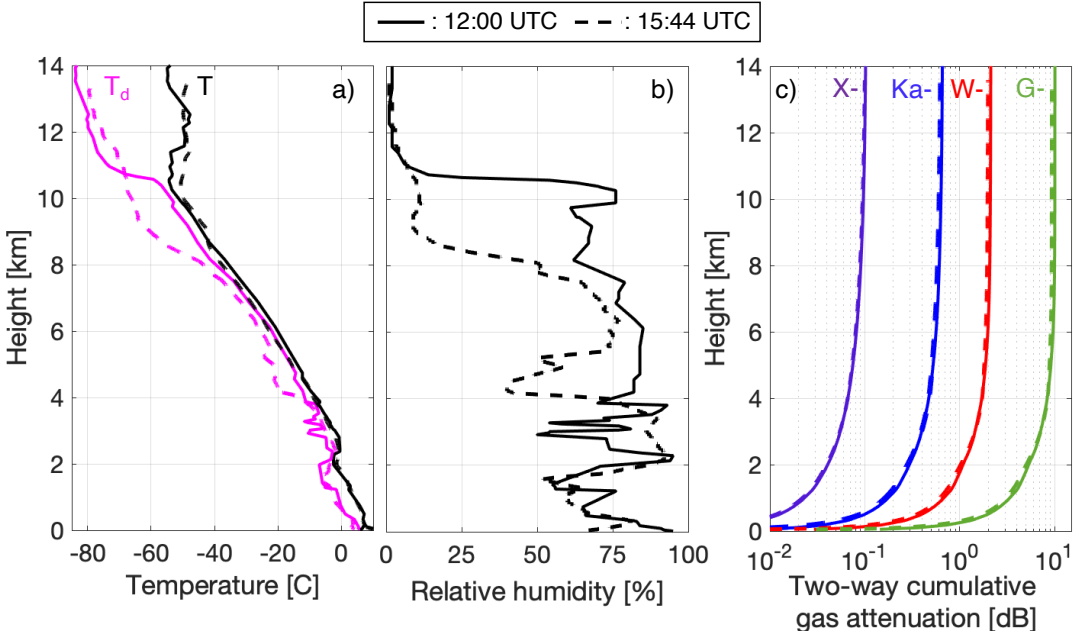

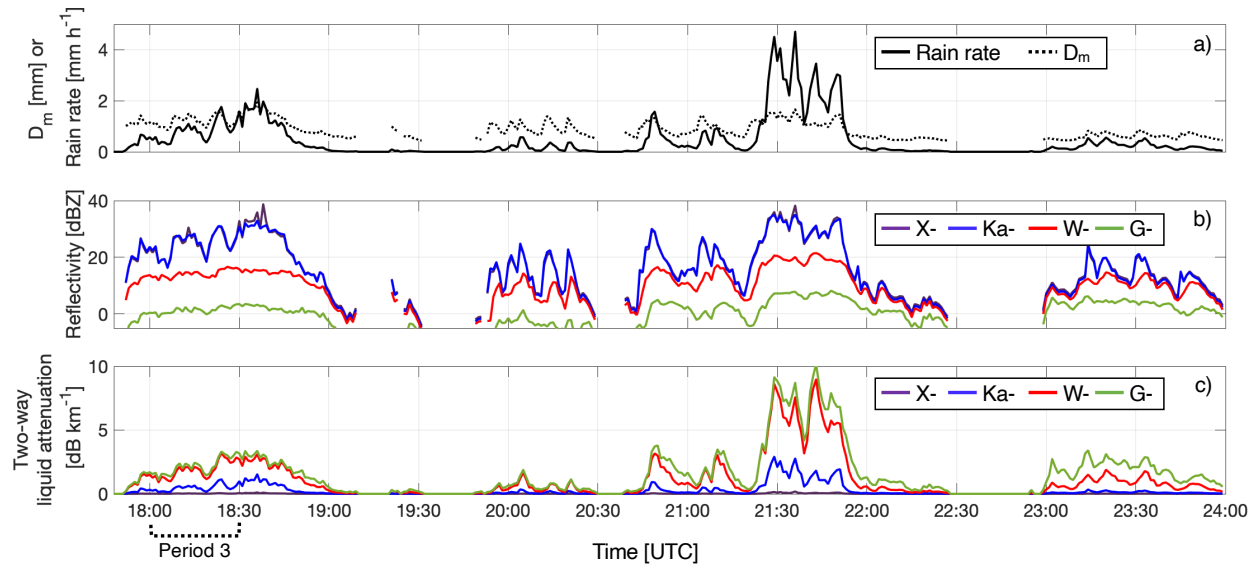

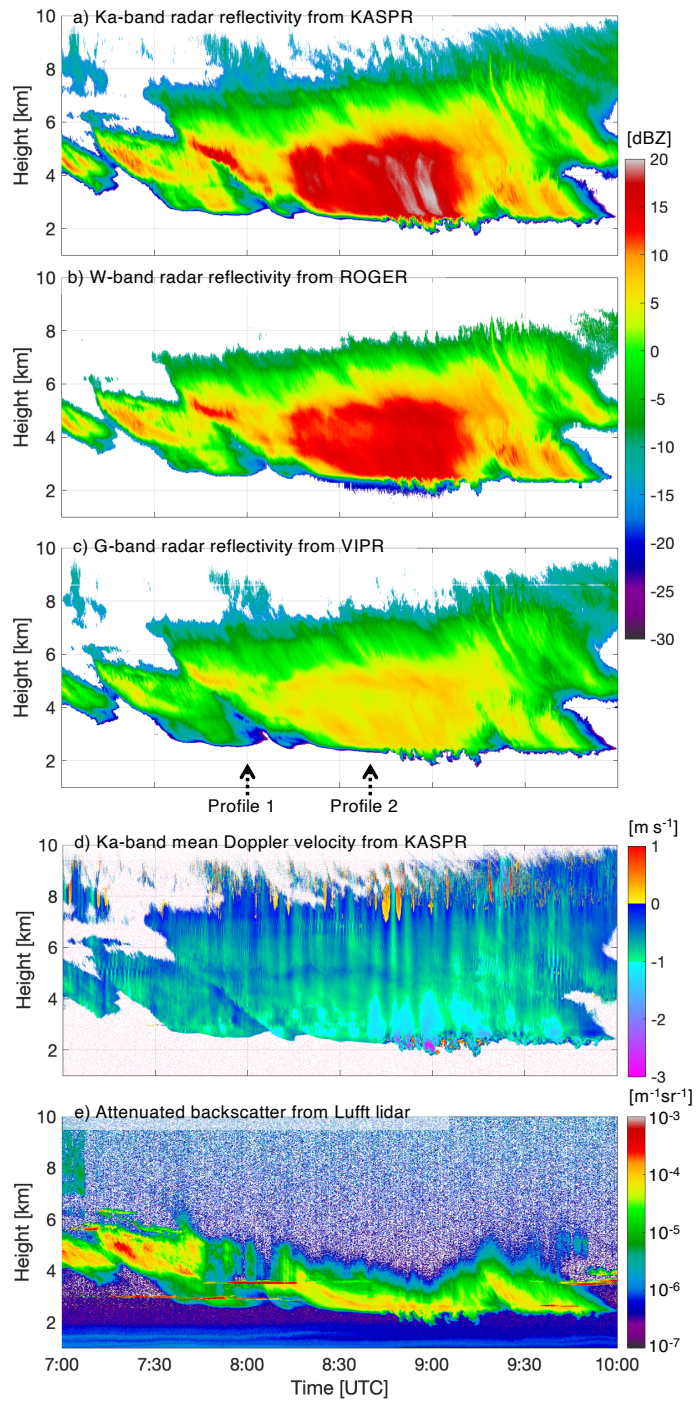

Figure 2: From sounding observations collected on 25 February 2020 at 12:00 UTC at the NWS Upton site (22 km east of SBRO; solid lines) and at 15:44 UTC from the SBRO (dashed lines); Profile of a) temperature (black) and dew-point temperature (magenta), b) relative humidity, c) two-way water vapor attenuation at X-band (purple), Ka-band (blue), W-band (red), and G-band (green).

725

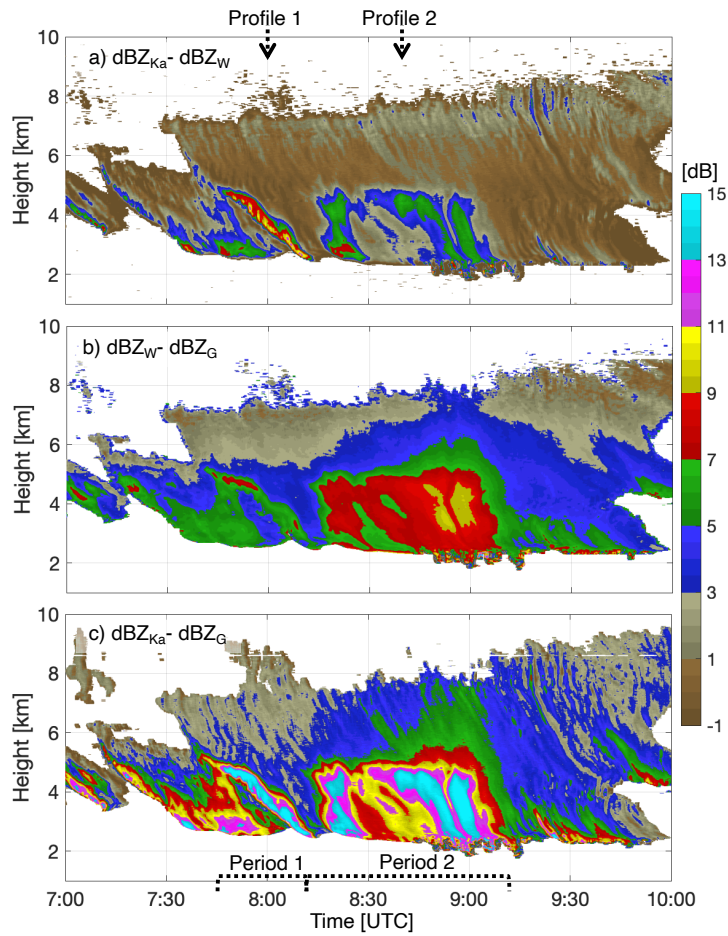

730

Figure 3: Based on measurements from the Parsivel2 disdrometer collected on 25 February 2020, time series of estimated a) particle size distribution mass-weighted mean diameter (D_m ; dotted line) and rain rate (solid line), b) radar reflectivity, and c) two-way liquid attenuation for X-band (purple), Ka-band (blue), W-band (red) and G-band (green).

735

Figure 4: Time-height of radar reflectivity measured by the a) KASPR, b) ROGER and c) VIPR, between 7:00 and 10:00 UTC on 25 February 2020. The arrows in (c) points to the time of the profiles displayed in Fig. 6. Also shown are a time-height of d) mean Doppler velocity measured by the KASPR (positive values indicate upward motion) and e) attenuated backscatter measured by the Luftt lidar.

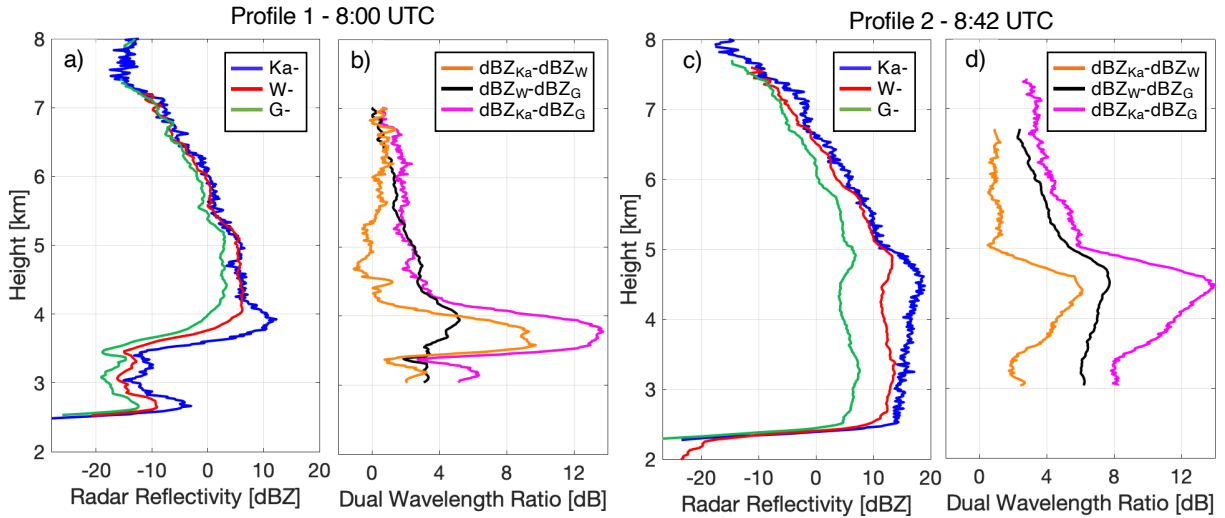

740

Figure 5: Time-height of dual wavelength ratio from a) the Ka-W pair, b) the W-G pair and c) the Ka-G pair estimated between 7:00 and 10:00 UTC on 25 February 2020 (same date and time as in Fig. 4). The arrows in (a) points to the time of the profiles displayed in Fig. 6, while the periods outlined in (c) are the focus of Fig. 7.

745

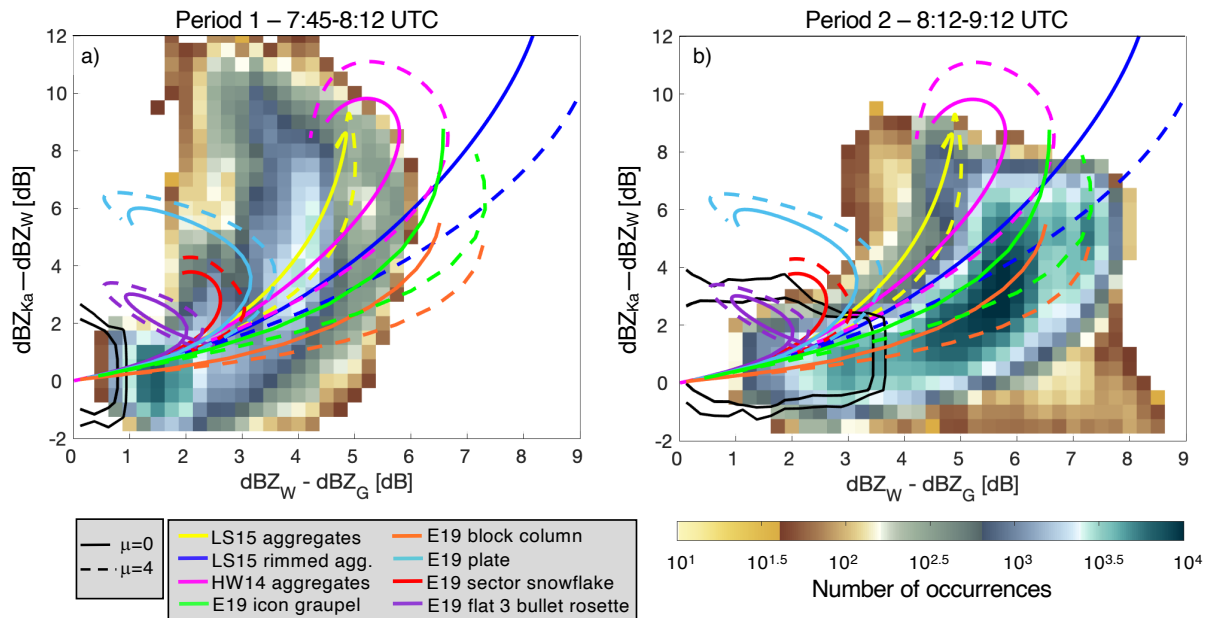

750

755 **Figure 6:** Profiles taken at 8:00 UTC during the ice cloud period, a) radar reflectivity measured by VIPR (G-band, green), ROGER (W-band, red), and KASPR (Ka-band, blue) and b) associated dual-wavelength ratio from the Ka-W pair (orange), the W-G pair (black) and the Ka-G pair (magenta). c) and d) show the same information for the profile taken at 8:42 UTC.

755

760

765 **Figure 7:** For observations collected a) between 7:45–8:12 UTC and b) between 8:12–9:12 UTC; distribution of Ka-W dual-wavelength ratio as a function of W-G dual-wavelength ratio for the cloud region between 2 and 5.5 km altitude (colormap) and for the cloud region between 5.75 and 7 km altitude (contours). Lines represent effective reflectivity calculated using scattering models with different particle type (colors) and with different particle size distribution shape parameter (line type). More details about these scattering models are given in the text.

765

770

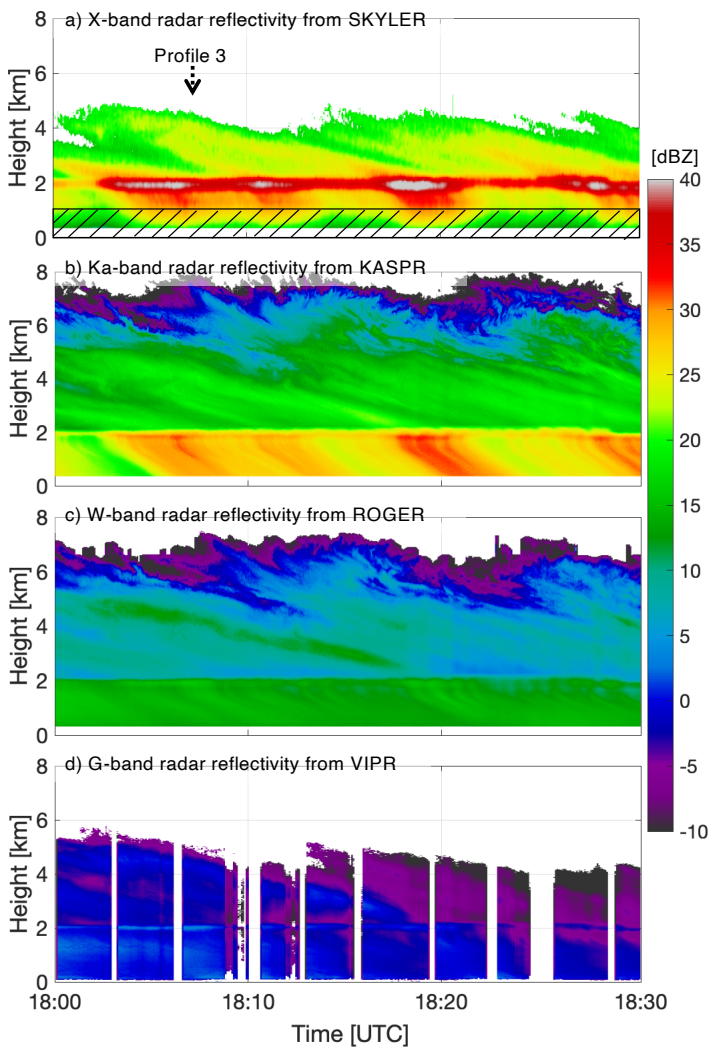

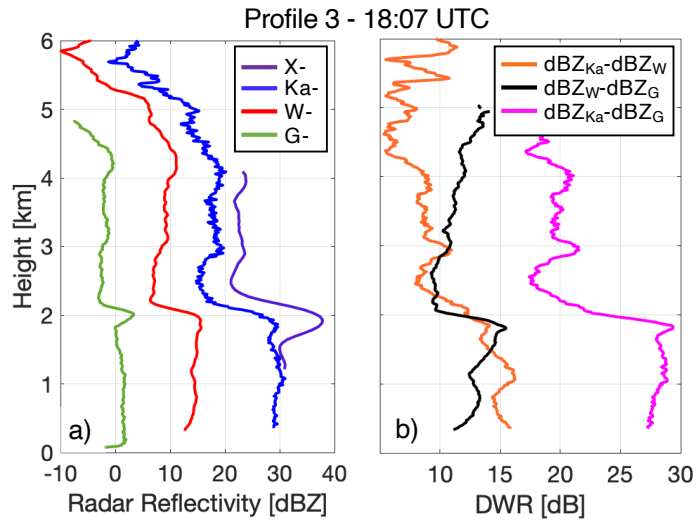

Figure 8: Time-height of radar reflectivity measured by the a) SKYLER, b) KASPR, c) ROGER and d) VIPR between 18:00 and 18:30 UTC on 25 February 2020. Observations covered by the hashed region in (a) are known to be biased low because of a human error in setting the radar receiver blanking parameters. The arrow in (a) points to the time of the profile displayed in Fig. 9.

775

780

785 **Figure 9: Profiles taken at 18:07 UTC during the rain period, a) radar reflectivity measured by VIPR (G-band, green), ROGER (W-band, red), KASPR (Ka-band, blue) and SKYLER (X-band, purple) and b) associated dual-wavelength ratio from the Ka-W pair (orange), the W-G pair (black) and the Ka-G pair (magenta).**
