Abstract. Iodine species are important in the marine atmosphere for oxidation and new-particle formation. Understanding iodine chemistry and iodine new-particle formation requires high time resolution, high sensitivity, and simultaneous measurements of many iodine species. Here, we describe the application of bromide chemical ionization mass spectrometers (Br-CIMS) to this task. During the iodine oxidation experiments in the Cosmics Leaving Outdoor Droplets (CLOUD) chamber, we have measured gas-phase iodine species and sulfuric acid using two Br-CIMS, one coupled to a Multi-scheme chemical IONization inlet (Br-MION-CIMS) and the other to a Filter Inlet for Gases and AEROSols inlet (Br-FIGAERO-CIMS). From offline calibrations and inter-comparisons with other instruments attached to the CLOUD chamber, we have quantified the sensitivities of the Br-MION-CIMS to HOI, I₂, and H₂SO₄ and obtain detection limits of 5.8×10^6 , 3.8×10^5 , and 2.0×10^5 molec cm⁻³, respectively, for a 2-min integration time. From binding energy calculations, we estimate the detection limit for HIO₃ to be 1.2×10^5 molec cm⁻³, based on an assumption of maximum sensitivity. Detection limits in the Br-FIGAERO-CIMS are around one order of magnitude higher than those in the Br-MION-CIMS; for example, the detection limits for HOI and HIO₃ are 3.3×10^7 and 5.1×10^6 molec cm⁻³, respectively. Our comparisons of the performance of the MION inlet and the FIGAERO inlet show that

bromide chemical ionization mass spectrometers using either atmospheric pressure or reduced pressure interfaces are well-matched to measuring iodine species and sulfuric acid in marine environments.

1 Introduction

Reactive iodine species are released into the atmosphere mainly by biological processes in marine environments (i.e. from macro- and micro-algae) (McFiggans et al., 2004), O₃ deposition on the sea surface (Carpenter et al., 2013), as well as from the sea ice (Spolaor et al., 2013) and snowpack in the polar region (Raso et al., 2017). Once emitted, iodine species can modify atmospheric oxidative capacity via a chain of catalytic reactions with O₃ that form iodine oxides, leading to about 20–28 % of O₃ loss in the marine boundary layer (Prados-Roman et al., 2015; Sherwen et al., 2016). Through convection, reactive iodine species can be transported from the lower troposphere to the upper troposphere-lower stratosphere, causing one third of the iodine-induced ozone loss in the upper troposphere-lower stratosphere (Koenig et al., 2020). Another important effect of iodine species is their contribution to atmospheric new-particle formation. O'Dowd et al. (O'Dowd et al., 2002) showed that particles are produced from condensable iodine-containing vapors at a coastal location (Mace Head in Ireland). Recent studies have demonstrated that iodine oxoacids (iodous acid, HIO₂ and iodic acid, HIO₃) dominate the iodine cluster formation processes (He et al., 2021a, 2021b), and drive the bursts of freshly-formed particles in coastal regions (Sipilä et al., 2016). This process thereby may enhance cloud condensation nuclei formation, affecting climate both directly and indirectly (Saiz-Lopez et al., 2012; Simpson et al., 2015).

Understanding iodine chemistry and iodine driven new-particle formation requires high time resolution, high sensitivity, and simultaneous measurements of iodine species. However, this has been a long-standing challenge due to their low abundance and short atmospheric lifetimes. Previous studies have achieved detection of relatively more abundant molecular iodine (I₂), iodine monoxide (IO), and iodine dioxide (OIO) via optical spectroscopy, such as differential optical absorption (Leigh et al., 2010), cavity ring-down (Bitter et al., 2005), cavity enhanced absorption (Vaughan et al., 2008), laser-induced fluorescence (Dillon et al., 2006), and resonance fluorescence (Gómez Martín et al., 2011). The spectroscopic techniques are invaluable; however, their very specificity limits them to the detection of a few iodine compounds, and they are less sensitive to other iodine species that have congested or broad absorption features, such as hypiodous acid (HOI) and iodic acid (HIO₃).

Another commonly used technique is mass spectrometry; it has a fast response time and a low detection limit, but extra calibration efforts are needed for the quantification of the detection sensitivity. For example, photoionization (Gómez Martín et al., 2013) and chemical ionization mass spectrometry (CIMS) have been employed to detect a suite of halogen species. Reagent ions used with CIMS include: SF₅⁺ for HCl and ClONO₂ (Marcy et al., 2004); iodide (I⁻) for atmospheric chlorine and bromine species such as ClONO₂, Cl₂, ClO, BrO, and BrCl (Kercher et al., 2009; Lee et al., 2018; Tham et al., 2016); superoxide (O₂⁻) for molecular iodine (I₂) (Finley and Saltzman, 2008); and both nitrate (NO₃⁻) (Sipilä et al., 2016) and protonated water (H₃O⁺) (Pfeifer et al., 2020) for HIO₃. The nitrate-CIMS and H₃O⁺-

CIMS suffer from the limited analyte affinity to the reagent ions. The iodide-CIMS can effectively measure chlorine and bromine species, but it is not suitable to detect iodine species due to the ambiguity in peak identification.

The bromide ion (Br^-) exhibits an affinity to a wide spectrum of iodine containing species. Br-CIMS has been routinely used to measure chlorine species (Lawler et al., 2011), HO_2 radicals (Sanchez et al., 2016), organic vapors and sulfuric acid (Rissanen et al., 2019), and nitric acid (Wang et al., 2020). Like chlorine species, iodine species are known to cluster with bromide ions via halogen (or hydrogen) bonds; as such, here we explore using the Br-CIMS to measure gas-phase iodine species and sulfuric acid simultaneously at concentrations relevant to the marine boundary layer. In this study, we demonstrate the detection of various gas-phase inorganic iodine species with the Br-CIMS and explore the effect of relative humidity (RH) on that detection. We then quantify the sensitivities of several gas-phase iodine species via inter-method calibration, offline calibration, and quantum chemical calculations. Finally, we compare the performance of Br-MION-CIMS and Br-FIGAERO-CIMS and show that both of them are well-suited for iodine species measurement in the marine boundary layer.

2 Methodology

2.1 The CLOUD facility

We conducted measurements and instrument inter-comparison at the CERN CLOUD facility, a 26.1 m³ electropolished stainless-steel chamber that enables new-particle formation experiments simulating the typical range of tropospheric conditions with scrupulous cleanliness and minimal contamination (Duplissy et al., 2016; Kirkby et al., 2011). The CLOUD chamber is mounted in a thermal housing, capable of keeping temperature constant in a range of -65 °C and +100 °C with ± 0.1 °C precision (Dias et al., 2017) and relative humidity commonly between < 0.5 % and 80 %. Photochemical processes are driven by different light sources, including four 200 W Hamamatsu Hg-Xe lamps with significant spectral irradiance between 250 and 450 nm, and an array of 48 green light LEDs at 528 nm with adjustable optical power up to 153 W. Ion-induced nucleation under different ionization levels is simulated with a combination of electric fields (electrodes at ± 30 kV at top and bottom of the chamber) which can be turned on to rapidly scavenge smaller ions, and a high-flux beam of 3.6 GeV pions (π^+) which enhances ion production when turned on. Mixing is accelerated with magnetically coupled fans mounted at the top and bottom of the chamber. The characteristic gas mixing time in the chamber during experiments is a few minutes. The loss rate of condensable vapors onto the chamber wall is comparable to the condensation sink in pristine boundary layer environments (e.g. $2.2 \times 10^{-3} \text{ s}^{-1}$ for H_2SO_4 at 5 °C). To avoid a memory effect between different experiments, the chamber is periodically cleaned by rinsing the walls with ultra-pure water and heating to 100 °C for at least 24 hours, ensuring extremely low contaminant levels of sulfuric acid ($< 5 \times 10^4 \text{ cm}^{-3}$) and total organics ($< 150 \text{ pptv}$) (Kirkby et al., 2016; Schnitzhofer et al., 2014). The CLOUD gas system is also built to the highest technical standards of cleanliness and performance.

The dry air supply for the chamber is provided by cryogenic nitrogen (Messer, 99.999 %) and cryogenic oxygen (Messer, 99.999 %) mixed at the atmospheric ratio of 79:21. Ultrapure water vapor, ozone and other trace gases can be precisely added to attain desired mixing ratios at different levels. The total injection rate of the humidified air is

fixed at 330 standard liters per minute (slpm) to compensate for the sampling consumption of various instruments. Molecular iodine (I_2) is injected into the chamber by passing a flow of cryogenic nitrogen through a crystalline iodine (I_2 , Sigma-Aldrich, 99.999 % purity) reservoir, which is temperature-controlled at 10 °C, to achieve levels of 0.4 to 168 pptv in the chamber. The sulfinert-coated injection lines are temperature stabilized to minimize line conditioning effects. High intensity green light emitting diodes (LEDs) are used to photolyze molecular iodine into iodine atoms and initiate the subsequent oxidation reactions in the presence of ozone and water vapor. The 48 green LEDs (light sabre 4, LS4) are mounted in pairs (one upward facing, one downward facing) on a copper cooling bar within a long quartz jacket that protrudes into the chamber in the mid plane. The maximum total optical power output is 153 W, centered on 528 nm. Actinic fluxes are regulated by controlling the number of LEDs used and the set point of individual LEDs. Light fluxes are monitored by two photodiodes and a spectrometer.

2.2 Br-MION-CIMS

We measured gas-phase iodine species with a bromide chemical ionization atmospheric pressure interface time-of-flight mass spectrometer (Junninen et al., 2010) coupled with a Multi-scheme chemical IONization inlet (Br-MION-CIMS) (Rissanen et al., 2019). The Br-MION inlet consists of an electrically grounded 24 mm inner diameter stainless steel flow tube, attached to an ion source. For the CLOUD measurements, the length of the sampling inlet was ~1.5 m and was designed to be in a laminar flow with a fixed total flow rate of 32 standard liters per minute (slpm). An ion filter, operated with positive and negative voltage, was placed at the front of the inlet to filter out any ions in the sample air prior to ion-molecule reaction chamber in the inlet. The reagent ions, bromide (Br^-) and the bromide-water cluster ($H_2O \cdot Br^-$), were produced by feeding 25 standard milliliters per minute (mlpm) of nitrogen (N_2) flow through a saturator containing dibromomethane (CH_2Br_2 ; > 99.0 %, Tokyo Chemical Industry) into the ion source, where the reagent was ionized by soft X-ray radiation. The resulting ions were then accelerated by a 2800 V ion accelerator array and focused by a 290 V ion deflector into the laminar sampling flow of the inlet via a 5 mm orifice. A small counter flow (~40 mlpm) was applied through the orifice to prevent any mixing of the electrically neutral reagent vapor with the sampling flow. The details of the inlet design, setup, and operation are described previously (He, 2017; Rissanen et al., 2019).

2.3 Br-FIGAERO-CIMS

We also measured both the gas- and particle-phase compositions via thermal desorption using a bromide chemical ionization time-of-flight mass spectrometer equipped with a Filter Inlet for Gases and AEROSols (Br-FIGAERO-CIMS) (Lopez-Hilfiker et al., 2014). FIGAERO is a manifold inlet for a CIMS with two operating modes. In the sampling mode, gases are directly sampled into a 150 mbar ion-molecule reactor, using coaxial core sampling to minimize their wall losses in the sampling line. The total flow is maintained at 18.0 slpm and the core flow at 4.5 slpm; the CIMS samples at the center of the core flow with a flow rate at ~1.6 slpm. Concurrently, particles are collected on a PTFE filter via a separate dedicated port with a flow rate of 6 slpm. In the desorption mode, the filter is automatically moved into a pure N_2 gas stream flowing into the ion molecule reactor, while the N_2 is progressively heated upstream

of the filter to evaporate the particles via temperature programmed desorption. Analytes are then chemically ionized by Br^- and extracted into a mass spectrometer.

We optimize the adduct-ion signals in both the Br-MION-CIMS and Br-FIGAERO-CIMS by tuning the electric field strengths in the first two low-pressure stages of the mass spectrometer as weak as possible to minimize collision induced cluster fragmentation while maintaining sufficient ion transmission. Optimization is achieved by maximizing the ratio of $\text{I}_2\text{Br}^-/\text{Br}^-$ at a constant I_2 concentration. We list relevant instrument specifications and operational conditions in Table S1. It should be noted that these values are specific to our instruments, thus can vary according to instrument parameters and may not be applicable to other instruments.

2.4 CE-DOAS

For the quantitative measurement of gas-phase molecular iodine (I_2), we deployed a Cavity Enhanced Differential Optical Absorption Spectroscopy instrument (CE-DOAS) (Meinen et al., 2010). CE-DOAS determines concentrations of trace gases from the strength of differential spectral features in a reference spectrum. The overall accuracy for the I_2 time series is estimated to be 20 %, never better than the detection limit (3-sigma precision), resulting from the uncertainty in cross sections and the stability of the baseline. It is thus an absolute method and does not depend on an instrument specific detection efficiency. To maximize the measurement sensitivity towards I_2 , we used a setup optimized for the green wavelength range (508-554 nm), where I_2 exhibits strong differential absorption features. The measurement light is provided by a green light emitting diode (LED Engin). Spectral dispersion is established with a Czerny-Turner grating spectrometer (Princeton Instruments Acton 150), resulting in an optical resolution of 0.73 nm full width at half maximum at 546 nm. Intensities are monitored with a CCD detector (Princeton Instruments PIXIS400B) cooled to -70 °C. Highly reflective mirrors (Advanced Thin Films) enhance the 1 m mirror separation to an effective optical path length of 15-23 km. The effective spectral mirror reflectivity was established by comparing light intensity spectra in the presence of N_2 and He (Washenfelder et al., 2008). The abundance of trace gases is then determined by comparing spectra of chamber air relative to reference spectra recorded with ultrapure N_2 without I_2 . Chamber air is drawn into the cavity with a constant flow rate of 1 slpm. Variations of the sampling flow did not result in changes in measured I_2 concentrations, indicating that photolysis from the measurement light within the instrument was negligible. The following absorbers were included in the fit: I_2 (Spietz et al., 2006), NO_2 (Vandaele et al., 1998), H_2O (Rothman et al., 2010), $\text{O}_2\text{-O}_2$ collision-induced absorption (Thalman and Volkamer, 2013), and a polynomial of sixth order. The setup allowed a 1-minute detection limit of 25 pptv, or 8 pptv for integration times of 10 minutes, respectively. Periodic automated recordings of N_2 reference spectra were recorded to ensure baseline stability. The optical path length at the time of measurement was continuously confirmed for consistency by the measurement of the $\text{O}_2\text{-O}_2$ collision-induced absorption and H_2O column in the same analysis window. The overall systematic accuracy for the I_2 time series is estimated to be 20 %, never better than the detection limit, resulting from the uncertainty in cross sections and the stability of the baseline.

2.5 Offline calibration setup

2.5.1 I₂ permeation device

We used an iodine permeation tube (VICI Metronic) as a source for offline laboratory calibration. The permeation tube was encased within an electronically controlled heating mantle (80 ~ 140 (\pm 2) °C) to allow for adjustable yet steady iodine permeation rates. The heating device (for holding the permeation tube) was made from a stainless steel tube (½-inch outer diameter, OD) with a length of 25 cm, encased within an electronically controlled heating mantle. The configuration of the permeation device has been described in Tham et al. (Tham et al., 2021). The iodine permeation device was run continuously for at least 72 hours before any calibration experiments to ensure that a complete equilibrium was reached in the system. We then confirmed the robustness of the permeation device by the constant I₂ signal measured with Br-MION-CIMS for over 24 hours.

To determine the permeation rate of I₂, we trapped iodine in n-hexane at cryogenic temperatures in an all-glass apparatus, following the method described in Chance et al. (Chance et al., 2010). We initially filled the absorption glass vessel with 20 ml n-hexane (99.95 %, Merck), and then weighed it to determine the combined mass. We then immersed the absorption vessel into a wide-necked Dewar vessel, filled with an acetone/dry ice mixture (at -80 ± 3 °C). After temperature equilibration, the I₂ molecules, carried by 50 mlpm N₂ flow from the permeation device, were bubbled through the absorption vessel. After a continuous collection for 5 hours, we removed the absorption apparatus from the cooling mixture, and allowed it to warm to room temperature prior to disassembling the setup to prevent any losses of iodine on the tip of the inlet capillary. The absorption vessel was then re-weighed; the mass compared with that prior to absorption was less than 2 %, indicating a negligible loss during the trapping process. The I₂ / n-hexane sample solutions were stored at 4 °C for 14 hours before being subjected to analysis.

We determined the I₂ concentration of the samples using a UV/Vis spectrophotometer (Shimadzu Model UV2450) at a wavelength of 522 nm. We established a calibration curve via a set of I₂ solutions ranging from 270 to 5300 nmol, diluted with n-hexane from a freshly prepared stock solution (0.5 g L⁻¹). Repetition of the same analysis after 2 and 7 days yielded identical results, confirming that the sample solutions were stable at 4 °C. As an alternative analytical approach, we also quantified the I₂ concentration in the sample solutions using an inductively coupled plasma mass spectrometer (ICP-MS, Agilent 7800). Before introducing to the ICP-MS, the sample solutions were treated with NaHSO₃ water solution (0.100 M), accomplishing efficient hexane-to-water extraction and simultaneous reduction of iodine to iodide (Schwehr et al., 2005) (Agilent Clinical Sample Preparation Guide (v3), *ref.* ISO 17294-2). The ICP-MS results were in good agreement (within 20 % discrepancies) with those from the UV/Vis spectrophotometry.

We conducted the I₂ trapping and quantification experiments in triplicate with satisfactory reproducibility (standard deviation < 10 %). The calculated iodine permeation rate at 50 mlpm N₂ flow and 140 °C oven temperature is 278 ± 12 ng min⁻¹ (mean \pm standard deviation). This result was used as the benchmark to estimate temperature-corrected permeation rates according to the formula provided by the permeation tube vendor (VICI Metronic). We checked the validity of the temperature-corrected values by conducting a second iodine absorption experiment in which the iodine

permeation tube was kept at 130 °C with an N₂ flow rate of 50 mlpm, and the determined permeation rate agreed within 10 % of the calculated value.

2.5.2 Cl₂ permeation device

We used a commercial chlorine permeation tube (VICI Metronic) as a source for offline calibration. We passed a 20 mlpm high-purity nitrogen (99.999 %) flow at room temperature through a 25 cm long stainless-steel tube (½" O.D.) containing the permeation tube. We quantified the permeation rate of Cl₂ following a procedure described in a previous study (Finley and Saltzman, 2008). The output of 20 mlpm flow was bubbled into a buffered aqueous potassium iodide solution (2.0 % KI (*m/v*), prepared in 1.00 mM aqueous phosphate buffer, pH = 7.0) filled in an all-glass two-stage serial absorption apparatus (stage 1 = 100 ml; stage 2 = 50 ml) for 3 hours and kept at room temperature. The Cl₂ oxidized the iodide (I⁻) into iodine (I₂) once contacting with the KI absorption solution, and the I₂ further reacted with the excess KI present in the absorption solution to form I₃⁻, which can be quantified by UV/Vis-spectrophotometry. We analyzed the resulting sample solutions with an UV/Vis spectrophotometer (Shimadzu Model UV-1800) using 1-cm quartz cells at 352 nm, corresponding to the I₃⁻. We detected no I₃⁻ in the second stage absorption solution, indicating that all the chlorine was quantitatively trapped and rapidly converted to I₃⁻ within the first absorption unit. The samples were quantified relative to I₃⁻ standards in the range of 5 to 68 × 10⁻⁶ M, prepared by dilution of a stock obtained by dissolving 174 mg iodine in 200 ml of a solution containing 2 % KI in 1.00 mM aqueous phosphate buffer, pH 7.0. From this calibration curve, we calculated a molar absorptivity of 26,800 L mol⁻¹ cm⁻¹, which is consistent with the values reported in the literature (Finley and Saltzman, 2008; Kazantseva et al., 2002). Samples and standard solutions were re-analyzed after being stored in the dark at room temperature for 24 hours, and the results were within 3 % of those obtained with the fresh solutions. We repeated the absorption experiment, and the calculated chlorine permeation rate at room temperature was 764 ± 74 ng Cl₂ min⁻¹ (mean ± standard deviation).

2.5.3 HOI calibrator

We produced a continuous HOI source via the reaction of I₂ and hydroxyl radicals (OH) in a setup similar to the sulfuric acid (H₂SO₄) calibrator (Kürten et al., 2012). The OH was generated by photolyzing H₂O with a mercury (Hg) lamp at 184.9 nm, whose calibrated intensity was used to estimate the OH concentration. We tested the system by removing the I₂ or OH source from the calibrator, upon which HOI production was undetectable, confirming that any single reactant did not produce HOI. A numerical model was constructed to predict the mean HOI concentration entering the Br-MION-CIMS, which is analogous to the model used for H₂SO₄ calibration (Kürten et al., 2012). We only included the formation pathway of I₂ + OH to HOI in the model for simplicity; the other pathway of IO + HO₂ was considered minor as its reaction rate is about an order of magnitude slower than that of I₂ + OH. Furthermore, IO is likely at negligible concentration in the calibration device due to the absence of O₃ for IO formation.

2.6 Quantum chemical calculations

We used quantum chemical calculations to estimate the cluster formation enthalpy of halogen containing species and bromide ions. The initial conformational sampling was performed using the Spartan '14 program. The cluster

geometry was then optimized using density function theory methods at the ω B97X-D/aug-cc-pVTZ-PP level of theory (Chai and Head-Gordon, 2008; Kendall et al., 1992). Iodine pseudopotential definitions were taken from the EMSL basis set library (Feller, 1996). Calculations were carried out using the Gaussian 09 program (Frisch et al., 2010). An additional coupled-cluster single-point energy correction was carried out on the lowest energy geometry to calculate the final cluster formation enthalpy. The coupled-cluster calculation was performed at the DLPNO-CCSD(T)/def2-QZVPP level using the ORCA program ver. 4.0.0.2 (Neese, 2012; Riplinger and Neese, 2013). In Table 1 we present calculated cluster formation enthalpies based on the optimized geometries.

3 Results and Discussion

3.1 Detection of gas-phase inorganic species by Br-MION-CIMS

We show in Fig. 1 the selected inorganic species observed with the Br-MION-CIMS during an iodine oxidation experiment in the CLOUD chamber. The peak identities are indicated in the labels. Observed species include I_2 and its various oxidation products. There are also a few other halogen-containing inorganic species such as Cl_2 , ICl and IBr , likely coming from the impurities in the iodine source. Non-halogen inorganic species such as H_2SO_4 can also react with bromide ions and are detected. Due to the large negative mass defect of the bromine and iodine atoms, and the high resolution (~ 10000 Th Th^{-1}) of the mass spectrometer, the peaks can be unambiguously distinguished and identified in the mass spectrum. As shown in the lower panel of Fig. 1, most of the iodine-containing species appear as a single peak in the unit mass range, except for $HIO_2 \cdot ^{79}Br^-$ ($m/z = 238.82$), which overlaps with the reagent ion cluster ($^{79}Br_2^{81}Br^-$) ($m/z = 238.75$).

The iodine oxidation experiments were conducted under experimental conditions typically found in the high-latitude marine boundary layer, with a temperature of -10 °C and a relative humidity of 69 %. As illustrated in Fig. 2, a typical experiment started with illumination of the chamber at constant I_2 (~ 60 pptv) using the green light to photolytically produce I atoms. The subsequent reactions of I and ~ 40 ppbv O_3 led to the formation of various oxidized iodine species within a few minutes. The most prominent species we observed from these experiments were IO, HOI and HIO_3 , with lower but significant levels of OIO, HIO_2 , and I_2O_4 . Among these iodine oxides, IO rose the most rapidly; this is consistent with the first-generation production of IO from the $I + O_3$ reaction. After a few steps of radical reactions, OIO, HIO_2 and HIO_3 reached steady state almost simultaneously. The only observed iodine oxide dimer was I_2O_4 in this event, while I_2O_2 , I_2O_3 and I_2O_5 were below the detection limit of both mass spectrometers. A noticeable dip in the HIO_3 traces a few minutes after the onset of the reactions is likely due to the participation of HIO_3 in new-particle formation, resulting in an extra loss term and a lower steady-state concentration. When we turned off the green light, the production of I radicals stopped and iodine species decayed away.

Figure 2. Evolution of selected iodine species during a typical run. The experiment was performed at 60 pptv I_2 , 40 ppbv O_3 , 69 % relative humidity and $-10\text{ }^\circ\text{C}$. The oxidized iodine species start to appear soon after switching on the green light at 08:11, 05 October 2018. The I atom production was halted at 10:21, 05 October 2018 by switching off the green light, and the concentration of oxidized iodine species decayed away afterwards. All species are color-coded in the same way as in Fig. 1.

3.2 Relative humidity dependence

Water molecules can cluster with I^- to form $H_2O \cdot I^-$ in the iodide CIMS. This enhances the instrument sensitivities for small molecules (i.e. chlorine and bromine) and reduces them for large molecules (i.e. oxygenated organics) (Lee et al., 2014). To investigate the role of water concentration in the sensitivity of the Br-MION-CIMS, we varied the relative humidity (RH) from 40 % to 80 % at a constant temperature of $-10\text{ }^\circ\text{C}$. We show in Fig. 3 the correlation of I_2 time series from the Br-MION-CIMS and the CE-DOAS throughout the experiment.

Chemical ionization relies on an ion-molecule reaction to transfer charge from a reagent ion to an analyte, forming either a product ion or a charged cluster between the analyte and the reagent ion with a rate coefficient k_{IM} . This occurs in an ion-molecule reactor, with a fixed flow rate and thus reaction time, dt , and ideally under pseudo first-order conditions where a small fraction of the analyte is ionized and the reagent ion concentration ($[Ion]$) remains constant. Under these (linear) conditions the fraction of analyte that is ionized is $k_{IM} \times [Ion] \times dt$. However, the primary ion source strength can vary with time, and so we normalize the analyte signal by reagent ion signal to account for those small variations in analyte signal.

During the RH transition, the ratio of the two reagent ions, Br^- and $H_2O \cdot Br^-$, changed in the Br-MION-CIMS. As shown in Fig. 3 (a) and (b), using either reagent ion alone for I_2 normalization results in discrepancies in recovered I_2 concentrations at different RH. However, if we use the sum of these two reagent ions ($Br^- + H_2O \cdot Br^-$) for normalization, the humidity effect vanishes, as shown in Fig. 3 (c). Separately, during the I_2 calibration using a permeation tube (section 3.3.2.1), the detection of I_2 molecules is robust and independent of RH between 20 % and 40 % at $25\text{ }^\circ\text{C}$, as long as a proper normalization method is used for the Br-MION-CIMS. Furthermore, we have also carried out the HOI calibration at $25\text{ }^\circ\text{C}$ (section 3.3.2.3) and used the same normalization method. During the calibration, we varied

the water content in the calibrator to vary OH concentrations. A good correlation between the modeled HOI concentrations and the measured HOI signals also indicates that the different H₂O concentrations in the system do not affect the HOI detection (Fig.4(d)). This assertion may also be applicable to molecules such as iodine monochloride (ICl) and iodine monobromide (IBr), which share similar chemical and physical properties with I₂; however, further confirmation is needed for other species such as oxygenated organics.

Figure 3. Signal normalization methods for the Br-MION-CIMS. Normalized I₂·Br⁻ signal intensity for variable I₂ concentrations, color coded by relative humidity (orange: 35-45 % relative humidity, red: 70-80 % relative humidity). The charger ions in the ion source of Br-MION-CIMS are Br⁻ and H₂O·Br⁻ (both ⁷⁹Br and ⁸¹Br). Their abundance depends both on the instrument tuning and the absolute humidity of the sampled flow. The normalization of the I₂·Br⁻ signal by only Br⁻ (a) or H₂O·Br⁻ (b) does not compensate for the humidity effect. Using the sum of Br⁻ and H₂O·Br⁻ (c) for normalization yields a tight correlation to the true I₂ as measured by CE-DOAS, independent of the humidity. The black dashed line indicates the fitted linear calibration.

3.3 Quantification of gas-phase inorganic species

Inter-method calibrations and offline calibrations were carried out to quantify the sensitivities of the Br-MION-CIMS to selected calibrants. For the inter-method calibrations, we used the CLOUD chamber as a stable source of I₂ and H₂SO₄, and inter-compared the signals in the Br-MION-CIMS with the CE-DOAS and a pre-calibrated nitrate-CIMS, respectively. For the offline calibrations, we carried out the experiments separately in a laboratory at the University of Helsinki, using permeation tubes to quantify I₂ and Cl₂, and a calibrator to quantify HOI.

3.3.1 Inter-method calibrations at CLOUD

3.3.1.1 I₂ calibration using the CE-DOAS

As shown in Fig. 3, we use the accurate I₂ time series measured with the CE-DOAS to calibrate normalized I₂ signals in the Br-MION-CIMS. The I₂ concentrations used for the calibration span approximately 2 orders of magnitude, reaching up to 4.6×10^{10} molec cm⁻³. A linear fit, limited to I₂ concentrations smaller than 10^{10} molec cm⁻³, establishes the calibration factor as follows:

$$[I_2] = 2.7 \times 10^{10} \text{ molec cm}^{-3} \times I_2 \cdot ^{79}\text{Br}^- / (^{79}\text{Br}^- + \text{H}_2\text{O} \cdot ^{79}\text{Br}^-)$$

For this range of concentrations, which are typically encountered in the atmosphere, the calibrated Br-MION-CIMS time series agrees within error with the CE-DOAS measurement (1-sigma accuracy 20 %, detection limit 25 pptv for

1 min data). Deviations between both time series are generally smaller than 10 % (25 and 75 percentile 0.88 and 1.03, respectively). These small differences may be explained by incomplete homogeneity of iodine concentrations in the chamber and the different sampling positions of CE-DOAS and Br-MION-CIMS.

3.3.1.2 H₂SO₄ calibration using a nitrate-CIMS

We derive the H₂SO₄ calibration coefficient for the Br-MION-CIMS using the absolute H₂SO₄ concentrations measured with a pre-calibrated nitrate-CIMS. The calibration protocol of H₂SO₄ in the nitrate-CIMS has been described in detail previously (Kürten et al., 2012). The H₂SO₄ time series used for the inter-method calibration covers a wide concentration range from less than 5.0×10^4 (detection limit of the nitrate-CIMS) to 6.0×10^7 molec cm⁻³. For Br-MION-CIMS, although both HSO₄⁻ and H₂SO₄·Br⁻ appear as distinct peaks for sulfuric acid, we only use the normalized H₂SO₄·⁷⁹Br⁻ for the inter-calibration, as HSO₄⁻ (m/z = 96.96) has substantial interference from the reagent ion H₂O·⁷⁹Br⁻ (m/z = 96.93). We show in Fig. 4 (a) the linear fit:

$$[\text{H}_2\text{SO}_4] = 4.1 \times 10^{10} \text{ molec cm}^{-3} \times \text{H}_2\text{SO}_4 \cdot ^{79}\text{Br}^- / (^{79}\text{Br}^- + \text{H}_2\text{O} \cdot ^{79}\text{Br}^-) - 9.3 \times 10^5$$

The H₂SO₄ calibration coefficient is thus 4.1×10^{10} molec cm⁻³ per normalized signal (cps cps⁻¹), and the correlation coefficient between the two H₂SO₄ traces is 0.95. The systematic 3-sigma accuracy is +50/-33 % for H₂SO₄ calibration using a nitrate-CIMS; detailed accuracy estimation has been discussed previously (Stolzenburg et al., 2020).

3.3.2 Offline laboratory calibrations for I₂, Cl₂, and HOI

For the I₂ calibration, we diluted the I₂ flow to seven different values and measured the flow with the Br-MION-CIMS. We repeated the calibration five times; we show the data along with a linear fit between the I₂ concentration and normalized I₂ signal in Fig. 4 (b). The slope of the line gives a calibration coefficient of 6.3×10^{10} molec cm⁻³ per normalized signal (cps cps⁻¹), with R² of 0.98 and an overall 1-sigma accuracy of ± 45 %.

For the Cl₂ calibration, the Cl₂ permeation source was run continuously for 12 hours prior to calibration experiments to ensure complete system equilibrium. A two-stage dilution system similar to the setup of (Gallagher et al., 1997) was set up for diluting the output of the Cl₂ permeation device. The 20 mlpm of N₂ stream emerging from the Cl₂ permeation device (operated at room temperature) was diluted in a stream of 6 slpm of dry N₂. Then, a small fraction of this mixture (50 to 300 mlpm) was further mixed with the total flow of 25 slpm of N₂ (20 slpm dry N₂ + 5 slpm humidified N₂) before being sampled by the Br-MION-CIMS. The calibration coefficient for Cl₂ was determined to be 3.5×10^{11} molec cm⁻³ per normalized signal (cps cps⁻¹) from three separate calibration experiments (Fig 4 (c)), with an 1-sigma accuracy of 30 %.

As for the HOI calibration, we produced a range of HOI concentrations by varying I₂ and OH concentrations in the calibrator. We show in Fig. 4 (d) the linear correlation between the modeled HOI concentrations and measured HOI signals. The slope of the fit corresponds to a calibration coefficient of 3.3×10^{11} molec cm⁻³ per normalized signal (cps cps⁻¹), with an overall 1-sigma accuracy of 55 %. The good correlation (R² = 0.97) including various H₂O levels also indicates that H₂O concentrations did not affect the HOI detection.

Figure 4. The normalized signals (cps cps^{-1}) vs. the absolute concentrations (molec cm^{-3}) measured with the Br-MION-CIMS for (a) H_2SO_4 , (b) I_2 , (c) Cl_2 , and (d) HOI . The red dashed lines are the linear fits. The overall 3-sigma accuracy of +50/-33 % on $[\text{H}_2\text{SO}_4]$ is not shown here.

3.3.3 Connecting sensitivity to binding enthalpy

Beyond the species for which we carried out calibrations, there are many more, especially iodine species, that cannot be directly calibrated due to a lack of authentic standards or generation methods. However, the sensitivity of an iodide-CIMS towards analytes can be predicted by the cluster binding enthalpy, calculated by relatively simple quantum chemical methods (Iyer et al., 2016). This holds for the Br-CIMS as well. In the instrument, ion clusters, formed from reactions between analytes and reagent ions, are guided and focused by ion optics during transmission to the detector. The electric forces applied to the clusters enhance their collision energies with carrier gas molecules. If sufficient energy is transferred during the collision, cluster fragmentation may occur, affecting the instrument sensitivity for the analytes (Passananti et al., 2019). However, clusters with higher binding enthalpy will be more easily preserved and detected. Analytes that bind to the reagent ions with enthalpies higher than a critical level are likely detected at

maximum sensitivity (kinetic-limited detection) by the instrument. For example, the calculated critical enthalpy is 25 kcal mol⁻¹ for the iodide-CIMS used in Iyer et al. (Iyer et al., 2016) and Lopez-Hilfiker et al. (Lopez-Hilfiker et al., 2016), calculated at the DLPNO-CCSD(T)/def2-QZVPP//PBE/aug-cc-pVTZ-PP level of theory.

For the bromide chemical ionization, there are two types of fragmentation pathways:

- 1) Reversion to the original form of Br⁻ and analyte

- 2) Proton transfer from the analyte to Br⁻

where the X-H is the hydrogen bond donor. An analyte should be detected at the maximum sensitivity when the dissociation enthalpy for the first pathway is either a) much higher than the critical enthalpy (dissociation of X-H·Br⁻ to X-H and Br⁻ does not occur), or b) lower than the critical enthalpy, but much higher than that of the second pathway (dissociation of X-H·Br⁻ to X-H and Br⁻ may occur, but dissociation to X⁻ and HBr is the dominant pathway). Whether the enthalpy for the second pathway is higher than the critical enthalpy does not directly affect the sensitivity, as both X-H·Br⁻ and X⁻ can be measured and counted. The sensitivity toward X-H would be reduced only when the first reversion pathway occurs to a non-negligible extent. Taking H₂SO₄ as an example, the dissociation enthalpies for the first and second pathways are 41.1 and 27.9 kcal mol⁻¹, respectively. If some of the H₂SO₄·Br⁻ dissociate, they preferably become HSO₄⁻ and are detectable by the Br-CIMS. Thus, H₂SO₄ can be detected at the maximum sensitivity.

While we were unable to experimentally establish a correlation between sensitivities and binding enthalpies due to limited quantifiable halogen species, we can predict the tentative critical enthalpy as the binding enthalpy of a species that is likely detected at the maximum sensitivity. We list the cluster formation enthalpies for a selection of halogen containing species in Table 1 and the corresponding cluster dissociation enthalpies in Table 2. Among all the calibration coefficients listed in Table 3, H₂SO₄ and I₂ have the lowest calibration coefficients (highest sensitivities). Thereby, we conclude that both H₂SO₄ and I₂ are detected at the maximum sensitivity, suggesting a critical enthalpy not higher than 33.7 kcal mol⁻¹. We can then infer the sensitivity for other species that are difficult to calibrate by comparing their binding enthalpies to those of the benchmark species. For example, ICl and IBr should have the maximum sensitivity, since the dissociation enthalpies for ICl·Br⁻ and IBr·Br⁻ are both much higher than 33.7 kcal mol⁻¹ (Table 2). Although HIO₃·Br⁻ has a lower dissociation enthalpy than the critical value, the favored dissociation pathway is proton transfer (the second pathway); HIO₃ can thus be considered as a maximum sensitivity species detectable as IO₃⁻ ions after proton transfer. This is consistent with the fact that both HIO₃·Br⁻ and IO₃⁻ are detected in Figure 1, so is the case with H₂SO₄. We thus assume that HIO₃ has a kinetic calibration coefficient of 4.1×10¹⁰ molec cm⁻³ cps cps⁻¹, the value for H₂SO₄. However, the lowest dissociation enthalpies of HOI·Br⁻ and Cl₂·Br⁻ are 26.9 and 22.3 kcal mol⁻¹, respectively, consistent with their higher calibration coefficients of 3.3×10¹¹ and 3.5×10¹¹ molec cm⁻³ cps cps⁻¹. The dissociation enthalpies for IO·Br⁻, OIO·Br⁻, and HIO₂·Br⁻ are 24.5, 23.2, and 29.2 kcal mol⁻¹, respectively. We would expect that their sensitivities are lower than the maximum sensitivity. Since the dissociation enthalpies for IO·Br⁻ and OIO·Br⁻ are between those of HOI·Br⁻ and Cl₂·Br⁻, a similar calibration coefficient may be

applied, but direct calibrations are more preferable. We note that when transferring the calibration factor from one species to another, the diffusivity difference should be accounted, since it affects the inlet line loss. This factor is not considered in the cluster enthalpies calculations.

Further, we estimate the detection limit of the calibrated species. The detection limit is defined as the analyte concentration, corresponding to the sum of the mean signal and three times the standard deviations (3σ) of the background fluctuations during a two-hour background measurement. We derive the detection limit of HOI, HIO₃, I₂, and H₂SO₄ to be 5.8×10^6 , 1.2×10^5 , 3.8×10^5 , and 2.0×10^5 molec cm⁻³ (or 0.2, 0.005, 0.015, and 0.008 pptv), respectively, for a 2-min integration time.

3.4 Comparison between Br-MION-CIMS and Br-FIGAERO-CIMS

While Br-MION-CIMS and Br-FIGAERO-CIMS use the same chemical ionization scheme, their designs differ in the ion-molecule reaction chamber (IMR). MION is an atmospheric pressure (1 bar) drift tube; analyte molecules gain an electric charge in an axial laminar flow. FIGAERO is connected to a cone-shaped IMR chamber operated at a reduced pressure (150 mbar); the sample flow is injected into the inlet via an orifice, necessarily causing turbulence and wall interactions in the IMR region. The atmospheric pressure and reduced pressure IMRs are both widely used for trace gas measurements. We thus compare iodine species measurements from Br-MION-CIMS and Br-FIGAERO-CIMS, to better understand the performance and applicability of the bromide ionization scheme.

We show in Fig. 5 the same iodine oxidation event as in Fig. 2, to illustrate the time series for HIO₃·Br⁻, HOI·Br⁻, IO·Br⁻, and I₂·Br⁻, measured with Br-MION-CIMS (red circles) and Br-FIGAERO-CIMS (grey sticks), respectively. Note that the FIGAERO alternates between gas and particle measurements; here we show only the gas-phase signals. Clear and concurrent signals of HIO₃, HOI, IO, and I₂ are evident from both the Br-MION-CIMS and Br-FIGAERO-CIMS. Prior to the iodine oxidation event (08:11), there was no photochemical production and thus virtually no signal of oxidized iodine species in both instruments. The dark reaction of ozone with I₂ did not proceed at a significant rate, due to the low rate coefficient and to low levels of I₂. Signals detected during this period are considered as the persistent background, coming from electronic noise or other sources such as the ionizer, carrier flows, or long-term “memory” in the case of the Br-FIGAERO-CIMS. Not surprisingly, the Br-MION-CIMS has a near-zero background for all analytes. For HIO₃ (Fig. 5 (a)), the background signal in the Br-FIGAERO-CIMS is also negligible; however, IO shows a substantial persistent background (Fig. 5 (c)) in the Br-FIGAERO-CIMS.

When we initiated the photochemistry, oxidized iodine signals rapidly built up toward an asymptote within timescales of minutes. The instrumental differences in these timescales are small for HIO₃ and HOI, but larger for IO. When colliding with the IMR surface, HIO₃ condenses irreversibly; it thus makes sense that the Br-MION-CIMS and Br-FIGAERO-CIMS signals show the same timescale for HIO₃. Semi-volatile HOI, however, can return to the gas phase from the walls depending on the surface coverage of HOI and the vapor concentration. Additionally, the heterogeneous reaction of aqueous iodide (I⁻) and ozone (Carpenter et al., 2013) could also contribute to the emission of HOI from

the IMR wall in the FIGAERO. As the evaporation flux is typically a function of the amount analyte on the surface, the buffering effect could degrade the instrument time response upon changes in analyte concentration. Here, however, we did not observe a significant memory effect, likely because the HOI concentration was too low to fully saturate the IMR surface or because any HOI evaporation was suppressed due to an enhanced accommodation coefficient of HOI on the metal surface. We expect IO to be prone to loss on the metal surface due to its radical nature.

After the iodine oxidation event (10:21), the photochemical production of oxidized iodine species was terminated and vapor concentrations decayed exponentially due to dilution and losses to chamber walls. Memory effects could also influence the signal time constant. The dilution loss rate was around $2.1 \times 10^{-4} \text{ s}^{-1}$ (4760 s time constant) for all species in the chamber, determined by the total chamber flow rate and the chamber volume. Wall loss rates, however, vary for species with different diffusion constants. The decay rates of HIO_3 are 400 s for the Br-MION-CIMS and 370 s for the Br-FIGAERO-CIMS, much faster than the dilution loss. For comparison, the time constant for H_2SO_4 vapor loss was 300 s. These time constants are thus consistent with wall loss (around $2.2 \times 10^{-3} \text{ s}^{-1}$). The IO decay time constant is 294 s for the Br-MION-CIMS and 435 s for the Br-FIGAERO-CIMS. The time constant for the Br-MION-CIMS indicates that the decay of IO is also driven by wall loss, so the net flux during this period was thus towards the wall rather than from the wall. Therefore, the difference of IO between instruments may well be attributed to the persistent background from the ionizer of the FIGAERO. The HOI signals have longer decay time constants in both instruments of 909 s for the Br-MION-CIMS and 714 s for the Br-FIGAERO-CIMS; this may reflect a time constant for depletion of HOI adsorbed to the chamber walls. The I_2 signal increases after the event termination because it is no longer photolyzed while its injection continues.

Applying the calibration coefficients, we convert the Br-MION-CIMS signals to absolute concentrations, and subsequently correlate them with signals measured with Br-FIGAERO-CIMS. We then estimate the tentative detection limits for HOI and HIO_3 in the Br-FIGAERO-CIMS to be 3.3×10^7 and $5.1 \times 10^6 \text{ molec cm}^{-3}$ (versus 5.8×10^6 and $1.2 \times 10^5 \text{ molec cm}^{-3}$ in the Br-MION-CIMS), respectively, at 3σ of the background signal for a 2-min integration time during a two-hour period; they are in general one order of magnitude higher than those in the Br-MION-CIMS. This is in line with the higher background signals observed in the Br-FIGAERO-CIMS. Note that for both HOI and HIO_3 the uncertainties introduced from the correlational analysis are negligible compared to the limited accuracy of the calibration sources (55 % for HOI and +50/-33 % for HIO_3). We are unable to estimate the I_2 detection limit in the Br-FIGAREO-CIMS, due to a lack of I_2 background measurement; but Br-FIGAERO-CIMS can and did detect I_2 at the low pptv level with good fidelity.

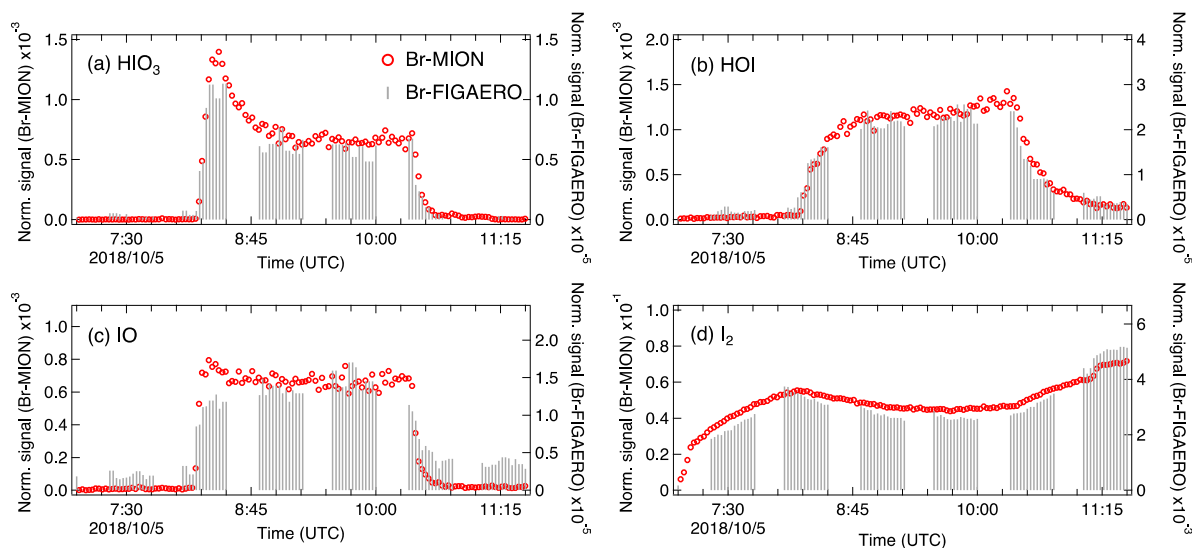

Figure 5. Signal comparison of selected iodine species measured with Br-MION-CIMS and (gas-phase) Br-FIGAERO-CIMS, respectively, during the same iodine oxidation experiment shown in Fig. 2.

4 Summary and conclusion

We confirm in this study that bromide chemical ionization is a suitable technique for the time-resolved, highly sensitive, and simultaneous measurements of iodine species and sulfuric acid. The Br-MION-CIMS shows constant sensitivity throughout the relative humidity range of 40 to 80 % at -10 °C, as long as the sum of the two reagent ions ($\text{Br}^- + \text{H}_2\text{O} \cdot \text{Br}^-$) is used for signal normalization. This demonstrates the applicability of this technique to field measurements in the ambient marine environment.

We quantify iodine species and sulfuric acid via offline calibrations (i.e. permeation tube and calibrator) and inter-method calibrations (i.e. CE-DOAS and pre-calibrated nitrate-CIMS). Further, we calculate the binding enthalpies between the calibrated species and reagent ions, which qualitatively agree with the corresponding calibration coefficients. This indicates that the quantum chemical calculations can be employed along with the calibration experiments to determine the sensitivities for unquantifiable species; more work is required to further establish the correlation between calibration coefficients and binding enthalpies.

Further, using inter-method and offline calibrations, we estimate the detection limits of HOI, HIO₃, I₂, and H₂SO₄ in Br-MION-CIMS being 5.8×10^6 , 1.2×10^5 , 3.8×10^5 , and 2.0×10^5 molec cm⁻³, respectively, for a 2-min integration time during a two-hour period. To our knowledge, the simultaneous measurements of various iodine species and sulfuric acid with low detection limits are unprecedented for online techniques. Detection limits for HOI and HIO₃ in the Br-FIGAERO-CIMS are 3.3×10^7 and 5.1×10^6 molec cm⁻³, which are in general one order of magnitude higher than those in the Br-MION-CIMS. The signal comparison between the two instruments also shows that the Br-CIMS can be coupled to both the atmospheric pressure and the reduced pressure interfaces for iodine species and sulfuric acid measurements in the marine environment.

Data availability. Data available on request from the authors.

Author Contributions. M.W., X.-C.H., Y.-J.T and H.F. wrote the manuscript. X.-C.H., Y.-J.T., M.W. and M.Sip. designed the experiments. X.-C.H., Y.-J.T. and J.S. carried out the Br-MION-CIMS measurements, M.W., D.C. and V.H. carried out the Br-FIGAERO-CIMS measurements, and H.F. carried out the CE-DOAS measurements. Y.-J.T., X.-C.H., H.F., D.C., J.S. and M.Sim. performed the calibrations. S.I., X.-C.H. and T.K. carried out the quantum chemical calculations. M.W. performed the comparison analysis of the Br-FIGAERO-CIMS and Br-MION-CIMS. N.-M.D., T.K., M.R., R.V. and M.Sip. commented on the manuscript. All other co-authors participated in either the development and preparations of the CLOUD facility and the instruments, and/or collecting and analyzing the data.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgement. We thank the European Organization for Nuclear Research (CERN) for supporting CLOUD with important technical and financial resources and for providing a particle beam from the CERN Proton Synchrotron. We also thank Juhani Virkanen and Heini Ali-Kovero for providing assistance in the laboratory analytical experiments.

Financial support. This research has received funding from the US National Science Foundation (AGS-1531284, AGS-1801574 and AGS-1801280), Academy of Finland (projects: 296628, 328290, Centre of Excellence 1118615) and the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (GASPARCON, grant agreement no. 714621). The FIGAERO-CIMS was supported by an MRI grant for the US NSF AGS-1531284 as well as the Wallace Research Foundation.

$\text{ICl} \cdot \text{Br}^- \rightarrow \text{ICl} + \text{Br}^-$	33.8
$\text{ICl} \cdot \text{Br}^- \rightarrow \text{IBr} + \text{Cl}^-$	39.8
$\text{ICl} \cdot \text{Br}^- \rightarrow \text{BrCl} + \text{I}^-$	42.0
$\text{IBr} \cdot \text{Br}^- \rightarrow \text{IBr} + \text{Br}^-$	36.7
$\text{IBr} \cdot \text{Br}^- \rightarrow \text{Br}_2 + \text{I}^-$	39.4
$\text{H}_2\text{SO}_4 \cdot \text{Br}^- \rightarrow \text{H}_2\text{SO}_4 + \text{Br}^-$	41.1
$\text{H}_2\text{SO}_4 \cdot \text{Br}^- \rightarrow \text{HSO}_4^- + \text{HBr}$	27.9

798

799 **Table 3: Calibration coefficients for selected species.**

Species	Calibration coefficient (molec cm ⁻³ cps cps ⁻¹)	Detection limit (molec cm ⁻³)
^a I ₂	2.7×10 ¹⁰	3.8×10 ⁵
^a H ₂ SO ₄	4.1×10 ¹⁰	2.0×10 ⁵
^b I ₂	6.3×10 ¹⁰	8.8×10 ⁵
^b Cl ₂	3.5×10 ¹¹	n/a
^b HOI	3.3×10 ¹¹	5.8×10 ⁶
^c HIO ₃	4.1×10 ¹⁰	1.2×10 ⁵

800 ^a Inter-method calibrations

801 ^b Offline calibrations

802 ^c Derived from dissociation enthalpies
