Abstract. Iodine species are important in the marine atmosphere for oxidation and new-particle formation. Understanding iodine chemistry and iodine new-particle formation requires high time resolution, high sensitivity, and simultaneous measurements of many iodine species. Here, we describe the application of bromide chemical ionization mass spectrometers (Br-CIMS) to this task. During the iodine oxidation experiments in the Cosmics Leaving Outdoor Droplets (CLOUD) chamber, we have measured gas-phase iodine species and sulfuric acid using two Br-CIMS, one coupled to a Multi-scheme chemical IONization inlet (Br-MION-CIMS) and the other to a Filter Inlet for Gases and AEROSols inlet (Br-FIGAERO-CIMS). From offline calibrations and inter-comparisons with other instruments, we have quantified the sensitivities of the Br-MION-CIMS to HOI, I₂, and H₂SO₄ and obtain detection limits of 5.8×10⁶, 3.8×10⁵, and 2.0×10⁵ molec cm⁻³, respectively, for a 2-min integration time. From binding energy calculations, we estimate the detection limit for HIO₃ to be 1.2×10⁵ molec cm⁻³, based on an assumption of maximum sensitivity. Detection limits in the Br-FIGAERO-CIMS are around one order of magnitude higher than those in the Br-MION-CIMS; for example, the detection limits for HOI and HIO₃ are 3.3×10⁷ and 5.1×10⁶ molec cm⁻³, respectively. Our comparisons of the performance of the MION inlet and the FIGAERO inlet show that bromide chemical ionization

46 mass spectrometers using either atmospheric pressure or reduced pressure interfaces are well-matched to measuring
47 iodine species and sulfuric acid in marine environments.

48

49 **1 Introduction**

50 Reactive iodine species are released into the atmosphere mainly by biological processes in marine environments (i.e.
51 from macro- and micro-algae) (McFiggans et al., 2004), O₃ deposition on the sea surface (Carpenter et al., 2013), as
52 well as from the sea ice (Spolaor et al., 2013) and snowpack in the polar region (Raso et al., 2017). Once emitted,
53 iodine species can modify atmospheric oxidative capacity via a chain of catalytic reactions with O₃ that form iodine
54 oxides, leading to about 20–28 % of O₃ loss in the marine boundary layer (Prados-Roman et al., 2015; Sherwen et al.,
55 2016). Through convection, reactive iodine species can be transported from the lower troposphere to the upper
56 troposphere-lower stratosphere, causing one third of the iodine-induced ozone loss in the upper troposphere-lower
57 stratosphere (Koenig et al., 2020). Another important effect of iodine species is their contribution to atmospheric new-
58 particle formation. O’Dowd et al. (O’Dowd et al., 2002) showed that particles are produced from condensable iodine-
59 containing vapors at a coastal location (Mace Head in Ireland). Recent studies have demonstrated that iodine oxoacids
60 (iodous acid, HIO₂ and iodic acid, HIO₃) dominate the iodine cluster formation processes (He et al., 2021a, 2021b),
61 and drive the bursts of freshly-formed particles in coastal regions (Sipil ä et al., 2016). This process thereby may
62 enhance cloud condensation nuclei formation, affecting climate both directly and indirectly (Saiz-Lopez et al., 2012;
63 Simpson et al., 2015).

64

65 Understanding iodine chemistry and iodine driven new-particle formation requires high time resolution, high
66 sensitivity, and simultaneous measurements of iodine species. However, this has been a long-standing challenge due
67 to their low abundance and short atmospheric lifetimes. Previous studies have achieved detection of relatively more
68 abundant molecular iodine (I₂), iodine monoxide (IO), and iodine dioxide (OIO) via optical spectroscopy, such as
69 differential optical absorption (Leigh et al., 2010), cavity ring-down (Bitter et al., 2005), cavity enhanced absorption
70 (Vaughan et al., 2008), laser-induced fluorescence (Dillon et al., 2006), and resonance fluorescence (Gómez Mart í
71 et al., 2011). The spectroscopic techniques are invaluable; however, their very specificity limits them to the detection
72 of a few iodine compounds, and they are less sensitive to other iodine species that have congested or broad absorption
73 features, such as hypiodous acid (HOI) and iodic acid (HIO₃).

74

75 Another commonly used technique is mass spectrometry; it has a fast response time and a low detection limit, but
76 extra calibration efforts are needed for the quantification of the detection sensitivity. For example, photoionization
77 (Gómez Mart í et al., 2013) and chemical ionization mass spectrometry (CIMS) have been employed to detect a suite
78 of halogen species. Reagent ions used with CIMS include: SF₅⁻ for HCl and ClONO₂ (Marcy et al., 2004); iodide (I⁻)
79 for atmospheric chlorine and bromine species such as ClONO₂, Cl₂, ClO, BrO, and BrCl (Kercher et al., 2009; Lee et
80 al., 2018; Tham et al., 2016); superoxide (O₂⁻) for molecular iodine (I₂) (Finley and Saltzman, 2008); and both nitrate
81 (NO₃⁻) (Sipil ä et al., 2016) and protonated water (H₃O⁺) (Pfeifer et al., 2020) for HIO₃. The nitrate-CIMS and H₃O⁺-

82 CIMS suffer from the limited analyte affinity to the reagent ions. The iodide-CIMS can effectively measure chlorine
83 and bromine species, but it is not suitable to detect iodine species due to the ambiguity in peak identification.

84
85 The bromide ion (Br^-) exhibits an affinity to a wide spectrum of iodine containing species. Br-CIMS has been routinely
86 used to measure chlorine species (Lawler et al., 2011), HO_2 radicals (Sanchez et al., 2016), organic vapors and sulfuric
87 acid (Rissanen et al., 2019), and nitric acid (Wang et al., 2020). Like chlorine species, iodine species are known to
88 cluster with bromide ions via halogen (or hydrogen) bonds; as such, here we explore using the Br-CIMS to measure
89 gas-phase iodine species and sulfuric acid simultaneously at concentrations relevant to the marine boundary layer. In
90 this study, we demonstrate the detection of various gas-phase inorganic iodine species with the Br-CIMS and explore
91 the effect of relative humidity (RH) on that detection. We then quantify the sensitivities of several gas-phase iodine
92 species via inter-method calibration, offline calibration, and quantum chemical calculations. Finally, we compare the
93 performance of Br-MION-CIMS and Br-FIGAERO-CIMS and show that both of them are well-suited for iodine
94 species measurement in the marine boundary layer.

95 96 **2 Methodology**

97 **2.1 The CLOUD facility**

98 We conducted measurements and instrument inter-comparison at the CERN CLOUD facility, a 26.1 m^3
99 electropolished stainless-steel chamber that enables new-particle formation experiments simulating the typical range
100 of tropospheric conditions with scrupulous cleanliness and minimal contamination (Duplissy et al., 2016; Kirkby et
101 al., 2011). The CLOUD chamber is mounted in a thermal housing, capable of keeping temperature constant in a range
102 of $-65 \text{ }^\circ\text{C}$ and $+100 \text{ }^\circ\text{C}$ with $\pm 0.1 \text{ }^\circ\text{C}$ precision (Dias et al., 2017) and relative humidity commonly between $< 0.5 \%$
103 and 80% . Photochemical processes are driven by different light sources, including four 200 W Hamamatsu Hg-Xe
104 lamps with significant spectral irradiance between 250 and 450 nm , and an array of 48 green light LEDs at 528 nm
105 with adjustable optical power up to 153 W . Ion-induced nucleation under different ionization levels is simulated with
106 a combination of electric fields (electrodes at $\pm 30 \text{ kV}$ at top and bottom of the chamber) which can be turned on to
107 rapidly scavenge smaller ions, and a high-flux beam of 3.6 GeV pions (π^+) which enhances ion production when turned
108 on. Mixing is accelerated with magnetically coupled fans mounted at the top and bottom of the chamber. The
109 characteristic gas mixing time in the chamber during experiments is a few minutes. The loss rate of condensable vapors
110 onto the chamber wall is comparable to the condensation sink in pristine boundary layer environments (e.g. 2.2×10^{-3}
111 s^{-1} for H_2SO_4 at $5 \text{ }^\circ\text{C}$). To avoid a memory effect between different experiments, the chamber is periodically cleaned
112 by rinsing the walls with ultra-pure water and heating to $100 \text{ }^\circ\text{C}$ for at least 24 hours, ensuring extremely low
113 contaminant levels of sulfuric acid ($< 5 \times 10^4 \text{ cm}^{-3}$) and total organics ($< 150 \text{ pptv}$) (Kirkby et al., 2016; Schnitzhofer
114 et al., 2014). The CLOUD gas system is also built to the highest technical standards of cleanliness and performance.

115
116 The dry air supply for the chamber is provided by cryogenic nitrogen (Messer, 99.999%) and cryogenic oxygen
117 (Messer, 99.999%) mixed at the atmospheric ratio of $79:21$. Ultrapure water vapor, ozone and other trace gases can
118 be precisely added to attain desired mixing ratios at different levels. The total injection rate of the humidified air is

119 fixed at 330 standard liters per minute (slpm) to compensate for the sampling consumption of various instruments.
120 Molecular iodine (I_2) is injected into the chamber by passing a flow of cryogenic nitrogen through a crystalline iodine
121 (I_2 , Sigma-Aldrich, 99.999 % purity) reservoir, which is temperature-controlled at 10 °C, to achieve levels of 0.4 to
122 168 pptv in the chamber. The sulf inert-coated injection lines are temperature stabilized to minimize line conditioning
123 effects. High intensity green light emitting diodes (LEDs) are used to photolyze molecular iodine into iodine atoms
124 and initiate the subsequent oxidation reactions in the presence of ozone and water vapor. The 48 green LEDs (light
125 sabre 4, LS4) are mounted in pairs (one upward facing, one downward facing) on a copper cooling bar within a long
126 quartz jacket that protrudes into the chamber in the mid plane. The maximum total optical power output is 153 W,
127 centered on 528 nm. Actinic fluxes are regulated by controlling the number of LEDs used and the set point of
128 individual LEDs. Light fluxes are monitored by two photodiodes and a spectrometer.

129

130 **2.2 Br-MION-CIMS**

131 We measured gas-phase iodine species with a bromide chemical ionization atmospheric pressure interface time-of-
132 flight mass spectrometer (Junninen et al., 2010) coupled with a Multi-scheme chemical IONization inlet (Br-MION-
133 CIMS) (Rissanen et al., 2019). The Br-MION inlet consists of an electrically grounded 24 mm inner diameter stainless
134 steel flow tube, attached to an ion source. For the CLOUD measurements, the length of the sampling inlet was ~1.5
135 m and was designed to be in a laminar flow with a fixed total flow rate of 32 standard liters per minute (slpm). An ion
136 filter, operated with positive and negative voltage, was placed at the front of the inlet to filter out any ions in the
137 sample air prior to ion-molecule reaction chamber in the inlet. The reagent ions, bromide (Br^-) and the bromide-water
138 cluster ($H_2O Br^-$), were produced by feeding 25 standard milliliters per minute (mlpm) of nitrogen (N_2) flow through
139 a saturator containing dibromomethane (CH_2Br_2 ; > 99.0 %, Tokyo Chemical Industry) into the ion source, where the
140 reagent was ionized by soft X-ray radiation. The resulting ions were then accelerated by a 2800 V ion accelerator array
141 and focused by a 290 V ion deflector into the laminar sampling flow of the inlet via a 5 mm orifice. A small counter
142 flow (~40 mlpm) was applied through the orifice to prevent any mixing of the electrically neutral reagent vapor with
143 the sampling flow. The details of the inlet design, setup, and operation are described previously (He, 2017; Rissanen
144 et al., 2019).

145

146 **2.3 Br-FIGAERO-CIMS**

147 We also measured both the gas- and particle-phase compositions via thermal desorption using a bromide chemical
148 ionization time-of-flight mass spectrometer equipped with a Filter Inlet for Gases and AEROSols (Br-FIGAERO-
149 CIMS) (Lopez-Hilfiker et al., 2014). FIGAERO is a manifold inlet for a CIMS with two operating modes. In the
150 sampling mode, gases are directly sampled into a 150 mbar ion-molecule reactor, using coaxial core sampling to
151 minimize their wall losses in the sampling line. The total flow is maintained at 18.0 slpm and the core flow at 4.5 slpm;
152 the CIMS samples at the center of the core flow with a flow rate at ~1.6 slpm. Concurrently, particles are collected on
153 a PTFE filter via a separate dedicated port with a flow rate of 6 slpm. In the desorption mode, the filter is automatically
154 moved into a pure N_2 gas stream flowing into the ion molecule reactor, while the N_2 is progressively heated upstream

155 of the filter to evaporate the particles via temperature programmed desorption. Analytes are then chemically ionized
156 by Br^- and extracted into a mass spectrometer.

157
158 We optimize the adduct-ion signals in both the Br-MION-CIMS and Br-FIGAERO-CIMS by tuning the electric field
159 strengths in the first two low-pressure stages of the mass spectrometer as weak as possible to minimize collision
160 induced cluster fragmentation while maintaining sufficient ion transmission. Optimization is achieved by maximizing
161 the ratio of $\text{I}_2\text{Br}^-/\text{Br}^-$ at a constant I_2 concentration. We list relevant instrument specifications and operational
162 conditions in Table S1. It should be noted that these values are specific to our instruments, thus can vary according to
163 instrument parameters and may not be applicable to other instruments.

164 165 **2.4 CE-DOAS**

166 For the quantitative measurement of gas-phase molecular iodine (I_2), we deployed a Cavity Enhanced Differential
167 Optical Absorption Spectroscopy instrument (CE-DOAS) (Meinen et al., 2010). CE-DOAS determines concentrations
168 of trace gases from the strength of differential spectral features in a reference spectrum. The overall accuracy for the
169 I_2 time series is estimated to be 20 %, never better than the detection limit (3-sigma precision), resulting from the
170 uncertainty in cross sections and the stability of the baseline. It is thus an absolute method and does not depend on an
171 instrument specific detection efficiency. To maximize the measurement sensitivity towards I_2 , we used a setup
172 optimized for the green wavelength range (508-554 nm), where I_2 exhibits strong differential absorption features. The
173 measurement light is provided by a green light emitting diode (LED Engin). Spectral dispersion is established with a
174 Czerny-Turner grating spectrometer (Princeton Instruments Acton 150), resulting in an optical resolution of 0.73 nm
175 full width at half maximum at 546 nm. Intensities are monitored with a CCD detector (Princeton Instruments
176 PIXIS400B) cooled to -70°C . Highly reflective mirrors (Advanced Thin Films) enhance the 1 m mirror separation to
177 an effective optical path length of 15-23 km. The effective spectral mirror reflectivity was established by comparing
178 light intensity spectra in the presence of N_2 and He (Washenfelder et al., 2008). The abundance of trace gases is then
179 determined by comparing spectra of chamber air relative to reference spectra recorded with ultrapure N_2 without I_2 .
180 Chamber air is drawn into the cavity with a constant flow rate of 1 slpm. Variations of the sampling flow did not result
181 in changes in measured I_2 concentrations, indicating that photolysis from the measurement light within the instrument
182 was negligible. The following absorbers were included in the fit: I_2 (Spietz et al., 2006), NO_2 (Vandaele et al., 1998),
183 H_2O (Rothman et al., 2010), $\text{O}_2\text{-O}_2$ collision-induced absorption (Thalman and Volkamer, 2013), and a polynomial of
184 sixth order. The setup allowed a 1-minute detection limit of 25 pptv, or 8 pptv for integration times of 10 minutes,
185 respectively. Periodic automated recordings of N_2 reference spectra were recorded to ensure baseline stability. The
186 optical path length at the time of measurement was continuously confirmed for consistency by the measurement of
187 the $\text{O}_2\text{-O}_2$ collision-induced absorption and H_2O column in the same analysis window. The overall systematic accuracy
188 for the I_2 time series is estimated to be 20 %, never better than the detection limit, resulting from the uncertainty in
189 cross sections and the stability of the baseline.

190 191 **2.5 Offline calibration setup**

192 2.5.1 I₂ permeation device

193 We used an iodine permeation tube (VICI Metronic) as a source for offline laboratory calibration. The permeation
194 tube was encased within an electronically controlled heating mantle (80 ~ 140 (± 2) °C) to allow for adjustable yet
195 steady iodine permeation rates. The heating device (for holding the permeation tube) was made from a stainless steel
196 tube (½-inch outer diameter, OD) with a length of 25 cm, encased within an electronically controlled heating mantle.
197 The configuration of the permeation device has been described in Tham et al. (Tham et al., 2021). The iodine
198 permeation device was run continuously for at least 72 hours before any calibration experiments to ensure that a
199 complete equilibrium was reached in the system. We then confirmed the robustness of the permeation device by the
200 constant I₂ signal measured with Br-MION-CIMS for over 24 hours.

201
202 To determine the permeation rate of I₂, we trapped iodine in n-hexane at cryogenic temperatures in an all-glass
203 apparatus, following the method described in Chance et al. (Chance et al., 2010). We initially filled the absorption
204 glass vessel with 20 ml n-hexane (99.95 %, Merck), and then weighed it to determine the combined mass. We then
205 immersed the absorption vessel into a wide-necked Dewar vessel, filled with an acetone/dry ice mixture (at $-80 \pm$
206 3 °C). After temperature equilibration, the I₂ molecules, carried by 50 mlpm N₂ flow from the permeation device, were
207 bubbled through the absorption vessel. After a continuous collection for 5 hours, we removed the absorption apparatus
208 from the cooling mixture, and allowed it to warm to room temperature prior to disassembling the setup to prevent any
209 losses of iodine on the tip of the inlet capillary. The absorption vessel was then re-weighed; the mass compared with
210 that prior to absorption was less than 2 %, indicating a negligible loss during the trapping process. The I₂ / n-hexane
211 sample solutions were stored at 4 °C for 14 hours before being subjected to analysis.

212
213 We determined the I₂ concentration of the samples using a UV/Vis spectrophotometer (Shimadzu Model UV2450) at
214 a wavelength of 522 nm. We established a calibration curve via a set of I₂ solutions ranging from 270 to 5300 nmol,
215 diluted with n-hexane from a freshly prepared stock solution (0.5 g L⁻¹). Repetition of the same analysis after 2 and 7
216 days yielded identical results, confirming that the sample solutions were stable at 4 °C. As an alternative analytical
217 approach, we also quantified the I₂ concentration in the sample solutions using an inductively coupled plasma mass
218 spectrometer (ICP-MS, Agilent 7800). Before introducing to the ICP-MS, the sample solutions were treated with
219 NaHSO₃ water solution (0.100 M), accomplishing efficient hexane-to-water extraction and simultaneous reduction of
220 iodine to iodide (Schwehr et al., 2005) (Agilent Clinical Sample Preparation Guide (v3), *ref.* ISO 17294-2). The ICP-
221 MS results were in good agreement (within 20 % discrepancies) with those from the UV/Vis spectrophotometry.

222
223 We conducted the I₂ trapping and quantification experiments in triplicate with satisfactory reproducibility (standard
224 deviation < 10 %). The calculated iodine permeation rate at 50 mlpm N₂ flow and 140 °C oven temperature is $278 \pm$
225 12 ng min⁻¹ (mean \pm standard deviation). This result was used as the benchmark to estimate temperature-corrected
226 permeation rates according to the formula provided by the permeation tube vendor (VICI Metronic). We checked the
227 validity of the temperature-corrected values by conducting a second iodine absorption experiment in which the iodine

228 permeation tube was kept at 130 °C with an N₂ flow rate of 50 mlpm, and the determined permeation rate agreed
229 within 10 % of the calculated value.

230

231 2.5.2 Cl₂ permeation device

232 We used a commercial chlorine permeation tube (VICI Metronic) as a source for offline calibration. We passed a 20
233 mlpm high-purity nitrogen (99.999 %) flow at room temperature through a 25 cm long stainless-steel tube (½" O.D.)
234 containing the permeation tube. We quantified the permeation rate of Cl₂ following a procedure described in a previous
235 study (Finley and Saltzman, 2008). The output of 20 mlpm flow was bubbled into a buffered aqueous potassium iodide
236 solution (2.0 % KI (*m/v*), prepared in 1.00 mM aqueous phosphate buffer, pH = 7.0) filled in an all-glass two-stage
237 serial absorption apparatus (stage 1 = 100 ml; stage 2 = 50 ml) for 3 hours and kept at room temperature. The Cl₂
238 oxidized the iodide (I⁻) into iodine (I₂) once contacting with the KI absorption solution, and the I₂ further reacted with
239 the excess KI present in the absorption solution to form I₃⁻, which can be quantified by UV/Vis-spectrophotometry.
240 We analyzed the resulting sample solutions with an UV/Vis spectrophotometer (Shimadzu Model UV-1800) using 1-
241 cm quartz cells at 352 nm, corresponding to the I₃⁻. We detected no I₃⁻ in the second stage absorption solution,
242 indicating that all the chlorine was quantitatively trapped and rapidly converted to I₃⁻ within the first absorption unit.
243 The samples were quantified relative to I₃⁻ standards in the range of 5 to 68 × 10⁻⁶ M, prepared by dilution of a stock
244 obtained by dissolving 174 mg iodine in 200 ml of a solution containing 2 % KI in 1.00 mM aqueous phosphate buffer,
245 pH 7.0. From this calibration curve, we calculated a molar absorptivity of 26,800 L mol⁻¹ cm⁻¹, which is consistent
246 with the values reported in the literature (Finley and Saltzman, 2008; Kazantseva et al., 2002). Samples and standard
247 solutions were re-analyzed after being stored in the dark at room temperature for 24 hours, and the results were within
248 3 % of those obtained with the fresh solutions. We repeated the absorption experiment, and the calculated chlorine
249 permeation rate at room temperature was 764 ± 74 ng Cl₂ min⁻¹ (mean ± standard deviation).

250

251 2.5.3 HOI calibrator

252 We produced a continuous HOI source via the reaction of I₂ and hydroxyl radicals (OH) in a setup similar to the
253 sulfuric acid (H₂SO₄) calibrator (Kürten et al., 2012). The OH was generated by photolyzing H₂O with a mercury (Hg)
254 lamp at 184.9 nm, whose calibrated intensity was used to estimate the OH concentration. We tested the system by
255 removing the I₂ or OH source from the calibrator, upon which HOI production was undetectable, confirming that any
256 single reactant did not produce HOI. A numerical model was constructed to predict the mean HOI concentration
257 entering the Br-MION-CIMS, which is analogous to the model used for H₂SO₄ calibration (Kürten et al., 2012). We
258 only included the formation pathway of I₂ + OH to HOI in the model for simplicity; the other pathway of IO + HO₂
259 was considered minor as its reaction rate is about an order of magnitude slower than that of I₂ + OH. Furthermore, IO
260 is likely at negligible concentration in the calibration device due to the absence of O₃ for IO formation.

261

262 2.6 Quantum chemical calculations

263 We used quantum chemical calculations to estimate the cluster formation enthalpy of halogen containing species and
264 bromide ions. The initial conformational sampling was performed using the Spartan '14 program. The cluster

265 geometry was then optimized using density function theory methods at the ω B97X-D/aug-cc-pVTZ-PP level of theory
266 (Chai and Head-Gordon, 2008; Kendall et al., 1992). Iodine pseudopotential definitions were taken from the EMSL
267 basis set library (Feller, 1996). Calculations were carried out using the Gaussian 09 program (Frisch et al., 2010). An
268 additional coupled-cluster single-point energy correction was carried out on the lowest energy geometry to calculate
269 the final cluster formation enthalpy. The coupled-cluster calculation was performed at the DLPNO-CCSD(T)/def2-
270 QZVPP level using the ORCA program ver. 4.0.0.2 (Neese, 2012; Riplinger and Neese, 2013). In Table 1 we present
271 calculated cluster formation enthalpies based on the optimized geometries.

272

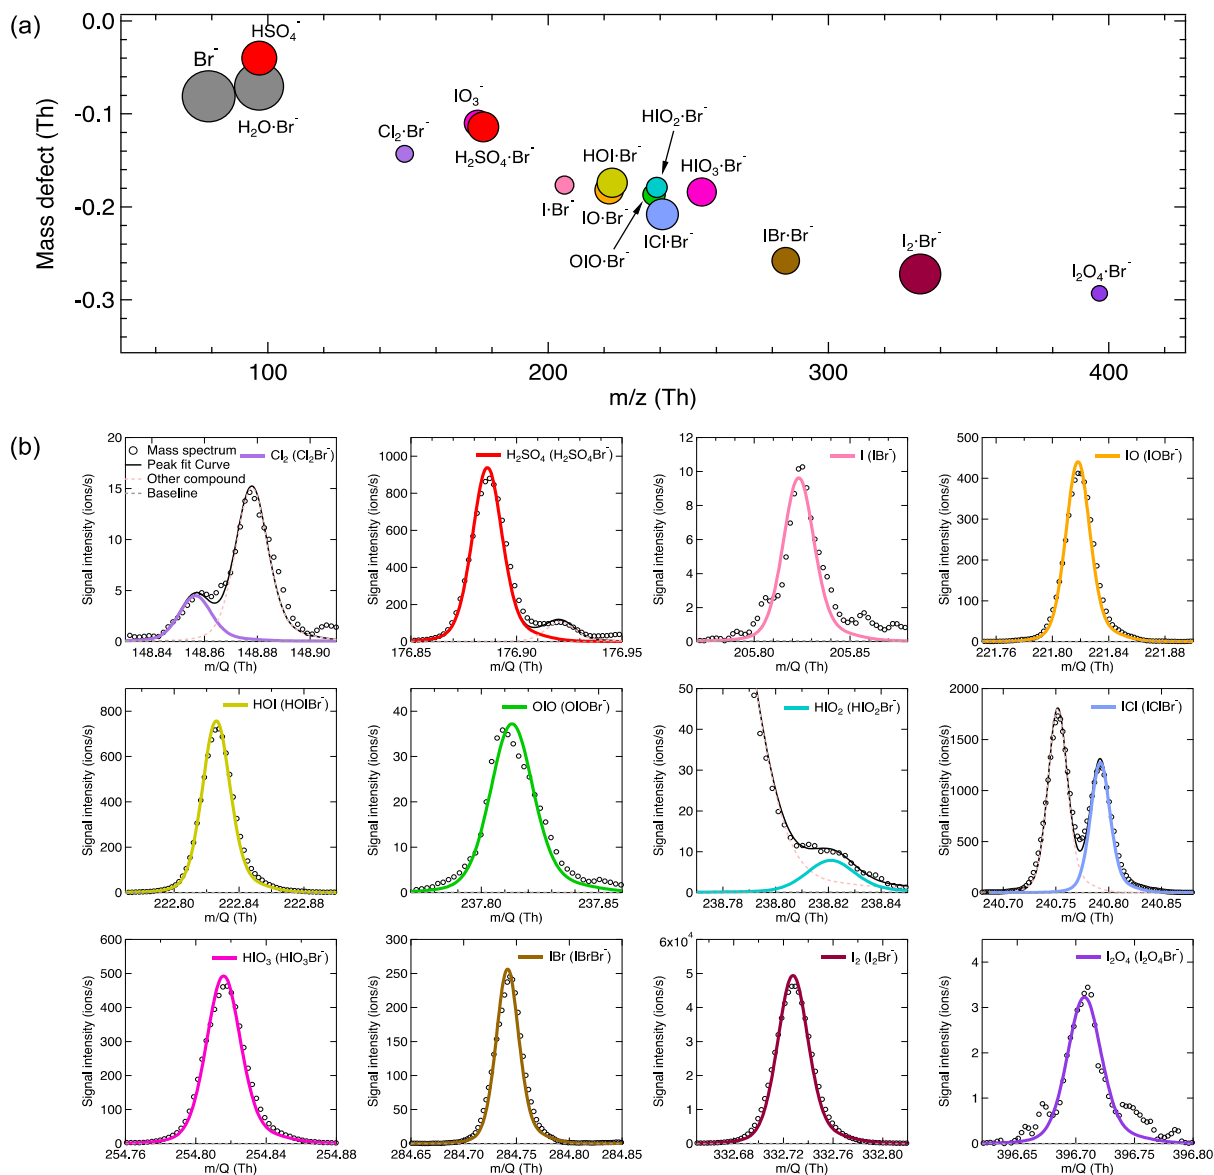

273 **3 Results and Discussion**

274 **3.1 Detection of gas-phase inorganic species by Br-MION-CIMS**

275 We show in Fig. 1 the selected inorganic species observed with the Br-MION-CIMS during an iodine oxidation
276 experiment in the CLOUD chamber. The peak identities are indicated in the labels. Observed species include I_2 and
277 its various oxidation products. There are also a few other halogen-containing inorganic species such as Cl_2 , ICl and
278 IBr , likely coming from the impurities in the iodine source. Non-halogen inorganic species such as H_2SO_4 can also
279 react with bromide ions and are detected. Due to the large negative mass defect of the bromine and iodine atoms, and
280 the high resolution (~ 10000 Th Th^{-1}) of the mass spectrometer, the peaks can be unambiguously distinguished and
281 identified in the mass spectrum. As shown in the lower panel of Fig. 1, most of the iodine-containing species appear
282 as a single peak in the unit mass range, except for HIO_2 $^{79}Br^-$ ($m/z = 238.82$), which overlaps with the reagent ion
283 cluster ($^{79}Br_2^{81}Br^-$) ($m/z = 238.75$).

284

285 The iodine oxidation experiments were conducted under experimental conditions typically found in the high-latitude
286 marine boundary layer, with a temperature of -10 °C and a relative humidity of 69 %. As illustrated in Fig. 2, a typical
287 experiment started with illumination of the chamber at constant I_2 (~ 60 pptv) using the green light to photolytically
288 produce I atoms. The subsequent reactions of I and ~ 40 ppbv O_3 led to the formation of various oxidized iodine
289 species within a few minutes. The most prominent species we observed from these experiments were IO, HOI and
290 HIO_3 , with lower but significant levels of OIO, HIO_2 , and I_2O_4 . Among these iodine oxides, IO rose the most rapidly;
291 this is consistent with the first-generation production of IO from the $I + O_3$ reaction. After a few steps of radical
292 reactions, OIO, HIO_2 and HIO_3 reached steady state almost simultaneously. The only observed iodine oxide dimer was
293 I_2O_4 in this event, while I_2O_2 , I_2O_3 and I_2O_5 were below the detection limit of both mass spectrometers. A noticeable
294 dip in the HIO_3 traces a few minutes after the onset of the reactions is likely due to the participation of HIO_3 in new-
295 particle formation, resulting in an extra loss term and a lower steady-state concentration. When we turned off the green
296 light, the production of I radicals stopped and iodine species decayed away.

297
 298 **Figure 1.** Gas-phase inorganic species measured with the Br-MION-CIMS. (a) Mass defect (difference of exact mass to integer
 299 mass) versus m/z of gas-phase halogen species and sulfuric acid during an iodine oxidation experiment at 69 % relative humidity
 300 and $-10\text{ }^{\circ}\text{C}$ (conducted on 05 October 2018). Ions shown here are either clustered with or formed via proton transfer to a bromide
 301 ion. The area of the markers is proportional to the logarithm of the signal (counts per second). (b) The high-resolution single peak
 302 fits for species in the mass defect plot in the upper panel. Species in both panels are color-coded in the same style.
 303

304
 305 **Figure 2.** Evolution of selected iodine species during a typical run. The experiment was performed at 60 pptv I₂, 40 ppbv O₃, 69 %
 306 relative humidity and -10 °C. The oxidized iodine species start to appear soon after switching on the green light at 08:11, 05 October
 307 2018. The I atom production was halted at 10:21, 05 October 2018 by switching off the green light, and the concentration of
 308 oxidized iodine species decayed away afterwards. All species are color-coded in the same way as in Fig. 1.
 309

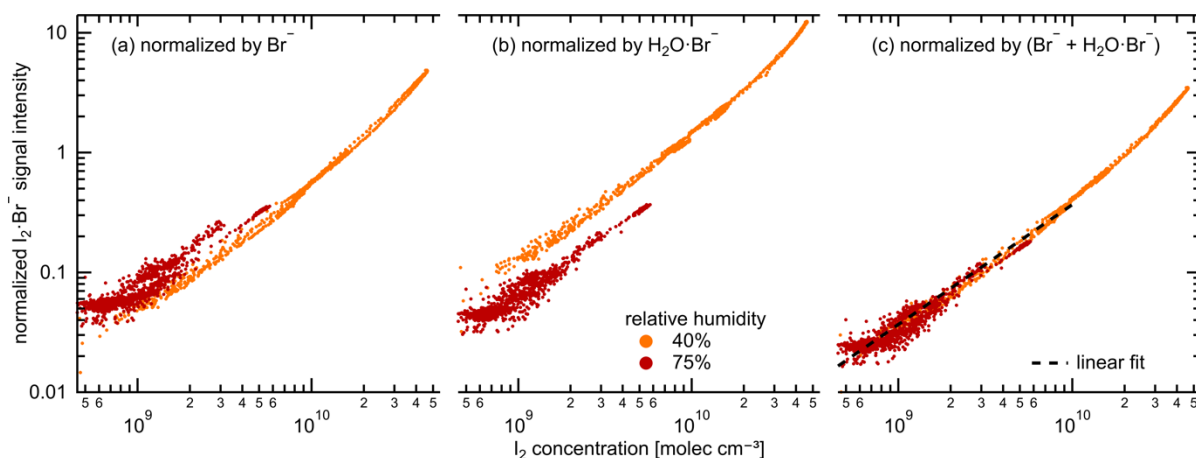

310 3.2 Relative humidity dependence

311 Water molecules can cluster with I⁻ to form H₂O I⁻ in the iodide CIMS. This enhances the instrument sensitivities for
 312 small molecules (i.e. chlorine and bromine) and reduces them for large molecules (i.e. oxygenated organics) (Lee et
 313 al., 2014). To investigate the role of water concentration in the sensitivity of the Br-MION-CIMS, we varied the
 314 relative humidity (RH) from 40 % to 80 % at a constant temperature of -10 °C. We show in Fig. 3 the correlation of
 315 I₂ time series from the Br-MION-CIMS and the CE-DOAS throughout the experiment.
 316

317 Chemical ionization relies on an ion-molecule reaction to transfer charge from a reagent ion to an analyte, forming
 318 either a product ion or a charged cluster between the analyte and the reagent ion with a rate coefficient k_{IM} . This occurs
 319 in an ion-molecule reactor, with a fixed flow rate and thus reaction time, dt , and ideally under pseudo first-order
 320 conditions where a small fraction of the analyte is ionized and the reagent ion concentration ($[Ion]$) remains constant.
 321 Under these (linear) conditions the fraction of analyte that is ionized is $k_{IM} \times [Ion] \times dt$. However, the primary ion
 322 source strength can vary with time, and so we normalize the analyte signal by reagent ion signal to account for those
 323 small variations in analyte signal.
 324

325 During the RH transition, the ratio of the two reagent ions, Br⁻ and H₂O Br⁻, changed in the Br-MION-CIMS. As
 326 shown in Fig. 3 (a) and (b), using either reagent ion alone for I₂ normalization results in discrepancies in recovered I₂
 327 concentrations at different RH. However, if we use the sum of these two reagent ions (Br⁻ + H₂O Br⁻) for normalization,
 328 the humidity effect vanishes, as shown in Fig. 3 (c). Separately, during the I₂ calibration using a permeation tube
 329 (section 3.3.2.1), the detection of I₂ molecules is robust and independent of RH between 20 % and 40 % at 25 °C, as
 330 long as a proper normalization method is used for the Br-MION-CIMS. Furthermore, we have also carried out the
 331 HOI calibration at 25 °C (section 3.3.2.3) and used the same normalization method. During the calibration, we varied

332 the water content in the calibrator to vary OH concentrations. A good correlation between the modeled HOI
 333 concentrations and the measured HOI signals also indicates that the different H₂O concentrations in the system do not
 334 affect the HOI detection (Fig.4(d)). This assertion may also be applicable to molecules such as iodine monochloride
 335 (ICl) and iodine monobromide (IBr), which share similar chemical and physical properties with I₂; however, further
 336 confirmation is needed for other species such as oxygenated organics.
 337

338 **Figure 3.** Signal normalization methods for the Br-MION-CIMS. Normalized I₂ Br⁻ signal intensity for variable I₂ concentrations,
 339 color coded by relative humidity (orange: 35-45 % relative humidity, red: 70-80 % relative humidity). The charger ions in the ion
 340 source of Br-MION-CIMS are Br⁻ and H₂O Br⁻ (both ⁷⁹Br and ⁸¹Br). Their abundance depends both on the instrument tuning and
 341 the absolute humidity of the sampled flow. The normalization of the I₂ Br⁻ signal by only Br⁻ (a) or H₂O Br⁻ (b) does not compensate
 342 for the humidity effect. Using the sum of Br⁻ and H₂O Br⁻ (c) for normalization yields a tight correlation to the true I₂ as measured
 343 by CE-DOAS, independent of the humidity. The black dashed line indicates the fitted linear calibration.
 344
 345

346 3.3 Quantification of gas-phase inorganic species

347 Inter-method calibrations and offline calibrations were carried out to quantify the sensitivities of the Br-MION-CIMS
 348 to selected calibrants. For the inter-method calibrations, we used the CLOUD chamber as a stable source of I₂ and
 349 H₂SO₄, and inter-compared the signals in the Br-MION-CIMS with the CE-DOAS and a pre-calibrated nitrate-CIMS,
 350 respectively. For the offline calibrations, we carried out the experiments separately in a laboratory at the University
 351 of Helsinki, using permeation tubes to quantify I₂ and Cl₂, and a calibrator to quantify HOI.
 352

353 3.3.1 Inter-method calibrations at CLOUD

354 3.3.1.1 I₂ calibration using the CE-DOAS

355 As shown in Fig. 3, we use the accurate I₂ time series measured with the CE-DOAS to calibrate normalized I₂ signals
 356 in the Br-MION-CIMS. The I₂ concentrations used for the calibration span approximately 2 orders of magnitude,
 357 reaching up to 4.6 × 10¹⁰ molec cm⁻³. A linear fit, limited to I₂ concentrations smaller than 10¹⁰ molec cm⁻³, establishes
 358 the calibration factor as follows:

$$359 \quad [I_2] = 2.7 \times 10^{10} \text{ molec cm}^{-3} \times I_2 \text{ } ^{79}\text{Br}^- / (^{79}\text{Br}^- + \text{H}_2\text{O } ^{79}\text{Br}^-)$$

360 For this range of concentrations, which are typically encountered in the atmosphere, the calibrated Br-MION-CIMS
 361 time series agrees within error with the CE-DOAS measurement (1-sigma accuracy 20 %, detection limit 25 pptv for

362 1 min data). Deviations between both time series are generally smaller than 10 % (25 and 75 percentile 0.88 and 1.03,
363 respectively). These small differences may be explained by incomplete homogeneity of iodine concentrations in the
364 chamber and the different sampling positions of CE-DOAS and Br-MION-CIMS.

365

366 3.3.1.2 H₂SO₄ calibration using a nitrate-CIMS

367 We derive the H₂SO₄ calibration coefficient for the Br-MION-CIMS using the absolute H₂SO₄ concentrations
368 measured with a pre-calibrated nitrate-CIMS. The calibration protocol of H₂SO₄ in the nitrate-CIMS has been
369 described in detail previously (Kürten et al., 2012). The H₂SO₄ time series used for the inter-method calibration covers
370 a wide concentration range from less than 5.0×10⁴ (detection limit of the nitrate-CIMS) to 6.0×10⁷ molec cm⁻³. For
371 Br-MION-CIMS, although both HSO₄⁻ and H₂SO₄ Br⁻ appear as distinct peaks for sulfuric acid, we only use the
372 normalized H₂SO₄ ⁷⁹Br⁻ for the inter-calibration, as HSO₄⁻ (m/z = 96.96) has substantial interference from the reagent
373 ion H₂O ⁷⁹Br⁻ (m/z = 96.93). We show in Fig. 4 (a) the linear fit:

$$374 \quad [\text{H}_2\text{SO}_4] = 4.1 \times 10^{10} \text{ molec cm}^{-3} \times \text{H}_2\text{SO}_4 \text{ } ^{79}\text{Br}^- / (^{79}\text{Br}^- + \text{H}_2\text{O } ^{79}\text{Br}^-) - 9.3 \times 10^5$$

375 The H₂SO₄ calibration coefficient is thus 4.1×10¹⁰ molec cm⁻³ per normalized signal (cps cps⁻¹), and the correlation
376 coefficient between the two H₂SO₄ traces is 0.95. The systematic 3-sigma accuracy is +50/-33 % for H₂SO₄ calibration
377 using a nitrate-CIMS; detailed accuracy estimation has been discussed previously (Stolzenburg et al., 2020).

378

379 3.3.2 Offline laboratory calibrations for I₂, Cl₂, and HOI

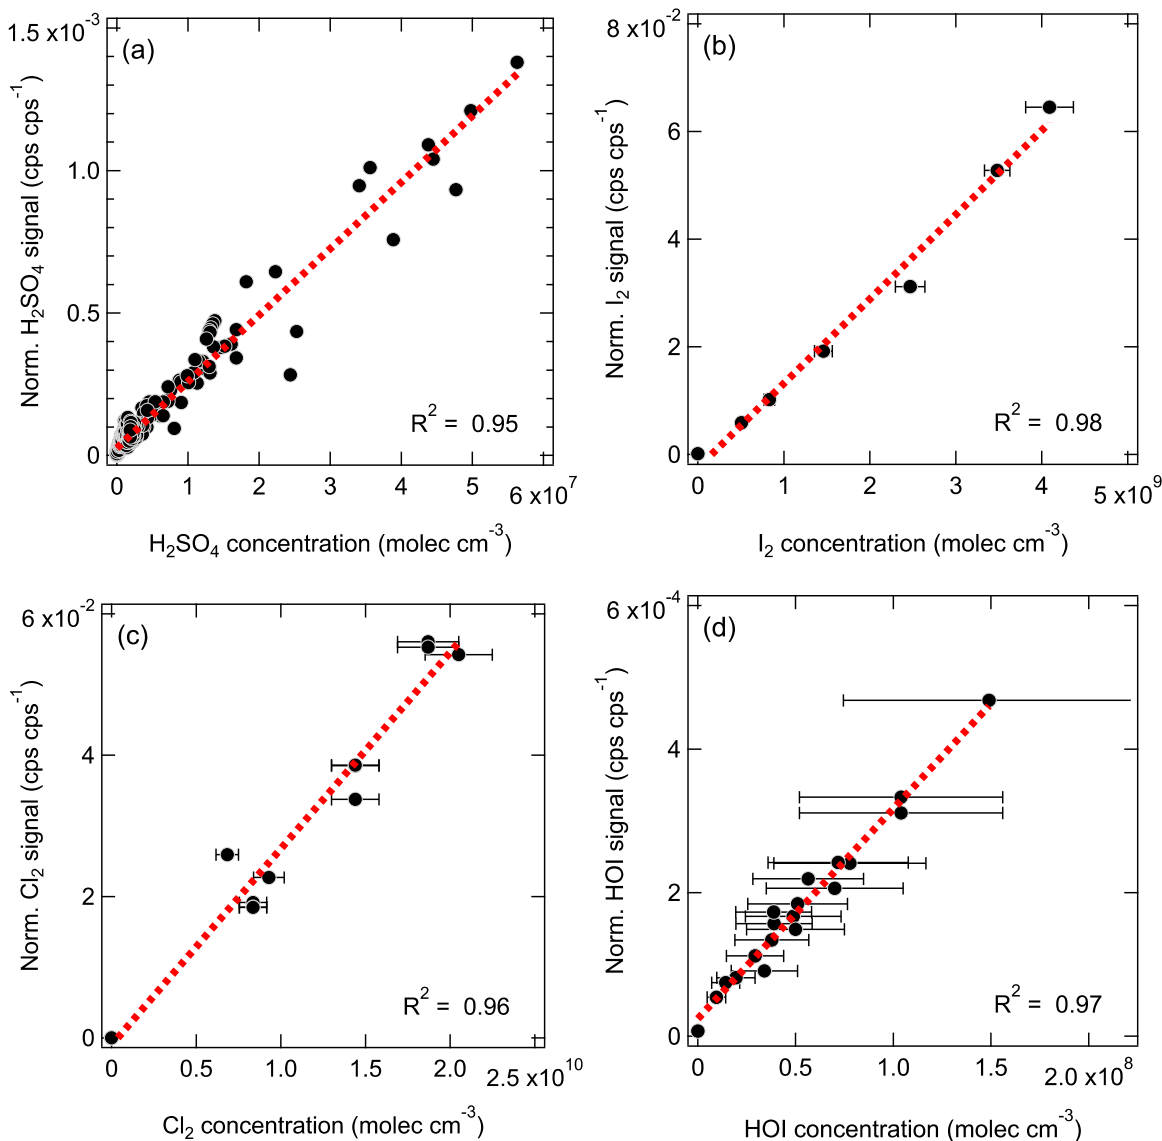

380 For the I₂ calibration, we diluted the I₂ flow to seven different values and measured the flow with the Br-MION-CIMS.
381 We repeated the calibration five times; we show the data along with a linear fit between the I₂ concentration and
382 normalized I₂ signal in Fig. 4 (b). The slope of the line gives a calibration coefficient of 6.3×10¹⁰ molec cm⁻³ per
383 normalized signal (cps cps⁻¹), with R² of 0.98 and an overall 1-sigma accuracy of ±45 %.

384

385 For the Cl₂ calibration, the Cl₂ permeation source was run continuously for 12 hours prior to calibration experiments
386 to ensure complete system equilibrium. A two-stage dilution system similar to the setup of (Gallagher et al., 1997)
387 was set up for diluting the output of the Cl₂ permeation device. The 20 mlpm of N₂ stream emerging from the Cl₂
388 permeation device (operated at room temperature) was diluted in a stream of 6 slpm of dry N₂. Then, a small fraction
389 of this mixture (50 to 300 mlpm) was further mixed with the total flow of 25 slpm of N₂ (20 slpm dry N₂ + 5 slpm
390 humidified N₂) before being sampled by the Br-MION-CIMS. The calibration coefficient for Cl₂ was determined to
391 be 3.5×10¹¹ molec cm⁻³ per normalized signal (cps cps⁻¹) from three separate calibration experiments (Fig 4 (c)), with
392 an 1-sigma accuracy of 30 %.

393

394 As for the HOI calibration, we produced a range of HOI concentrations by varying I₂ and OH concentrations in the
395 calibrator. We show in Fig. 4 (d) the linear correlation between the modeled HOI concentrations and measured HOI
396 signals. The slope of the fit corresponds to a calibration coefficient of 3.3×10¹¹ molec cm⁻³ per normalized signal (cps
397 cps⁻¹), with an overall 1-sigma accuracy of 55 %. The good correlation (R² = 0.97) including various H₂O levels also
398 indicates that H₂O concentrations did not affect the HOI detection.

400
 401 **Figure 4.** The normalized signals (cps cps^{-1}) vs. the absolute concentrations (molec cm^{-3}) measured with the Br-MION-CIMS for
 402 (a) H_2SO_4 , (b) I_2 , (c) Cl_2 , and (d) HOI. The red dashed lines are the linear fits. The overall 3-sigma accuracy of +50/-33 % on
 403 [H_2SO_4] is not shown here.
 404

405 3.3.3 Connecting sensitivity to binding enthalpy

406 Beyond the species for which we carried out calibrations, there are many more, especially iodine species, that cannot
 407 be directly calibrated due to a lack of authentic standards or generation methods. However, the sensitivity of an iodide-
 408 CIMS towards analytes can be predicted by the cluster binding enthalpy, calculated by relatively simple quantum
 409 chemical methods (Iyer et al., 2016). This holds for the Br-CIMS as well. In the instrument, ion clusters, formed from
 410 reactions between analytes and reagent ions, are guided and focused by ion optics during transmission to the detector.
 411 The electric forces applied to the clusters enhance their collision energies with carrier gas molecules. If sufficient
 412 energy is transferred during the collision, cluster fragmentation may occur, affecting the instrument sensitivity for the

413 analytes (Passananti et al., 2019). However, clusters with higher binding enthalpy will be more easily preserved and
414 detected. Analytes that bind to the reagent ions with enthalpies higher than a critical level are likely detected at
415 maximum sensitivity (kinetic-limited detection) by the instrument. For example, the calculated critical enthalpy is 25
416 kcal mol⁻¹ for the iodide-CIMS used in Iyer et al. (Iyer et al., 2016) and Lopez-Hilfiker et al. (Lopez-Hilfiker et al.,
417 2016), calculated at the DLPNO-CCSD(T)/def2-QZVPP//PBE/aug-cc-pVTZ-PP level of theory.

418

419 For the bromide chemical ionization, there are two types of fragmentation pathways:

420 1) Reversion to the original form of Br⁻ and analyte

422 2) Proton transfer from the analyte to Br⁻

424 where the X-H is the hydrogen bond donor. An analyte should be detected at the maximum sensitivity when the
425 dissociation enthalpy for the first pathway is either a) much higher than the critical enthalpy (dissociation of X-H Br⁻
426 to X-H and Br⁻ does not occur), or b) lower than the critical enthalpy, but much higher than that of the second pathway
427 (dissociation of X-H Br⁻ to X-H and Br⁻ may occur, but dissociation to X⁻ and HBr is the dominant pathway). Whether
428 the enthalpy for the second pathway is higher than the critical enthalpy does not directly affect the sensitivity, as both
429 X-H Br⁻ and X⁻ can be measured and counted. The sensitivity toward X-H would be reduced only when the first
430 reversion pathway occurs to a non-negligible extent. Taking H₂SO₄ as an example, the dissociation enthalpies for the
431 first and second pathways are 41.1 and 27.9 kcal mol⁻¹, respectively. If some of the H₂SO₄ Br⁻ dissociate, they
432 preferably become HSO₄⁻ and are detectable by the Br-CIMS. Thus, H₂SO₄ can be detected at the maximum sensitivity.

433

434 While we were unable to experimentally establish a correlation between sensitivities and binding enthalpies due to
435 limited quantifiable halogen species, we can predict the tentative critical enthalpy as the binding enthalpy of a species
436 that is likely detected at the maximum sensitivity. We list the cluster formation enthalpies for a selection of halogen
437 containing species in Table 1 and the corresponding cluster dissociation enthalpies in Table 2. Among all the
438 calibration coefficients listed in Table 3, H₂SO₄ and I₂ have the lowest calibration coefficients (highest sensitivities).
439 Thereby, we conclude that both H₂SO₄ and I₂ are detected at the maximum sensitivity, suggesting a critical enthalpy
440 not higher than 33.7 kcal mol⁻¹. We can then infer the sensitivity for other species that are difficult to calibrate by
441 comparing their binding enthalpies to those of the benchmark species. For example, ICl and IBr should have the
442 maximum sensitivity, since the dissociation enthalpies for ICl Br⁻ and IBr Br⁻ are both much higher than 33.7 kcal
443 mol⁻¹ (Table 2). Although HIO₃ Br⁻ has a lower dissociation enthalpy than the critical value, the favored dissociation
444 pathway is proton transfer (the second pathway); HIO₃ can thus be considered as a maximum sensitivity species
445 detectable as IO₃⁻ ions after proton transfer. This is consistent with the fact that both HIO₃ Br⁻ and IO₃⁻ are detected in
446 Figure 1, so is the case with H₂SO₄. We thus assume that HIO₃ has a kinetic calibration coefficient of 4.1 × 10¹⁰ molec
447 cm⁻³ cps cps⁻¹, the value for H₂SO₄. However, the lowest dissociation enthalpies of HOI Br⁻ and Cl₂ Br⁻ are 26.9 and
448 22.3 kcal mol⁻¹, respectively, consistent with their higher calibration coefficients of 3.3 × 10¹¹ and 3.5 × 10¹¹ molec cm⁻³
449 cps cps⁻¹. The dissociation enthalpies for IO Br⁻, OIO Br⁻, and HIO₂ Br⁻ are 24.5, 23.2, and 29.2 kcal mol⁻¹,

450 respectively. We would expect that their sensitivities are lower than the maximum sensitivity. Since the dissociation
451 enthalpies for IO Br⁻ and OIO Br⁻ are between those of HOI Br⁻ and Cl₂ Br⁻, a similar calibration coefficient may be
452 applied, but direct calibrations are more preferable. We note that when transferring the calibration factor from one
453 species to another, the diffusivity difference should be accounted, since it affects the inlet line loss. This factor is not
454 considered in the cluster enthalpies calculations.

455
456 Further, we estimate the detection limit of the calibrated species. The detection limit is defined as the analyte
457 concentration, corresponding to the sum of the mean signal and three times the standard deviations (3σ) of the
458 background fluctuations during a two-hour background measurement. We derive the detection limit of HOI, HIO₃, I₂,
459 and H₂SO₄ to be 5.8×10⁶, 1.2×10⁵, 3.8×10⁵, and 2.0×10⁵ molec cm⁻³ (or 0.2, 0.005, 0.015, and 0.008 pptv), respectively,
460 for a 2-min integration time.

461

462 **3.4 Comparison between Br-MION-CIMS and Br-FIGAERO-CIMS**

463 While Br-MION-CIMS and Br-FIGAERO-CIMS use the same chemical ionization scheme, their designs differ in the
464 ion-molecule reaction chamber (IMR). MION is an atmospheric pressure (1 bar) drift tube; analyte molecules gain an
465 electric charge in an axial laminar flow. FIGAERO is connected to a cone-shaped IMR chamber operated at a reduced
466 pressure (150 mbar); the sample flow is injected into the inlet via an orifice, necessarily causing turbulence and wall
467 interactions in the IMR region. The atmospheric pressure and reduced pressure IMRs are both widely used for trace
468 gas measurements. We thus compare iodine species measurements from Br-MION-CIMS and Br-FIGAERO-CIMS,
469 to better understand the performance and applicability of the bromide ionization scheme.

470
471 We show in Fig. 5 the same iodine oxidation event as in Fig. 2, to illustrate the time series for HIO₃ Br⁻, HOI Br⁻,
472 IO Br⁻, and I₂ Br⁻, measured with Br-MION-CIMS (red circles) and Br-FIGAERO-CIMS (grey sticks), respectively.
473 Note that the FIGAERO alternates between gas and particle measurements; here we show only the gas-phase signals.
474 Clear and concurrent signals of HIO₃, HOI, IO, and I₂ are evident from both the Br-MION-CIMS and Br-FIGAERO-
475 CIMS. Prior to the iodine oxidation event (08:11), there was no photochemical production and thus virtually no signal
476 of oxidized iodine species in both instruments. The dark reaction of ozone with I₂ did not proceed at a significant rate,
477 due to the low rate coefficient and to low levels of I₂. Signals detected during this period are considered as the persistent
478 background, coming from electronic noise or other sources such as the ionizer, carrier flows, or long-term “memory”
479 in the case of the Br-FIGAERO-CIMS. Not surprisingly, the Br-MION-CIMS has a near-zero background for all
480 analytes. For HIO₃ (Fig. 5 (a)), the background signal in the Br-FIGAERO-CIMS is also negligible; however, IO
481 shows a substantial persistent background (Fig. 5 (c)) in the Br-FIGAERO-CIMS.

482
483 When we initiated the photochemistry, oxidized iodine signals rapidly built up toward an asymptote within timescales
484 of minutes. The instrumental differences in these timescales are small for HIO₃ and HOI, but larger for IO. When
485 colliding with the IMR surface, HIO₃ condenses irreversibly; it thus makes sense that the Br-MION-CIMS and Br-
486 FIGAERO-CIMS signals show the same timescale for HIO₃. Semi-volatile HOI, however, can return to the gas phase

487 from the walls depending on the surface coverage of HOI and the vapor concentration. Additionally, the heterogeneous
488 reaction of aqueous iodide (I⁻) and ozone (Carpenter et al., 2013) could also contribute to the emission of HOI from
489 the IMR wall in the FIGAERO. As the evaporation flux is typically a function of the amount analyte on the surface,
490 the buffering effect could degrade the instrument time response upon changes in analyte concentration. Here, however,
491 we did not observe a significant memory effect, likely because the HOI concentration was too low to fully saturate
492 the IMR surface or because any HOI evaporation was suppressed due to an enhanced accommodation coefficient of
493 HOI on the metal surface. We expect IO to be prone to loss on the metal surface due to its radical nature.

494
495 After the iodine oxidation event (10:21), the photochemical production of oxidized iodine species was terminated and
496 vapor concentrations decayed exponentially due to dilution and losses to chamber walls. Memory effects could also
497 influence the signal time constant. The dilution loss rate was around $2.1 \times 10^{-4} \text{ s}^{-1}$ (4760 s time constant) for all species
498 in the chamber, determined by the total chamber flow rate and the chamber volume. Wall loss rates, however, vary
499 for species with different diffusion constants. The decay rates of HIO₃ are 400 s for the Br-MION-CIMS and 370 s for
500 the Br-FIGAERO-CIMS, much faster than the dilution loss. For comparison, the time constant for H₂SO₄ vapor loss
501 was 300 s. These time constants are thus consistent with wall loss (around $2.2 \times 10^{-3} \text{ s}^{-1}$). The IO decay time constant
502 is 294 s for the Br-MION-CIMS and 435 s for the Br-FIGAERO-CIMS. The time constant for the Br-MION-CIMS
503 indicates that the decay of IO is also driven by wall loss, so the net flux during this period was thus towards the wall
504 rather than from the wall. Therefore, the difference of IO between instruments may well be attributed to the persistent
505 background from the ionizer of the FIGAERO. The HOI signals have longer decay time constants in both instruments
506 of 909 s for the Br-MION-CIMS and 714 s for the Br-FIGAERO-CIMS; this may reflect a time constant for depletion
507 of HOI adsorbed to the chamber walls. The I₂ signal increases after the event termination because it is no longer
508 photolyzed while its injection continues.

509
510 Applying the calibration coefficients, we convert the Br-MION-CIMS signals to absolute concentrations, and
511 subsequently correlate them with signals measured with Br-FIGAERO-CIMS. We then estimate the tentative detection
512 limits for HOI and HIO₃ in the Br-FIGAERO-CIMS to be 3.3×10^7 and $5.1 \times 10^6 \text{ molec cm}^{-3}$ (versus 5.8×10^6 and 1.2×10^5
513 molec cm^{-3} in the Br-MION-CIMS), respectively, at 3σ of the background signal for a 2-min integration time during
514 a two-hour period; they are in general one order of magnitude higher than those in the Br-MION-CIMS. This is in line
515 with the higher background signals observed in the Br-FIGAERO-CIMS. Note that for both HOI and HIO₃ the
516 uncertainties introduced from the correlational analysis are negligible compared to the limited accuracy of the
517 calibration sources (55 % for HOI and +50/-33 % for HIO₃). We are unable to estimate the I₂ detection limit in the Br-
518 FIGAREO-CIMS, due to a lack of I₂ background measurement; but Br-FIGAERO-CIMS can and did detect I₂ at the
519 low pptv level with good fidelity.

520

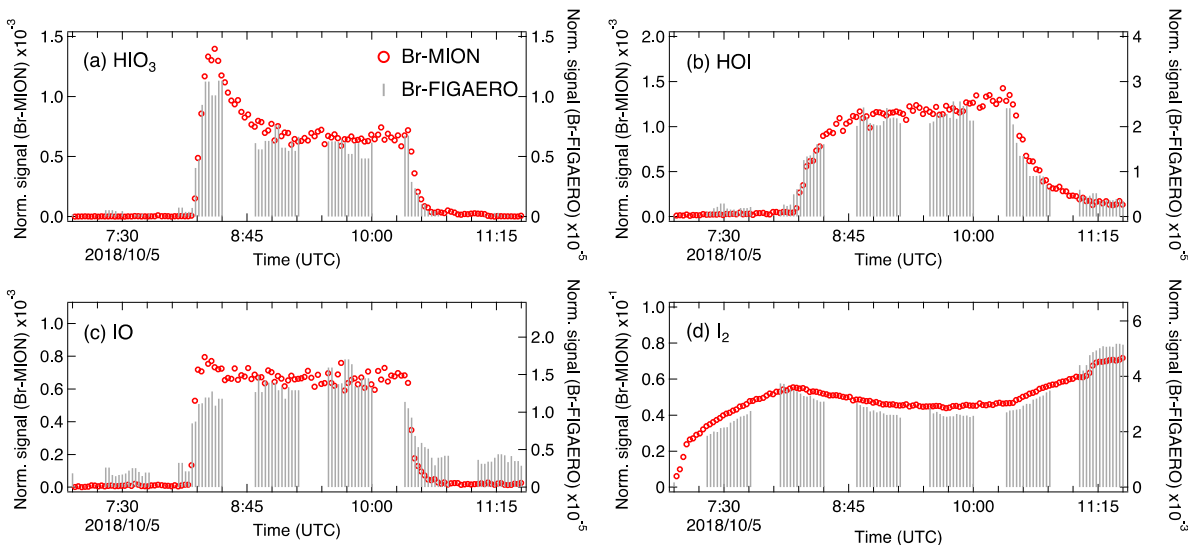

Figure 5. Signal comparison of selected iodine species measured with Br-MION-CIMS and (gas-phase) Br-FIGAERO-CIMS, respectively, during the same iodine oxidation experiment shown in Fig. 2.

521
522
523
524

525 4 Summary and conclusion

526 We confirm in this study that bromide chemical ionization is a suitable technique for the time-resolved, highly
527 sensitive, and simultaneous measurements of iodine species and sulfuric acid. The Br-MION-CIMS shows constant
528 sensitivity throughout the relative humidity range of 40 to 80 % at -10 °C, as long as the sum of the two reagent ions
529 ($\text{Br} + \text{H}_2\text{O Br}^-$) is used for signal normalization. This demonstrates the applicability of this technique to field
530 measurements in the ambient marine environment.

531 We quantify iodine species and sulfuric acid via offline calibrations (i.e. permeation tube and calibrator) and inter-
532 method calibrations (i.e. CE-DOAS and pre-calibrated nitrate-CIMS). Further, we calculate the binding enthalpies
533 between the calibrated species and reagent ions, which qualitatively agree with the corresponding calibration
534 coefficients. This indicates that the quantum chemical calculations can be employed along with the calibration
535 experiments to determine the sensitivities for unquantifiable species; more work is required to further establish the
536 correlation between calibration coefficients and binding enthalpies.
537

538 Further, using inter-method and offline calibrations, we estimate the detection limits of HOI, HIO₃, I₂, and H₂SO₄ in
539 Br-MION-CIMS being 5.8×10^6 , 1.2×10^5 , 3.8×10^5 , and 2.0×10^5 molec cm⁻³, respectively, for a 2-min integration time
540 during a two-hour period. To our knowledge, the simultaneous measurements of various iodine species and sulfuric
541 acid with low detection limits are unprecedented for online techniques. Detection limits for HOI and HIO₃ in the Br-
542 FIGAERO-CIMS are 3.3×10^7 and 5.1×10^6 molec cm⁻³, which are in general one order of magnitude higher than those
543 in the Br-MION-CIMS. The signal comparison between the two instruments also shows that the Br-CIMS can be
544 coupled to both the atmospheric pressure and the reduced pressure interfaces for iodine species and sulfuric acid
545 measurements in the marine environment.

549 *Data availability.* Data available on request from the authors.

550

551 *Author Contributions.* M.W., X.-C.H., Y.-J.T and H.F. wrote the manuscript. X.-C.H., Y.-J.T., M.W. and M.Sip.
552 designed the experiments. X.-C.H., Y.-J.T. and J.S. carried out the Br-MION-CIMS measurements, M.W., D.C. and
553 V.H. carried out the Br-FIGAERO-CIMS measurements, and H.F. carried out the CE-DOAS measurements. Y.-J.T.,
554 X.-C.H., H.F., D.C., J.S. and M.Sim. performed the calibrations. S.I., X.-C.H. and T.K. carried out the quantum
555 chemical calculations. M.W. performed the comparison analysis of the Br-FIGAERO-CIMS and Br-MION-CIMS.
556 N.-M.D., T.K., M.R., R.V. and M.Sip. commented on the manuscript. All other co-authors participated in either the
557 development and preparations of the CLOUD facility and the instruments, and/or collecting and analyzing the data.

558

559 *Competing interests.* The authors declare that they have no conflict of interest.

560

561 *Acknowledgement.* We thank the European Organization for Nuclear Research (CERN) for supporting CLOUD with
562 important technical and financial resources and for providing a particle beam from the CERN Proton Synchrotron.
563 We also thank Juhani Virkanen and Heini Ali-Kovero for providing assistance in the laboratory analytical experiments.

564

565 *Financial support.* This research has received funding from the US National Science Foundation (AGS-1531284,
566 AGS-1801574 and AGS-1801280), Academy of Finland (projects: 296628, 328290, Centre of Excellence 1118615)
567 and the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation
568 programme (GASPARCON, grant agreement no. 714621). The FIGAERO-CIMS was supported by an MRI grant for
569 the US NSF AGS-1531284 as well as the Wallace Research Foundation.

791 **Table 1: Cluster formation enthalpies of different species with bromide ions.** The cluster geometries are optimized
 792 at the ω B97X-D/aug-cc-pVTZ-PP level at 298.15 K. The enthalpies are calculated at the DLPNO-CCSD(T)/def2-
 793 QZVPP// ω B97xD/aug-cc-pVTZ-PP level at 298.15 K.

Cluster formation pathway	Formation enthalpies (kcal mol ⁻¹)
$\text{Cl}_2 + \text{Br}^- \rightarrow \text{Cl}_2 \text{Br}^-$	-22.3
$\text{OIO} + \text{Br}^- \rightarrow \text{OIO} \text{Br}^-$	-23.2
$\text{IO} + \text{Br}^- \rightarrow \text{IO} \text{Br}^-$	-24.5
$\text{HIO}_3 + \text{Br}^- \rightarrow \text{HIO}_3 \text{Br}^-$	-26.6
$\text{HOI} + \text{Br}^- \rightarrow \text{HOI} \cdot \text{Br}^-$	-26.9
$\text{HIO}_2 + \text{Br}^- \rightarrow \text{HIO}_2 \text{Br}^-$	-29.2
$\text{I}_2 + \text{Br}^- \rightarrow \text{I}_2 \text{Br}^-$	-33.7
$\text{ICl} + \text{Br}^- \rightarrow \text{ICl} \cdot \text{Br}^-$	-33.8
$\text{IBr} + \text{Br}^- \rightarrow \text{IBr} \cdot \text{Br}^-$	-36.7
$\text{H}_2\text{SO}_4 + \text{Br}^- \rightarrow \text{H}_2\text{SO}_4 \text{Br}^-$	-41.1
$\text{I}_2\text{O}_4 + \text{Br}^- \rightarrow \text{I}_2\text{O}_4 \text{Br}^-$	-42.6
$\text{I}_2\text{O}_5 + \text{Br}^- \rightarrow \text{I}_2\text{O}_5 \text{Br}^-$	-53.2

794
 795 **Table 2: Fragmentation reaction enthalpies of different species with bromide ions.** The cluster geometries are
 796 optimized at the ω B97X-D/aug-cc-pVTZ-PP level at 298.15 K. The enthalpies are calculated at the DLPNO-
 797 CCSD(T)/def2-QZVPP// ω B97xD/aug-cc-pVTZ-PP level at 298.15 K.

Cluster fragmentation pathway	Fragmentation enthalpies (kcal mol ⁻¹)
$\text{Cl}_2 \text{Br}^- \rightarrow \text{Cl}_2 + \text{Br}^-$	22.3
$\text{Cl}_2 \text{Br}^- \rightarrow \text{BrCl} + \text{Cl}^-$	22.3
$\text{HIO}_3 \text{Br}^- \rightarrow \text{HIO}_3 + \text{Br}^-$	26.6
$\text{HIO}_3 \text{Br}^- \rightarrow \text{IO}_3^- + \text{HBr}$	20.8
$\text{HIO}_3 \text{Br}^- \rightarrow \text{IO}_2^- + \text{HOBr}$	52.0
$\text{HOI} \text{Br}^- \rightarrow \text{HOI} + \text{Br}^-$	26.9
$\text{HOI} \text{Br}^- \rightarrow \text{IO}^- + \text{HBr}$	57.7
$\text{HOI} \text{Br}^- \rightarrow \text{I}^- + \text{HOBr}$	31.3
$\text{HIO}_2 \text{Br}^- \rightarrow \text{HIO}_2 + \text{Br}^-$	29.2
$\text{HIO}_2 \text{Br}^- \rightarrow \text{IO}_2^- + \text{HBr}$	43.8
$\text{HIO}_2 \text{Br}^- \rightarrow \text{IO}^- + \text{HOBr}$	42.2
$\text{I}_2 \text{Br}^- \rightarrow \text{I}_2 + \text{Br}^-$	33.7

$I_2 + Br^- \rightarrow IBr + I^-$	33.8
$ICl + Br^- \rightarrow ICl + Br^-$	33.8
$ICl + Br^- \rightarrow IBr + Cl^-$	39.8
$ICl + Br^- \rightarrow BrCl + I^-$	42.0
$IBr + Br^- \rightarrow IBr + Br^-$	36.7
$IBr + Br^- \rightarrow Br_2 + I^-$	39.4
$H_2SO_4 + Br^- \rightarrow H_2SO_4 + Br^-$	41.1
$H_2SO_4 + Br^- \rightarrow HSO_4^- + HBr$	27.9

798

799 **Table 3: Calibration coefficients for selected species.**

Species	Calibration coefficient (molec cm ⁻³ cps cps ⁻¹)	Detection limit (molec cm ⁻³)
^a I ₂	2.7×10 ¹⁰	3.8×10 ⁵
^a H ₂ SO ₄	4.1×10 ¹⁰	2.0×10 ⁵
^b I ₂	6.3×10 ¹⁰	8.8×10 ⁵
^b Cl ₂	3.5×10 ¹¹	n/a
^b HOI	3.3×10 ¹¹	5.8×10 ⁶
^c HIO ₃	4.1×10 ¹⁰	1.2×10 ⁵

800 ^a Inter-method calibrations

801 ^b Offline calibrations

802 ^c Derived from dissociation enthalpies
