**Abstract.** The portable microAeth® MA200 (MA200) is widely applied for measuring black carbon in human exposure profiling and mobile air quality monitoring. Due to its relatively new on the market, the field lacks a refined assessment of the instruments performance under various settings and data post-processing approaches. This study assessed the mobile real-time performance of the MA200 to determine a suitable noise reduction algorithm in an urban area, Augsburg, Germany. Noise reduction and negative value mitigation were explored via different data post-processing methods (i.e., local polynomial regression (LPR), optimized noise reduction averaging (ONA), and centered moving average (CMA)) under common sampling interval times (i.e., 5, 10, and 30 s). After noise reduction, the treated-data were evaluated and compared by (1) the amount of useful information attributed to retention of microenvironmental characteristics; (2) relative number of negative values remaining; (3) reduction and retention of peak samples; and (4) the amount of useful signal retained after correction for local background conditions. Our results identify CMA as a useful tool for isolating the central trends of raw black carbon concentration data in real time while reducing non-sensical negative values and the occurrence and magnitudes of peak samples that affect visual assessment of the data without substantially affecting bias. Correction for local background concentrations improved the CMA treatment by bringing nuanced microenvironmental changes into more visible. This analysis employs a number of different post-processing methods for black carbon data, providing comparative insights for

39 researchers looking for black carbon data smoothing approaches, specifically in a mobile monitoring  
40 framework and data collected using the microAeth® series of aethalometers.

41 Keywords: Black carbon; Mobile measurement; Noise reduction; peak sample; Background correction

## 42 **1 Introduction**

43 Black carbon particulate matter with size ranging from 0.01 to 1  $\mu\text{m}$  (Zhou et al., 2020), is a pollutant  
44 comprised of a range of carbonaceous materials produced by the incomplete combustion of fossil fuel  
45 and biomass containing carbon (Goldberg, 1985), and is suspected of exerting significant impact on  
46 health (Anenberg et al., 2012; Janssen et al., 2011; Nichols et al., 2013). Black carbon also has an  
47 important role in climate systems due to its strong radiative forcing potential (Kutzner et al., 2018,  
48 Sadiq et al., 2015). The International Agency for Research on Cancer (IARC) has classified black  
49 carbon as a 2B carcinogen, while researchers have linked black carbon exposures to cardiovascular,  
50 respiratory, and neurological diseases (e.g., Nichols et al., 2013). However, the high spatial variability  
51 of black carbon among small-scale urban blocks is difficult to characterize with existing monitoring  
52 networks which typically rely on fixed monitors (Apte et al., 2017), especially for on-road  
53 concentrations. Recently, mobile monitoring has been widely applied for the collection of real-time air  
54 quality measurements to assess local air quality, and air pollutant exposures (Liu et al., 2020, 2021).  
55 This method can improve the spatiotemporal resolution of measurement data in the urban environment  
56 and enables the collection of data such as the traffic-related air pollutant concentrations (Liu et al.,  
57 2019). Therefore, mobile measurements are favourably used in human exposure studies to quantify  
58 individual exposures and to demonstrate the importance of exposure differences in different  
59 microenvironments.

60 Instrument manufacturers in the USA have recently developed a new instrument for measuring black  
61 carbon concentrations in a variety of exposure-related contexts, including personal exposure  
62 assessment, ambient and vertical profiling, and indoor emissions concentration measurements, among  
63 others. This instrument, the microAeth® MA200 (MA200; AethLabs, San Francisco, CA, USA),  
64 continuously collects aerosol particles on a filter and measures the optical attenuation (ATN) at 5  
65 wavelengths (880, 625, 528, 470, and 375 nm) with a data collection time base as frequent as 1 Hz.  
66 This instrument supports the DualSpot® loading compensation method, which corrects the optical  
67 loading effect (Virkkula et al., 2007) and provides more additional information about aerosol optical  
68 properties. However, the raw data recorded by the MA200 at high frequencies (e.g., 1 Hz) can exhibit  
69 noise that obscures nuanced signals surrounding the central tendency of the data, increasing the  
70 difficulty of analysis in mobile settings or during rapidly changing micro-environmental characteristics.  
71 These negative values usually contain valid information required for noise reduction or smoothing, and  
72 so simply removing them may result in bias. Noise reduction of the raw data without direct removal of  
73 negative values is thereby recommended to enhance data quality and temporal resolution (Liu et al.,  
74 2020). In addition, when the sampling equipment traverses from a highly polluted to a low polluted

75 area, such as a park, the instrument produces strong negative values due to the measurement principle  
76 of the instrument and the strength of the pollution gradient between microenvironments. Therefore, the  
77 raw black carbon concentrations collected by MA200 need to be post-processed to ensure that  
78 researchers can adequately analyse the spatiotemporal distribution of black carbon.

79 Some progress has been made in the study of black carbon monitoring (Apte et al., 2011; Dons et al.,  
80 2012; Cao et al., 2020), however, noise reduction algorithms have not been fully assessed for the new  
81 generation of micro-aethalometers and for mobile monitoring contexts. In previous studies, Hagler et al.  
82 (2011) and Cheng et al. (2013) evaluated optimized noise reduction averaging (ONA) for  
83 post-processing mobile monitoring data. Due to the high spatial heterogeneity of black carbon, the  
84 ONA algorithm may ignore important microenvironmental effects and lead researchers to perhaps  
85 incorrectly conclude that resolution of microenvironmental source information cannot be determined  
86 from their data.

87 In this study, we aim to determine a suitable noise reduction algorithm for the MA200 aethalometer,  
88 starting with ONA, and moving on to two additional smoothing techniques offered by AethLabs in  
89 their suite of free online data post-processing (i.e., noise reduction) tools: the local polynomial  
90 regression (LPR) and centered moving average (CMA) algorithms. The interpretation accuracy of data  
91 analysed and reported upon in black carbon mobile monitoring study can be increased by assessing the  
92 relative performance of these post-processing methods to each other and to ONA. The quality of each  
93 noise reduction approach was assessed on data collected in an urban environment and post-processed  
94 with ONA, LPR, and CMA. Assessment criteria included (1) retention of detailed information  
95 attributed to microenvironmental characteristic; (2) relative number of negative values remained; (3)  
96 reduction and retention of peak samples; and (4) retention of detailed information on  
97 microenvironmental characteristics after background correction.

## 98 **2 Methods**

### 99 **2.1 Instrumentation**

#### 100 **2.1.1 Sampling Equipment**

101 The MA200 measures optical ATN from black carbon on a filter across 5 optical wavelengths: infrared,  
102 red, green, blue, and ultra-violet (880, 625, 528, 470, and 375 nm, respectively). A common black  
103 carbon metric called “equivalent black carbon” (eBC) is assessed via the 880 nm channel. The  
104 detection limit of the MA200 is reported at 30 ng/m<sup>3</sup> eBC under a 5 min time base and 150 mL/min  
105 flow rate (SingleSpot™ mode) and with resolution of 1 ng/m<sup>3</sup> (AethLabs, 2018). In mobile monitoring,  
106 the MA200 can be used to estimate personal exposure and quantify eBC mass concentrations in  
107 different microenvironments. It should be noted that a predecessor instrument to the MA200, the AE51,  
108 has demonstrated some sensitivity to mechanical shock during mobile measurements (Cai et al., 2013).  
109 When AethLabs took control of manufacturing the AE51, which was originally produced by Magee

110 Scientific (Berkeley, CA, USA), instrument opto-electronics were redesigned to reduce such sensitivity.  
 111 Researchers using redesigned AE51 demonstrated only a small effect on data. Supporting this  
 112 improvement, Cai et al (2013) found evidence of a substantial improvement in data quality related to  
 113 vibration-related spikes after an equipment upgrade by AethLabs. In addition, there were no major  
 114 mechanical shocks to or unique vibrational effects on the instrument and no major differences of  
 115 accelerometer data in the raw data, precluding these as potential confounders on all instruments.

## 116 2.1.2 Instruments preparation

117 In this study, seven MA200 portable black carbon monitors (serial numbers MA200-0051,  
 118 MA200-0053, MA200-0059, MA200-0060, MA200-0155, MA200-0153, MA200-159) were used  
 119 simultaneously to measure black carbon levels at the city centre under different interval times (5 s, 10 s,  
 120 and 30 s). To evaluate the relative performance of MA200, this study analysed black carbon data  
 121 collected from multiple MA200 devices, identified individually by serial numbers. The instruments  
 122 were prepared and adjusted in our laboratory before each walk, consisting of “zero” calibration checks,  
 123 the examination of the MA200 filter cassette, battery, GPS, and memory checks. Flow calibrations  
 124 were adjusted with a factory-calibrated flow meter (Alicat Scientific, Inc. Tucson, AZ, USA).

125 Comparative measurements of the MA200 and a stationary Aethalometer (AE33, Magee Scientific,  
 126 Berkeley, USA) taken approximately 30 to 60 min between walks showed a good agreement (Pearson’s  
 127  $r = 0.933$ ) (Liu et al., 2021). In addition, it is worth noting that when the AE33 was used for monitoring  
 128 black carbon at the same time as the MA200, the AE33 was placed in a fixed station, while the MA200  
 129 was used outdoors (in the stroller) during the individual walks, which may have presented different  
 130 relative humidity and temperature values. This condition did not influence the consistency of eBC  
 131 concentration measured with both instruments. Information about the date, duration, and time  
 132 resolution (time base) of each MA200 device are summarised in Table 1. To demonstrate the  
 133 unit-to-unit comparability between the MA200 units, we performed intercomparisons at fixed  
 134 monitoring stations (Table S1) and during collocated mobile measurements (Fig. S2). No wavelength  
 135 dependence was observed between different instruments for fixed and mobile monitoring  
 136 measurements.

137 **Table 1** Measurements of black carbon by different MA200 devices.

Measurement number	Date (dd/mm/yyyy)	Serial number	Start time (hh:mm:ss)	End time (hh:mm:ss)	Time base (s)	Site
1	27/09/2018	MA200-0051	10:29:10	13:38:20	10	Augsburg, Germany
2	15/11/2018	MA200-0059	11:53:42	16:13:12	10	
3	16/11/2018	MA200-0053	11:34:06	16:33:56	10	
4	26/08/2019	MA200-0060	11:01:56	15:44:46	10	
5	21/02/2020	MA200-0155	10:00:10	13:10:00	5	
6	21/02/2020	MA200-0153	10:00:10	13:10:00	10	
7	21/02/2020	MA200-0159	10:00:10	13:10:00	30	

8	24/11/2020	MA200-0059	09:40:57	11:09:07	10	Munich, Germany
9	01/12/2020	MA200-0051	13:29:05	15:19:00	5	
10	18/12/2020	MA200-0051	14:39:30	15:19:30	30	

138 **2.2 Study design and routes**

139 The MA200 instrument is able to measure black carbon in 1 s, 5 s, 10 s, 30 s, 60 s, and 300 s interval  
140 times. The 1 s time base exhibits the most challenging interpretation because of low signal to noise  
141 ratio especially at low concentrations, which is similar to other optical black carbon monitors (Hagler  
142 et al., 2011). Therefore, 1 s measurement resolution may be most useful when sampling in high  
143 concentration environments, performing direct emissions testing and requiring high time resolution for  
144 the application. However, the eBC average concentration is low in the city centre of Augsburg,  
145 Germany, (measured at 2.62  $\mu\text{g}/\text{m}^3$  in winter by Gu, (2012)) thus we did not use the 1 s time base.  
146 Moreover, 60 s and 300 s are too long distance for mobile monitoring, which may affect the accuracy  
147 of the spatial variation of pollutants, hence both time bases were also not selected in this study. In order  
148 to better understand at which interval time of sampling might be most useful in this context – mobile  
149 measurements at low eBC concentrations – three MA200 devices were used in parallel to measure eBC  
150 concentrations with the interval times of 5 s, 10 s, and 30 s (Measurement numbers 5-7 in Table 1).

151 To account for the different land-use types of the microenvironments, a fixed walking route within the  
152 centre of the city was determined. Wherever possible, the mobile measurements were carried out on the  
153 right side of the road simulating people’s common habits (driving and walking on the right side in  
154 Germany). All walks along the route were conducted on weekdays, with clear skies and calm winds to  
155 avoid misrepresentation of typical urban exposure conditions. The route started from Augsburg  
156 University of Applied Sciences (UAS) and continued approximately 14 km for 3 h average walking  
157 time, passing through different types of land-use to ensure that different microenvironments were  
158 represented the entire areas and the validity of the results (Fig. S1). Meanwhile, as performed in our  
159 previous study (Liu et al., 2021), we divided the monitoring route into four microenvironment groups  
160 in Augsburg, including high traffic flow (H\_Traffic, average 500-1000 vehicles/h), medium traffic flow  
161 (M\_Traffic, average 200-500 vehicles/h), low traffic flow (L\_Traffic, average 1-200 vehicles/h), and  
162 park area (N\_Traffic, average 0 vehicles/h), according to the actual traffic density examined during the  
163 daytime and determining from the traffic flow observed by street views.

164 Briefly, the study consisted of the following phases, (1) collecting raw black carbon data using the  
165 sampling instruments (MA200); (2) smoothing the acquired raw black carbon data under different  
166 post-processing methods (i.e., noise reduction); (3) comparing the noise reduction data based on the  
167 detail of microenvironmental characteristic and number of negative values; (4) following the peak  
168 samples identification by the coefficient of variation (COV) and (5) following the background  
169 estimation and correction by thin plate regression spline (TPRS); and (6) finally, selecting the best  
170 noise reduction approach.

## 171 **2.3 Post-processing methods**

172 In order to reduce the noise of concentration data obtained using high time resolutions, post-processing  
173 algorithms can be used. AethLabs offers tools for applying several noise reduction algorithms (ONA,  
174 LPR, and CMA) to MA-series device data on its website (<https://aethlabs.com> [note: a free account is  
175 required]). The relative utility of the different post-processing methods is determined by (1) the ability  
176 to perceive nuanced differences between microenvironmental pollution characteristics after noise  
177 reduction; (2) the relative number of negative eBC values remaining; (3) the reduction and retention of  
178 peak samples; and (4) the ability to perceive nuanced differences between microenvironmental  
179 pollution characteristics with the noise-reduced data after background correction.

### 180 **2.3.1 ONA (optimized noise reduction averaging)**

181 ONA is based on the time series of three parameters in the original observation data, namely the  
182 observation time, the original eBC concentration, and the amount of change in optical ATN over time,  
183 as specifically described by Hagler et al. (2011). Briefly, a  $\Delta$ ATN threshold is manually set to prevent  
184 the algorithm from recalculating eBC until a certain amount of ATN has been detected (e.g., enough  
185 black carbon has deposited on the filter to “confidently” calculate an eBC concentration). The aim is to  
186 reduce erroneous and spurious estimation by dynamically extending the effective sample time base,  
187 hence, there is sufficient ATN to significantly reduce the error effects of instrument noise. This  
188 effective time base will be longer in low concentrations than at higher concentrations and, hence, when  
189 operating properly, \*no\* negatives and less eBC noise will be reported. When using the ONA  
190 algorithm, this  $\Delta$ ATN threshold needs to be manually assigned. Hagler et al., (2011) implemented a  
191  $\Delta$ ATN threshold of 0.05 to post-process data from a fixed monitoring site by different Aethalometer  
192 models (AE21, AE42, and AE51). However, when applied to MA200 data, a  $\Delta$ ATN threshold of 0.05  
193 results in a very smooth curve and may obscure more information than is necessary to provide a  
194 usefully smoothed curve. For this reason, a lower  $\Delta$ ATN threshold of 0.01 was selected for the mobile  
195 measurement data of our study (Fig. S3).

### 196 **2.3.2 LPR (local polynomial regression)**

197 The LPR algorithm is a non-parametric tool similar to a moving average, but it operates on polynomial  
198 regression rather than simple averaging (Masry, 1996, Breidt and Opsomer, 2000, Kai et al., 2010). In  
199 LPR, the number of points across which to smooth must be manually identified. This value should be  
200 chosen to balance effective smoothing of the measured values and the sensitivity required to provide  
201 spatial resolution in mobile measurements (e.g., the distance over which the average was taken). The  
202 distance resolution was chosen at approximately 100 m. Assuming the sampling speed is 1.3 m/s, when  
203 the interval time is 5 s, 10 s, and 30 s, the smoothing number of points are 15, 7, and 3, respectively.

### 204 **2.3.3 CMA (centered moving average)**

205 The CMA algorithm is a smoothing technique used to make the long-term trends of a time series  
206 clearer (Easton and McColl, 1997). Unlike a simple moving average, CMA has no shift or group delay

207 in the data processing, as it incorporates data from both before and after the datapoint that is being  
208 smoothed. The smoothing number of points was determined as previously described in the LPR  
209 algorithm, assuming a sampling speed of 1.3 m/s.

## 210 **2.4 Comparison analysis after noise reduction approach**

### 211 **2.4.1 The nuance of microenvironmental characteristics and the proportion of negative values.**

212 After post-processing data, the characteristic change of the treated data is used as criterion to select the  
213 best method. In this regard, when the treated data provide more detailed microenvironmental  
214 characteristics, the data reflect the actual situation of air pollutants and facilitate the identification of  
215 pollution sources. However, if microenvironmental trends are less pronounced, it may hinder the  
216 identification of the pollution source. Therefore, more detailed microenvironmental features result in  
217 more accurate information. In addition, the number of remaining negative values is determined as  
218 another criterion to propose the best method. Specifically, the method with the smallest proportion of  
219 the negative values is selected as the best method. The proportion of negative values (NV) remaining  
220 was calculated as the number of negative values divided by the total sample size.

### 221 **2.4.2 Peak sample identification**

222 An earlier study by Brantley et al. (2014) compared several methods for identifying and eliminating  
223 peak samples in mobile air pollution measurements. These include identifying samples outside of a  
224 threshold based on a median produced using road segmentation, an  $\alpha$ -trimmed arithmetic average (Van  
225 den Bossche et al., 2015), a running coefficient of variation (COV) (Hagler et al., 2012), an estimate of  
226 background standard deviation (Drewnick et al., 2012), a running low 25 % quantile (Choi et al., 2012)  
227 and 3 times the standard deviation (Wang et al., 2015). The formula for the running method used in this  
228 analysis is previously described by Hagler et al. (2012) with minor modification (Eq. 1):

$$229 \quad COV_t = \frac{\sqrt{\frac{1}{7} \sum_{i=t-3}^{i=t+3} (x_i - \bar{x})^2}}{\bar{x}_{all}} \quad (1)$$

230 where  $COV_t$  is the 70 s sliding COV of the t-th eBC sample under a 10s time base (representing 30 s  
231 prior to the sample, the sample, and 30 seconds after the sample),  $x_i$  is the i-th eBC sample,  $\bar{x}$  is the  
232 average of the t-th eBC sample and the three samples before and after it, and  $\bar{x}_{all}$  is the average of all  
233 eBC data in one experiment. The 99th quantile of the 70 s sliding COV of all eBC data is used as the  
234 threshold for determining “peak sample”. The eBC samples that are greater than this threshold are  
235 flagged as peak samples along with the eBC samples 3 data points before and after. However, under  
236 different time bases (e.g., 5 s, and 30 s), the sliding COV of the t-th black carbon sample is different.  
237 Accordingly, the COV equation is required for modification under different time base.

238 To calculate the reduction of peak samples (RP), the number of peak samples was calculated before  
239 and after post-processing data, and the difference value was obtained. Then the change in the number

240 of peak samples was divided by the total number of peak samples before post-processing data. After  
241 noise reduction, we compared the reduction and the number of peak samples to further evaluate  
242 post-processing methods. In short, if the reduction of peak samples is high, the treated data has a high  
243 peak noise reduction without removing the numbers of peak samples. Therefore, the method with high  
244 reduction of peak samples and retaining the number of peak samples after post-processing is  
245 considered as the better method.

#### 246 **2.4.3 Background estimation and correction**

247 The ability of a processing method to adequately remove the estimated background concentration was  
248 used to evaluate which method provides the most useful information related to microenvironmental  
249 effects. A noise reduction method that appears to better facilitate background estimation and correction  
250 (as described below calculated from noise-reduced data via a defined background estimation and  
251 evaluation approach) is assessed to select a better post-processing method.

252 Background correction methods include the single sample standardization method, the sliding  
253 minimum method, the linear regression post-processing method, and the spline (of minimum)  
254 regression post-processing method. Brantley et al. (2014) suggests that a thin plate regression spline  
255 (TPRS) method can reliably evaluate the background value of mobile measurements, and be used to  
256 examine the “useful” information in the noise-reduced data (i.e. non-spurious, non-background  
257 pollution trends). Briefly, the TPRS approach includes three steps: first, the noise reduction data of  
258 pollutant was processed by a 30 s moving average; second, the results of the 30 s moving average were  
259 sequentially processed by the specified time window (i.e., 5 and 10 min), and the position of the  
260 minimum sample of pollutant concentration was identified in each window; and finally, thin-plate  
261 spline regression was used to fit the sample of minimum pollutant concentration obtained in the  
262 previous step, then the background concentration at each time point was obtained.

### 263 **3 Results and discussion**

264 The average eBC concentrations of raw, ONA-processed, LPR-processed, and CMA-processed data  
265 (Measurements 1-10) monitored by all instruments were compared in this study (Table S2). The results  
266 show that the three post-processing methods accounted of approximately 1 % bias from the average of  
267 raw concentrations (except measurement 5, ONA-processed data at 5 s). This indicates that the average  
268 concentration under each post-processing method did not affect the average concentration of the raw  
269 unprocessed data.

#### 270 **3.1 Post-processing data under different interval time**

271 As shown in Figure 1, three MA200s were used at the time bases of 5 s, 10 s, and 30 s. The proportion  
272 of negative values in the raw data collected under different time base of was 42.1 %, 37.6 %, and  
273 30.5 %, for 5 s, 10 s, and 30 s, respectively (Fig. 1a, Table 2, Fig S4a). Following this, the raw data  
274 were processed using ONA, LPR, and CMA (Fig. 1b, 1c, and 1d).

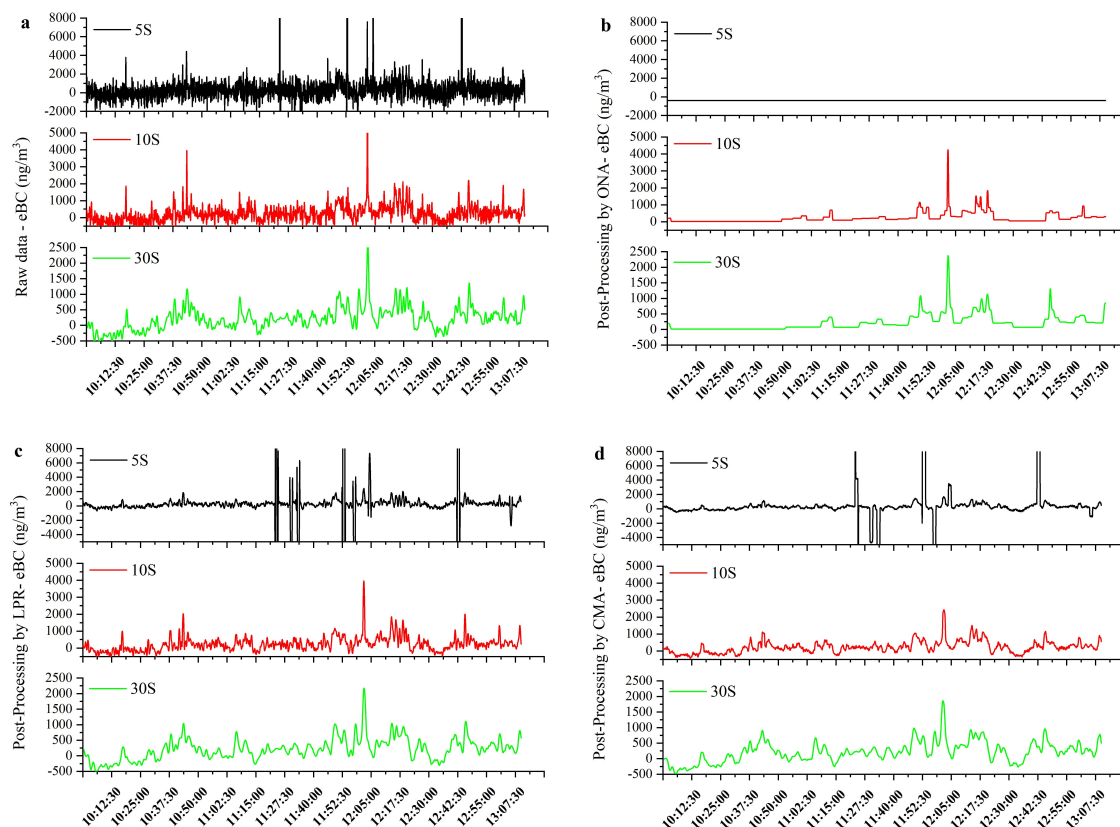

275 In the 5 s time base, the eBC values changed very rapidly (Fig. 1a), and the ONA processing of the data  
276 resulted in only one value (which was negative) (Fig. 1b). Thus, the microenvironmental characteristics  
277 of the eBC concentration were not reproduced. We found all  $\Delta\text{ATN}$  ( $\text{ATN}_{t(0)+\Delta t} - \text{ATN}_0$ ) data were  
278 negative in the raw data collected at 5 s, which, according to the ONA method described above,  
279 resulted in only a single value. In short, after the first measurement, the  $\Delta\text{ATN}$  threshold (which is  
280 positive) for calculating the next value was never reached. The first value was likely a negative value  
281 due to a combination of instrument noise, coincidence, and a low background concentration (i.e., low  
282 baseline instrument signal), which is consistent with both the raw data measurements and the typical  
283 low eBC concentrations in the city centre of Augsburg, Germany (Gu, 2012). It is unclear why  $\Delta\text{ATN}$   
284 remained negative, but, given the long series of low concentration values at the beginning of the  
285 sampling and the initial negative measurement, it is possible that the summed  $\Delta\text{ATN}$  became  
286 increasingly negative as a result of the initial negative  $\Delta\text{ATN}$  measurement. The subsequent  
287 measurements at low-concentration did not exceed the magnitude of the initial negative  $\Delta\text{ATN}$  value.  
288 Under these conditions, a cumulative negative sum of  $\Delta\text{ATN}$  would prevent the positive  $\Delta\text{ATN}$   
289 threshold from being achieved at all. If true, this condition highlights one potential weakness of the  
290 ONA algorithm, such as difficulty registering a signal under low concentrations and requires further  
291 investigation of the conditions under which ONA is truly unbiased. The observed event prevented the  
292 use of ONA in the 5 s time base (Fig. 1b). Previous studies in which ONA was successfully applied  
293 implemented a 1 s time base (Hagler et al., 2011; Van den Bossche et al. 2015). After post-processing  
294 with LPR and CMA, the microenvironmental characteristics retained more detailed information of the  
295 eBC concentration. Further comparison of their negative values revealed that the remaining negative  
296 values comprised 28.1 % and 22.9 % of the dataset for LPR and CMA, respectively, after  
297 post-processing.

298 In the 10 s interval time base, negative values were not found after ONA processing, suggesting that a  
299 reasonable smoothing effect is obtained at low black carbon concentration. The microenvironmental  
300 characteristic presented strong changes against the raw data, remaining less detailed information of air  
301 pollution. After post-processing with LPR and CMA, the microenvironmental characteristics revealed  
302 more detailed information of air pollution, with 30.2 % of negative values for LPR and 25.3 % for  
303 CMA. In the 30 s interval time base, the negative values comprised 0 % of the post-processed data for  
304 ONA, 25.5 % for LPR, and 22.4 % for CMA. The 30 s interval dataset presented the lowest proportion  
305 of negative values before and after post-processing, due to the longer interval times of sampling.  
306 However, the longer 30 s measurement period results in more distance covered during each  
307 measurement, given the mobile nature of the sampling device. Thus, 30 s black carbon measurements  
308 may be too long to detect local concentration peaks in urban contexts that supported another study  
309 (Kerckhoffs et al., 2016).

310 The ONA algorithm showed a strong tendency to remove negative values and, depending on the  $\Delta\text{ATN}$   
311 threshold employed by the user, can remove potentially meaningful low peaks. As a result, the  
312 ONA-treated data may present bias that obscure nuanced microenvironmental trends (Fig. 1b).  
313 Interestingly, LPR and CMA post-processing are capable of decreasing negative values while retaining

314 microenvironmental trends. Both methods are promising for the analysis of spatiotemporal changes in  
 315 pollutant concentrations with sensitivity to local sources. Previous studies have shown that the  
 316 spatiotemporal variability of black carbon is highly heterogeneous (Liu et al., 2019; Liu et al., 2021);  
 317 the ability to capture spatiotemporal variability of microenvironments is critical for assessing  
 318 differential exposures among populations.

319

320 **Figure 1** The temporal fluctuations of the black carbon levels measured with the MA200 at sampling  
 321 time bases of 5 s, 10 s, and 30 s during a typical sampling period (about 190 min), (a), raw data without  
 322 noise reduction, (b), data treated with optimized noise reduction averaging, (c), data treated with local  
 323 polynomial regression, and (d), data treated with centered moving average. The analysis was carried  
 324 out on data streams from three MA200s all collected during a single sampling run (Measurements 5, 6  
 325 and 7).

326 **Table 2** The proportion of negative values and average reduction of peak samples under the different  
 327 post-processing methods (values are shown as (%), NV [%]: Proportion of negative values remained,  
 328 RP [%]: Average reduction of peak samples. -, no data, measurements 1-10).

Interval time	Factor	RAW	ONA	LPR	CMA
5 s	NV	42.1	-	28.1	22.9
	RP	0	100	72.0	87.4
10 s	NV	37.6	0	30.2	25.3

	RP	0	5.54	22.3	47.7
30 s	NV	30.5	0	25.5	22.4
	RP	0	0.62	6.24	39.1

### 329 3.2 Reduction and number of peak samples after post-processing methods

330 The processing of peak sample is a pivotal evaluation index for the measurement of time-averaged  
 331 roadside air quality. Passing vehicles, for example, may bias estimates of typical local concentrations  
 332 due to their contribution to the dataset of peak concentrations that may substantially related to  
 333 arithmetic averages. Therefore, after noise reduction, we compare the reduction and the retained  
 334 number of peak samples to further evaluate the post-processing methods.

335 In the interval time 5 s, the average reduction of peak samples (RP) for the LPR and CMA algorithms  
 336 was 72.0 % and 87.4 %, respectively (as discussed above, the ONA method could not be used). In this  
 337 interval time, the reduction of peak samples was relatively high, indicating that when monitoring black  
 338 carbon at low concentrations and high sample frequencies, drastic noise may occur in the raw data, and  
 339 higher noise reduction may affect the actual values. Therefore, a suitable interval time should be  
 340 considered when monitoring low eBC concentrations. In the interval time 10 s, the average reduction of  
 341 peak samples for the CMA (47.7 %) is higher than ONA (5.54 %) and LPR (22.7 %). In the interval  
 342 time 30 s, CMA presented the greatest average reduction of peak samples (39.1 %) compared to ONA  
 343 (6.24 %) and LPR (0.62 %) (Table 2, Fig. S4b). The retention of peak samples remaining after  
 344 post-processing was also assessed using the COV method (Measurements 1-10). The result showed that  
 345 all three algorithms retained all peak samples before and after post-processing. In this regard, CMA  
 346 retained all peak samples despite the highest reduction in their magnitude. Therefore, CMA highlights  
 347 microenvironmental trends while preserving the identity of peak samples, facilitating the identification  
 348 of local pollution sources, and may thus be a better post-processing method than ONA or LPR (Table 2,  
 349 Fig. S4b).

350 To further characterise the distribution of peak sample concentration under CMA, we performed an  
 351 intensive graphical analysis on a single data stream (Measurement 4; Fig. 2). As shown in Figure 2,  
 352 eBC values along the main roads and intersections were higher than other locations, presumably due in  
 353 large part to stop-and-go traffic and cars in close proximity to the mobile monitor (Fig. 2). It can be  
 354 seen from Figure 2a that the peak samples of black carbon were mainly found in 4 locations,  
 355 represented by red triangles. Vehicle counts and traffic in these locations vary depending on the time of  
 356 measurement. The highest eBC values were repeatedly found in the streets with moderately high traffic  
 357 volumes and dense coverage with relatively high buildings (street canyon situation), indicating that  
 358 heterogeneity in air pollution concentrations in Augsburg and similar settings is largely caused by a  
 359 combination of effects from traffic and topography (Buonanno et al., 2011). To determine whether  
 360 peak samples are due to local sources or instrumental artefacts, and to provide further evidence that  
 361 traffic and topography effects are primary contributors to spatial heterogeneity in pollution  
 362 concentrations, we compared the data measurements of the three collocated MA200 units during

363 Measurements 5, 6, and 7. The results showed that there were no major differences in the hot spot areas  
364 (an indicator of considerable peak samples) identified by the measurements of the three instruments  
365 (Fig. S5).

366

### 370 3.3 Comparison of background estimation and correction after noise reduction

371 Local air pollution can be highly affected by long-range and regional transport. The timing and  
372 magnitude of such transports vary in space and time and are highly dependent upon the stochasticity of  
373 meteorology. As a result, local background concentration changes may vary, affecting the  
374 comparability of measurements made at the same location at different times (Brantley et al., 2014). For  
375 this reason, reliable comparison of time-variable mobile measurements across a city (and thus reliable  
376 pinpointing of hotspots and pinpointing of key local sources) requires effective methods to estimate,  
377 isolate, and remove the effects of fluctuations in background concentration. Our analysis indicates that  
378 the effectiveness of background correction is affected by the noise reduction method chosen during  
379 post-processing.

380 After post-processing, the data were evaluated using the TPRS method. We calculated the 5 min and 10  
381 min background concentrations under different post-processing approaches. As shown in Figures 3a  
382 and b, the background concentration after LPR processing has both the largest proportion of negative  
383 values and the most negative values (i.e. negative values of the greatest absolute magnitude), resulting  
384 in estimates of background-corrected concentrations that are greater than actual monitored  
385 concentrations. Background concentrations calculated after ONA and CMA post-processing presented  
386 fewer and lower negative values than LPR, but were not convincingly different from each other.  
387 Therefore, to further compare the ONA and CMA algorithm, we also compared concentrations after  
388 background correction (Fig. 3c and d). As shown in Figures 3c and d, when the concentration is lower

389 than  $1 \mu\text{g}/\text{m}^3$ , the background-corrected results after the ONA processing are smoother than after CMA.  
 390 This result dampens the signal of local pollutant sources, resulting in a lower utility of post-processed  
 391 data.

392  
 393 **Figure 3** Background concentration of black carbon under different time-series :**(a)**, spline of 5 min  
 394 minimums, **(b)**, spline of 10 min minimums; and background correction of black carbon under different  
 395 time-series **(c)** spline of 5 min minimums; **(d)**, spline of 10 min minimums. Analyses are based on  
 396 Measurement 4.

397 In order to verify the CMA applicability and its advantages, this study further analysed the eBC  
 398 concentrations measured by a fixed background monitoring station at the University of Applied  
 399 Sciences (UAS) (Fig. S6) (Cyrus et al., 2006). The background value under the 5 min window exhibits  
 400 wave-like characteristics, and the fitting curve in the 10 min window is relatively smooth. However, the  
 401 TPRS-based background value often does not fluctuate greatly over short periods, and the black carbon  
 402 background value curve under the 5 min window does not conform to the “actual” urban background  
 403 situation as estimated using the fixed-site monitor data, which are assumed to primarily represent the  
 404 fluctuations in background concentrations. Moreover, by comparing the curve produced by the spline  
 405 of 10 min minimums with the eBC background concentration (Background-UAS, Fig. S6), it can be

406 found that the background correction method based on the time series can well characterize the  
407 time-varying characteristics of background pollution in each experiment, suggesting that, of the two  
408 options, 10 min showed the better window for fitting the background value curve of black carbon.

409 Under the TPRS method, the background concentration of eBC can be fitted at any sampling time. The  
410 TPRS-estimated background contribution of the observed eBC concentration averaged 37.8 % of the  
411 total measured concentration. However, when the contribution of background concentration to a single  
412 measurement was examined, a large fluctuation (10.4 -71.3 %) was observed, which may be closely  
413 related to sizeable changes in the meteorological conditions, traffic conditions along the road (and over  
414 time at the same point in the road), and urban street canyon effects in each measurement. Therefore,  
415 based on the comparison of background correction, the CMA showed better applications for estimating  
416 the background concentration and location source contribution.

### 417 **3.4 Generalizability**

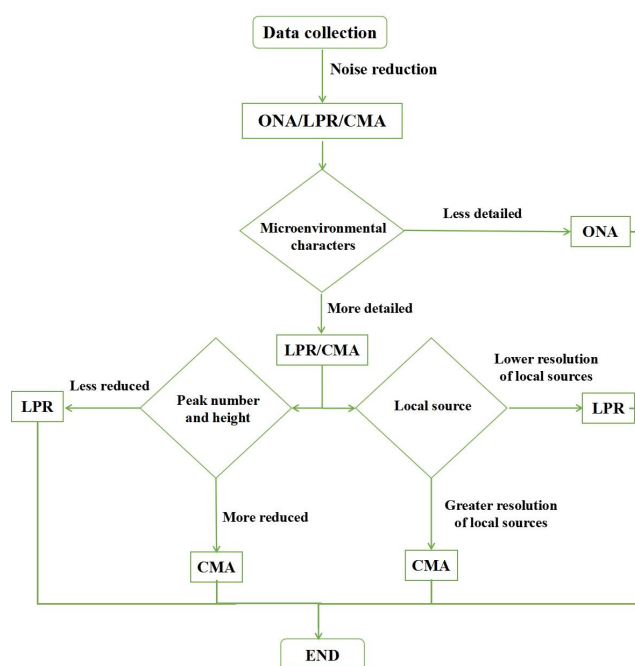

418 To verify the generalizability of our assessment, we performed another three measurement runs in  
419 Munich (Measurement 8, 9, 10). Raw data were post-processed for noise reduction using CMA (Fig.  
420 S7). The results showed that the following method is equally applicable in a city like Munich as in our  
421 study site in Augsburg, two cities that differ in location and environmental characteristics (e.g.,  
422 population, economy, traffic density etc.). After treated by CMA, the peak samples can be identified in  
423 different interval times (Fig. S8), and the estimated background concentrations showed few negative  
424 values (Fig. S9). Further research into the transferability of our results to a more diverse set of contexts  
425 is still needed.

### 426 **3.5 Practical implications**

427 The MA200 is widely used to measure human exposure to black carbon and for mobile air quality  
428 monitoring. In this study the MA200 were applied in mobile measurements in an urban area  
429 (Augsburg), and the sensitivity of the final analysis to various data post-processing methods was  
430 investigated. In contrast to our findings, Hagler et al., (2011) suggested the use of the ONA algorithm  
431 to post-process Aethalometer data from microAeth AE51, portable AE42, and rackmount AE21  
432 aethalometers (Magee Scientific, Berkeley, CA, USA). In their analysis, ONA demonstrated a strong  
433 noise reduction in all datasets and retained spatiotemporal variation. ONA also reduced the occurrence  
434 of negative data values in low concentration sampling environments. However, for the microAeth®  
435 series of black carbon monitoring instruments, our study showed that ONA under reasonable delta ATN  
436 thresholding may lead to a considerable dampening of spatiotemporal resolution in local black carbon  
437 signals at street level - an effect that is lower under CMA post-processing.

438 In addition, our analysis highlights that the selection of an appropriate data post-processing method is  
439 crucial to the proper assessment and interpretation of exposure-relevant microenvironmental  
440 contributors to pollution concentrations in urban areas. This analysis is important when estimating  
441 exposures that occur during transit, where spatiotemporal variability in pollution concentrations is vast,

442 like in commuter traffic (Snyder *et al.*, 2013). Due to the typically low-but-heterogeneous nature of  
 443 eBC concentrations in many areas like Augsburg, noisy measurement with the MA200 under  
 444 high-frequency sampling may obscure actual trends in measured values. This study demonstrated that  
 445 post-processing MA200 data using CMA can reliably extract the actual signals from such noise and,  
 446 alternatively, that post-processing via ONA and LPR could be less reliable. Future researchers and  
 447 agencies may find a distillation of our results in the form of the flow diagram in Scheme 1 useful in  
 448 determining how to reliably assess spatiotemporal variability of MA200 measurements for black  
 449 carbon in different microenvironments.

450

#### 452 **4 Conclusion**

453 A mobile monitoring campaign was conducted in the city centre of Augsburg, Germany to determine a  
 454 suitable noise reduction algorithm for the MA200 aethalometer. Our results showed that, at the interval  
 455 time of 5 s, 10 s, and 30 s, CMA post-processing effectively removed spurious negative concentrations  
 456 without major bias and reliably highlighted effects from local sources, effectively increasing  
 457 spatiotemporal resolution in mobile measurements. Evaluation of the effects of each method on peak  
 458 sample reduction and the estimation of background concentrations further support the reliability of the  
 459 CMA. Further analysis is needed to understand how well these findings apply in different seasons;  
 460 across different diurnal patterns; and in more-rural, more-urban, and non-German locations.
