18

19 **Abstract:** Mobile differential optical absorption spectroscopy (mobile DOAS) has become an
20 important tool for the quantification of emission sources, including point sources (e.g., individ-
21 ual power plants) and area emitters (e.g., entire cities). In this study, we focused on the error
22 budget of mobile DOAS measurements from point sources, and we also offered recommenda-
23 tions for the optimum settings of such measurements. First we established a Gaussian plume
24 model from which the NO_x and SO₂ distribution from the point source was determined. In a
25 second step the simulated distributions are converted into vertical column densities of NO_x and
26 SO₂ according to the mobile DOAS measurement technique. With assumed parameters, we then

drove the forward model in order to simulate the emissions, after which we performed the analysis. Following this analysis, we conclude that: **(1)** Larger sampling resolution clearly results in larger flux error. The proper resolution we suggest is between 5 m and 50 m. Even larger resolutions may also be viable, but > 100 m is not recommended. **(2)** Error effects vary with measurement distance from the source. We found that undetectable flux (measured VCDs are under the detection limit) is the main error source when measuring far from the source, for both NO_x and SO₂. When measuring close to the source, low sampling frequency results in large flux error. **(3)** The wind field primarily affects 2 aspects of the flux measurement error. When measuring far from the source, dispersion results in more undetectable flux, which is the main error source. When measuring close to the source, wind field uncertainty becomes the main error source of SO₂ flux, but not of NO_x. We suggested that the proper wind speed for mobile DOAS measurements is between 1 m/s and 4 m/s. **(4)** The study of NO_x atmospheric chemistry reactions indicated that a [NO_x]/[NO₂] ratio correction has to be applied when measuring very close to the emission source. But even when such a correction is applied, the remaining errors can be significant. To minimize the [NO_x]/[NO₂] ratio correction error, we recommended 0.05 NO₂ maximum reaction rate as the accepted NO_x steady-state thus to determine the proper starting measurement distance. **(5)** The error of the spectral retrieval is not a main emission flux error source and its error budget varies with the measuring distance. **(6)** Increasing the number of measurements can lower the flux error that results from wind field uncertainty and retrieval error. This directly indicates that SO₂ flux error could be lowered if the measurements are repeated when not too far from the emission source. With regard to NO_x, more measurement times can only work effectively when not very close or too far from the source. **(7)** Also the effects of the temporal and spatial sampling are investigated. When the sampling resolution is prescribed, the integration depends on the driving speed and the corresponding flux error is mainly determined by the undetectable flux. When the car speed is prescribed, the integration time is determined by the sampling resolution for measuring near the source, while undetectable flux predominates when far away. **(8)** As a general recommendation, our study suggests that emission rates < 30 g/s for NO_x and < 50 g/s for SO₂ are not recommended for mobile DOAS

55 measurements. The source height affects the undetectable flux, but has little influences on the
56 total error.

57 Based on the model simulations our study indicates that mobile DOAS measurements are
58 very well suited tool to quantify point source emissions. The results of our sensitivity studies
59 are important to make optimum use of such measurements.

60 **1 Introduction**

61 Nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) and sulphur dioxide (SO_2), poisonous and harmful trace
62 gases in the atmosphere, are critical participants in tropospheric chemical reactions (Seinfeld
63 and Pandis, 1998; Beirle et al., 2003). NO_x and SO_2 are emitted into the atmosphere via natural
64 and anthropogenic emissions, especially from traffic and industries. In recent years, China has
65 experienced large areas of haze pollution, which have drawn worldwide scrutiny due to their
66 NO_x , SO_2 , and VOC content, although strict policies designed to control the emission of pol-
67 lution gases have been implemented (Richter, et al., 2005; Ding et al., 2015; Jin et al., 2016). It
68 is of great significance to study gas emission pollution both qualitatively and quantitatively.

69 Differential Optical Absorption Spectroscopy (DOAS) is a technique developed in the 1970s
70 that focuses on the telemetering of atmospheric gases, particularly trace gases (Platt and Stutz,
71 2008). After years of research, various types of DOAS technology have been comprehensively
72 developed, including LP-DOAS, MAX-DOAS, and mobile DOAS.

73 Mobile DOAS technology was originally used to measure volcanic SO_2 emissions
74 (Bobrowski et al., 2003; Edmonds et al., 2003; Galle et al., 2003), and it was then developed to
75 measure the NO_2 and SO_2 emission fluxes from industrial parks (Johansson et al., 2006). In
76 2008, Mattias Johansson used a mobile mini-DOAS device to quantify the total emission of air
77 pollutants from Beijing and evaluated the measurement error, mainly in terms of the uncertain-
78 ties in the wind field, experimental setup, sunlight scattering in the lower atmosphere, and re-
79 trieval error. During the MCMA 2006 field campaign, C. Rivera et al. (2009) used a mobile
80 mini-DOAS instrument to measure the NO_2 and SO_2 emissions of the Tula industrial complex
81 in Mexico and also estimated the flux error. In O. Ibrahim et al. (2010), T. Wagner et al. (2010),

82 and R. Shaiganfar et al. (2011, 2017), air mass factor (AMF), sampling resolution, NO_x chem-
83 ical reactions, and atmospheric lifetime were introduced in order to analyze the emission flux
84 error. The analysis of emission flux error sources has gradually come to focus on the wind field
85 uncertainty, sampling resolution measurement error (GPS error), Slant Column Density (SCD)
86 retrieval error, AMF error, and other error sources. The aforementioned studies primarily con-
87 centrated on regional/industry park emission fluxes, as opposed to point sources.

88 Different from regional/industry park measuring, point source emission flux can be measured
89 in diverse ways, with different measuring distances, varying sampling resolutions, and so on.
90 Therefore, the error sources and influence factors affecting the flux measurements are different.
91 In order to investigate the impact of these factors and thereby recommend optimum settings for
92 point source flux measuring using mobile DOAS, we performed an in-depth study on the effects
93 of error sources and influence factors on point source emission flux measuring.

94 There are innate deficiencies in the experimental method used to analyze the emission flux
95 error since there are so many scenarios that need to be verified, and the various factors cannot
96 be well controlled during experiments. Therefore, a convenient way to assist the analysis is
97 sorely needed. In the absence of precise requirements, the simulation method is a good alterna-
98 tive for facilitating the analysis of mobile DOAS emission flux error, given its convenience and
99 feasibility.

100 Using a model based on Gaussian plume dispersion and the mobile DOAS emission flux
101 measurement method, we here performed a simulation to study the measurement of NO_x and
102 SO₂ point source emission flux.

103 This paper is organized as follows: In Section 2, the methodological framework is presented.
104 In Section 3, the parameters used to drive the simulation are delineated. Section 4 describes the
105 simulation performance and data analysis, Section 5 presents our conclusions, and the Appendix
106 displays the overall simulation results.

107 2 Methodology and forward model

108 2.1 Overview of methodology

109 Since individual experiments take place in complex and variable scenarios, in order to inves-
110 tigate the error sources and influence factors that impact the flux measurement error, typical
111 mobile DOAS measurements of the NO_x and SO₂ emission fluxes were modeled with the fol-
112 lowing assumptions:

113 (1) NO_x and SO₂ gas continuously exhaust from an isolated and elevated point source at the
114 position (0 m, 0 m, 235 m). The plume rises approximately 15 m.

115 (2) The topography around the point source is flat and the background concentration of the
116 pollutants is 0.

117 (3) Air turbulence is constant in space and time.

118 (4) A zenith-sky mobile DOAS measures the gas underneath the plume in the y-direction at
119 around noon (see Figure 1). Spectra, GPS data, and wind profiles are available for individual
120 measurements.

121 (5) The sunlight radiance received by the mobile DOAS instrument is stable.

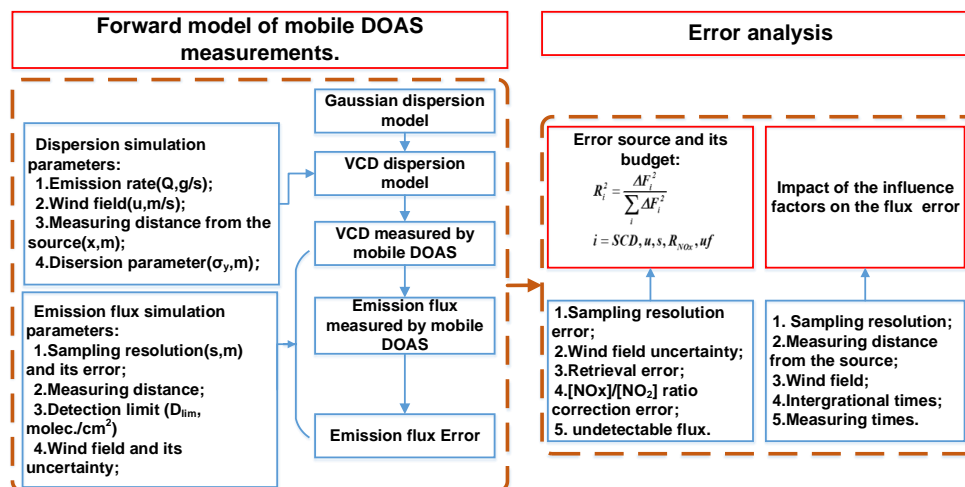

122 Figure 1 presents the schematic diagram of the modeled mobile DOAS measurement of a
123 point source.

124

125 Figure 1. Schematic diagram of the modeled mobile DOAS measurement underneath the plume

126 Based on the performance of typical mobile DOAS measurements, a forward model of flux
127 calculations was generated and error analysis performed according to the forward model, as
128 shown in Figure 2.

129
 130

Figure 2. Forward model of mobile DOAS measurements and error analysis

131

The forward model of mobile DOAS measurements can be divided into 2 steps:

132

(1) Dispersion simulation. In this step, a dispersion model is established to generate the vertical column densities (VCDs) measured by the mobile DOAS in the modeled typical measurement.

135

(2) Emission flux simulation. After the VCD sequence along the measurement route is generated, the next step is calculating the emission flux and the emission flux error.

137

Error analysis:

138

This step concentrates on the error sources and their budget, and the influence factors that affect the emission flux error.

140

The emission flux and VCD retrieval calculation model can be directly introduced into our forward model, as it has in previous studies. However, some questions concerning the forward model still exist:

143

(1) Is the existing dispersion model suitable for the mobile DOAS measurement depicted in Figure 1?

145

(2) How can VCDs be simulated in the same way as mobile DOAS measurements in theory?

146

(3) Mobile DOAS can measure NO_2 instead of NO_x . How can the $\text{NO} \leftrightarrow \text{NO}_2$ conversion be added to the existing dispersion model in terms of this simulation?

148

These questions will be explored in Sections 2.2–2.6.

149 **2.2 Description of Gaussian dispersion model**

150 **2.2.1 Steady-state Gaussian dispersion model**

151 An appropriate air dispersion model needed to be chosen for generating the forward model
 152 of mobile DOAS measurements. Since the concentrations of pollutants at individual points in
 153 the plume can be calculated based on the Gaussian dispersion model (Arystanbekova et al.,
 154 2004; Lushi et al., 2010; de Visscher, 2014), we applied the Gaussian dispersion model in this
 155 study. The plume, as reflected by the surface due to the ground boundary effect and the disper-
 156 sion model, can be expressed as Eq. (1).

$$157 \quad c(x, y, z) = \frac{DQ}{2\pi u \sigma_y \sigma_z} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \cdot \left\{ \exp\left[-\frac{(z+H)^2}{2\sigma_z^2}\right] + \exp\left[-\frac{(z-H)^2}{2\sigma_z^2}\right] \right\} \quad (1)$$

158 where Q is the emission rate (g/s); u is the wind speed (m/s) and the wind direction is along the
 159 x-direction; σ_y (m) is the dispersion parameter in the y-direction; σ_z (m) is the dispersion pa-
 160 rameter in the z-direction, with σ_y and σ_z dependent on x; and H is the plume height (m).

161 $D = \exp\left(-\varphi \frac{x}{u}\right)$ is the decay term, mainly consisting of the chemical reactions and deposits;
 162 φ is the decay coefficient; and $\varphi = \frac{\ln 2}{T_{1/2}}$, in which $T_{1/2}$ is the pollutant half-life in seconds.

163 The dispersion parameters are determined by the atmospheric stability. The classification of
 164 atmospheric stability, which was created by Pasquill and Gifford and is widely used, sorts at-
 165 mospheric stability into 6 classes ranging from A–F (de Visscher, 2014). We only considered
 166 the classifications under strong solar radiation (see Table 1) in this study.

167 Table 1. Pasquill–Gifford atmospheric stability classifications:

Wind Speed at 10m above the surface (m/s)	Strong Solar Radiation class
<2	A
2~3	between A and B
3~5	B
5~6	C
>6	C

168 A: very unstable; B: moderately unstable; C: slightly unstable

169 Based on the atmospheric stability class and the terrain type surrounding the emission point,
 170 the parameters σ_y and σ_z can be calculated. Since we assumed the surrounding area to be

171 flat, rural terrain, the σ_y and σ_z parameters could be calculated using Briggs's (1973) for-
 172 mulas, listed in Table 2

173 Table 2. Rural area air dispersion parameters (Briggs, 1973)

Stable classes	$\sigma_y(x)$	$\sigma_z(x)$
A	$0.22x(1+0.0001x)^{-0.5}$	$0.2x$
B	$0.16x(1+0.0001x)^{-0.5}$	$0.12x$
C	$0.11x(1+0.0001x)^{-0.5}$	$0.08x(1+0.0002x)^{-0.5}$
D	$0.08x(1+0.0001x)^{-0.5}$	$0.06x(1+0.0015x)^{-0.5}$
E	$0.06x(1+0.0001x)^{-0.5}$	$0.03x(1+0.0003x)^{-1}$
F	$0.04x(1+0.0001x)^{-0.5}$	$0.016x(1+0.0003x)^{-1}$

174 in which x is the horizontal distance from the source, m.

175 Since the wind field varies with time in actual measurements, the y -direction dispersion pa-
 176 rameter needs to be adjusted using Eqs. (2) and (3), while z for the plume height does not, as
 177 we assume it to be higher than 200 m (de Visscher, 2014).

178
$$\sigma_{y2} = \sigma_{y1} \left(\frac{t_2}{t_1} \right)^p \quad (2)$$

179
$$\sigma_{y3} = \sqrt{\sigma_{y2}^2 + 0.1\Delta h^2} \quad (3)$$

180 where σ_{y1} (regarded as the Table 2 value) and σ_{y2} are the dispersion parameters obtained
 181 with averaging times of t_1 and t_2 , respectively, with t_1 set to 10 min and t_2 to 60 min; σ_{y3} is
 182 the final dispersion parameter after correction. p is an empirical value of approximately 0.2
 183 and Δh is the plume rise.

184 It should be noted that Briggs's equations are only suitable under the condition of x lower
 185 than 10 km. In addition, the model accuracy significantly decreases in the case of wind speeds
 186 either < 1.2 m/s or too strong (de Visscher, 2014). The upper wind speed has not been specified,
 187 so we set it to be 8 m/s.

188 2.2.2 NO_x dispersion

189 Eq. (1) is suitable for SO₂ dispersion, while for NO_x, mobile DOAS can only measure NO₂
190 effectively. Hence, Eq. (1) should be adjusted for NO₂ dispersion based on NO_x atmospheric
191 chemical reactions. In this study, we did not take Volatile Organic Compounds (VOCs) into
192 consideration; thus, a NO_x balance would not be broken. The typical reactions of NO, NO₂, O₃,
193 and O₂ are:

197 The reaction rates of reactions 1, 2 and 3 form a cyclic reaction. The reaction rate of NO₂
198 is:

$$199 \quad r_{\text{NO}_2} = -j_3[\text{NO}_2] + k_5[\text{NO}][\text{O}_3]_t \quad (4)$$

200 where [gas] stands for the concentration of a particular gas; $[\text{O}_3]_t$ is the O₃ mean concentration
201 in the plume at time t ; t is the time period after NO_x is emitted into the atmosphere; j_3 is the
202 NO₂ photochemical rate constant, equal to approximately $8 \times 10^{-3} \text{ s}^{-1}$; and k_5 is the rate constant
203 of reaction 3, equal to approximately $1.8 \times 10^{-14} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$. It should be noted that these
204 rates are for a temperature of 25°C. Fortunately, they are not sensitive to temperature, so tem-
205 perature sensitivity did not need to be considered.

206 The [NO_x]/[NO₂] ratio depends on the mixing ratio of O₃. We assumed that at the beginning
207 there is no O₃ in the air parcel of the plume. During the mixing with outside air, the O₃ concen-
208 tration within the air parcel increases. For simplicity, we assumed that the O₃ concentration
209 within the air parcel of the plume is the same everywhere. The mixing ratio of O₃ within the air
210 parcel of the plume can then be estimated as:

$$211 \quad [\text{O}_3]_t = [\text{O}_3] \frac{V_t - V_0}{V_t} = [\text{O}_3] \frac{S_t \Delta t - S_0 \Delta t}{S_t \Delta t} = [\text{O}_3] \left(1 - \frac{S_0}{S_t}\right) \quad (5)$$

212 where V_0 is the initial gas volume of the plume and S_0 is the initial gas cross-section of the

213 plume; while V_t is the gas volume of the plume at time t and S_t is the gas cross-section of
 214 the plume in the atmosphere at time t . Here, $[O_3]$ is the ambient O_3 concentration. The NO_2
 215 concentration at time t is given by:

$$216 \quad [NO_2]_t = \int_0^t r_{NO_2} dt \quad (6)$$

217 Since the NO_2 initial concentration was very low, we assumed the NO_2 initial concentration
 218 $[NO_2]_0 = 0$. Consequently, $[NOx]_t = [NO]_0$ (with no decay).

219 The $[NOx]/[NO_2]$ ratio at time t is:

$$220 \quad R_{NOx} = \frac{[NOx]_t}{[NO_2]_t} \quad (7)$$

221 Different from SO_2 , the number of NOx molecules is conserved, as opposed to their mass.
 222 The NOx dispersion model should thus be expressed as:

$$223 \quad c_{NOx}(x, y, z) = \frac{DQ_{mNOx}}{2\pi u \sigma_y \sigma_z} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \cdot \left\{ \exp\left[-\frac{(z+H)^2}{2\sigma_z^2}\right] + \exp\left[-\frac{(z-H)^2}{2\sigma_z^2}\right] \right\} \quad (8)$$

224 where $Q_{mNOx} = \frac{Q \cdot NA}{m_{NOx}}$. m_{NOx} is the mean molar mass of the initial NOx and NA is Avoga-
 225 dro's constant of 6.02×10^{23} molecules mol^{-1} . Substituting Eq. (7) into Eq. (8), the NO_2 disper-
 226 sion model can then be expressed as:

$$227 \quad c_{NO_2}(x, y, z) = \frac{c_{NOx}(x, y, z)}{R_{NOx}} \quad (9)$$

228 2.3 VCD dispersion model

229 As discussed above, mobile DOAS retrieves the VCD, while results of the dispersion model
 230 are point concentrations. Based on the definition of VCD, we integrate the concentration along
 231 the vertical direction, i.e., the z -direction from the ground to the upper troposphere, as in:

$$232 \quad VCD(x, y) = \int_0^{+\infty} Dc(x, y, z) dz = \frac{DQ}{\sqrt{2\pi u \sigma_y \sigma_z}} \int_0^{+\infty} \left\{ \exp\left[-\frac{(z+H)^2}{2\sigma_z^2}\right] + \exp\left[-\frac{(z-H)^2}{2\sigma_z^2}\right] \right\} dz$$

$$= \frac{DQ}{\sqrt{2\pi u \sigma_y}} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \quad (10)$$

233 Eq. (10) is suitable for SO₂. For NO_x, the VCD dispersion is

$$234 \quad VCD_{NO_x}(x, y) = \frac{DQ_{mNO_x}}{\sqrt{2\pi}u\sigma_y} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \quad (11)$$

235 The NO₂ VCD dispersion model is

$$236 \quad VCD_{NO_2}(x, y) = \frac{VCD_{NO_x}(x, y)}{R_{NO_x}} \quad (12)$$

237 Eqs. (10), (11), and (12) lay the mathematical foundation of the VCD distribution model
 238 for mobile DOAS measuring.

239 2.4 VCD measured by mobile DOAS

240 As shown in Figure 3, the flux of the plume cross-section can be calculated using the follow-
 241 ing equation:

$$242 \quad \Delta F = u \cdot \int_l VCD(x, y) ds \quad (13)$$

243 For actual measurements, ΔF should be given by Eq. (14)

$$244 \quad \Delta F = VCD_j \cdot u \cdot s \quad (14)$$

245 where s is the distance between 2 measuring points and VCD_j can be derived from the spectrum
 246 of measurement j . Based on Eqs. (13) and (14), VCD_j can be expressed by Eq. (15)

$$247 \quad VCD_j = \frac{1}{s} \int_l VCD(x, y) ds \quad (15)$$

248 Eq. (15) indicates that the VCD_j derived from individual mobile DOAS measurements is the
 249 average of $VCD(x, y)$ along the measurement route. The discretization of the VCD can signif-
 250 icantly affect the emission flux error and will be discussed in Section 4.1.

251
 252

Figure 3. Model of VCD measured by mobile DOAS

253 2.5 Description of emission flux measured by mobile DOAS

254 The equation for calculating emission flux in the discrete form is expressed as

$$255 F = \sum_i VCD_i \cdot \vec{u}_i \cdot \vec{n}_i \cdot s_i \quad (16)$$

256 where F is the emission flux; VCD_i is the VCD for DOAS measurement i along the measure-
257 ment route; \vec{u}_i is the wind field; \vec{n}_i is the vector pointing to the right of the driving direction
258 and parallel to the Earth's surface; and s_i is the sampling resolution. Since the SO_2 lifetime
259 scale is longer than the dispersion time scale, a decay correction is not needed for SO_2 , but for
260 NOx it can be necessary.

261 The NOx emission flux is then:

$$262 F_{NOx} = \frac{R_{NOx}}{D} F_{NO2} \quad (17)$$

263 In fact, the decay correction for NOx should be applied for cases with low wind speeds, while
264 the effect for high wind speeds is very small.

265 2.6 Measurement errors of emission flux

266 The emission flux measurement errors by mobile DOAS have several sources: SCD retrieval
267 errors, AMF errors, wind field uncertainties, sampling resolution error, and undetectable flux.
268 The undetectable flux is attributed to the ambient SCD below the mobile DOAS detection limit,
269 which results in undetectable SCDs as well as undetectable flux. The total relative error of the
270 emission flux is given by:

$$271 E_{total} = \frac{F_{err}}{D \cdot Q} = \frac{\sqrt{\Delta F_{uf}^2 + \Delta F_{VCD}^2 + \Delta F_u^2 + \Delta F_s^2}}{D \cdot Q} \times 100\% \quad (18)$$

272 where F_{err} is the flux error, and ΔF_{VCD} is the flux error introduced by VCD error, which
273 mainly arises from the SCD retrieval error and the AMF error. For the low plume heights and
274 small amounts of aerosols within the plume in this study, the SCD could always be assumed to
275 be equal to the VCD. The AMF error is thus negligible. ΔF_{uf} is the undetectable flux; ΔF_u
276 is the flux error introduced by wind speed uncertainty and wind direction uncertainty, i.e., the
277 wind field uncertainty; and ΔF_s is the emission flux error introduced by sampling resolution

278 measuring error.

279 Eq. (18) is appropriate for SO₂. With regard to NO_x, the NO_x flux error is also introduced
280 by the decay correction and the [NO_x]/[NO₂] ratio correction error. Hence, the NO_x flux rela-
281 tive error is:

$$282 \quad E_{NO_x} = \frac{F_{err}}{D \cdot Q} = \frac{\sqrt{\Delta F_D^2 + \Delta F_{R_{NO_x}}^2 + \Delta F_{uf}^2 + \Delta F_{VCD}^2 + \Delta F_u^2 + \Delta F_s^2}}{D \cdot Q} \times 100\% \quad (19)$$

283 where ΔF_D is the flux error due to decay correction, and $\Delta F_{R_{NO_x}}$ is the flux error due to
284 [NO_x]/[NO₂] ratio correction.

285 In order to quantify the contributions/budget of individual error sources, the ratios are calcu-
286 lated as Eq. (20)

$$287 \quad R_i^2 = \frac{\Delta F_i^2}{F_{err}^2} \quad (20)$$

288 where i represents the individual error sources. Note that $\sum_i R_i^2 = 1$.

289 3 Parameter assumption and numerical simulation

290 In Section 2, the forward model for mobile DOAS measurements of emission flux was es-
291 tablished. In this section, reasonable values of the parameters in the forward model are dis-
292 cussed and prepared in order to drive the forward model.

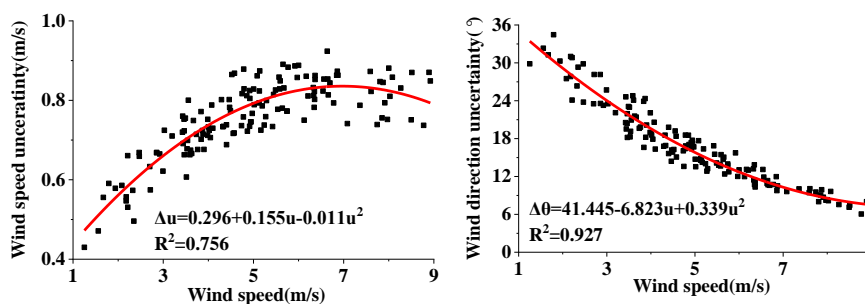

293 For most factories, including power plants, the emission rates of NO_x and SO₂ are different.
294 Since a higher emission rate is an ideal condition for mobile DOAS measurements, higher emis-
295 sions could be outside the scope of our study. Therefore, the emission rate that we simulated
296 was < 200 g/s, and we set the Q value within this range. Since the Gaussian dispersion model
297 is appropriate for moderate wind speed and scale, the wind speed was set to range from 1.2–8
298 m/s and the dispersion distance was approximately 0–10 km. Given the car speed and mobile
299 DOAS spectrometer integration times t_{int} , the sampling resolution was set from 5–500 m. The
300 NO_x mean daytime lifetime is approximately 5 h ± 1 h (Spicer, 1982), while the SO₂ daytime
301 lifetime is more than 1 day (S. Beirle, 2014). Compared with the dispersion time scale, the SO₂

302 daytime lifetime uncertainty could be neglected. When time approaches infinity, the NO_x reac-
 303 tion steady-state could be determined by ambient [O₃] according to Eq. (4). We here assumed a
 304 typical [O₃] value 1.389×10^{12} molec./cm³ thus the steady-state [NO_x]/[NO₂] ratio is 1.32. The
 305 [NO_x]/[NO₂] ratio inside the air parcel of the plume varying with the distance could be deter-
 306 mined by Eqs. (4), (5), (6) and (7).

307 The VCD error can mainly be attributed to the DOAS fit error of the SCD. Previous studies
 308 have indicated that the typical errors of NO₂ and SO₂ VCDs are $\sim 2.5 \times 10^{15}$ molecules cm⁻² and
 309 $\sim 4 \times 10^{15}$ molecules cm⁻², respectively. The sampling resolution error is primarily attributed to
 310 the drift of GPS and but it is negligible in actual measurements due to individual GPS errors
 311 cancel each other.

312 The wind field uncertainty includes both wind direction uncertainty and wind speed uncer-
 313 tainty. In order to quantify the 2 uncertainties, the 1-month wind profile data at the height of
 314 250 m during the time period 9:00–16:00 from 1 April–30 April 2019 were derived from the
 315 Doppler wind profile radar located in Shijiazhuang (38.17°N, 114.36°E). The average wind
 316 fields and standard deviations were calculated for each hour, as shown in Figure 4. Two-order
 317 polynomials were applied in order to derive the function of standard deviation versus average
 318 value for both wind speed and wind direction. Some sample values calculated using these pol-
 319 nomials are listed in Table 3. Table 4 lists all the simulation parameters of NO_x and SO₂ that
 320 were required.

325

Table 4. Simulation parameters and data range of NO_x and SO₂

Parameter	Values
Emission rate(g/s)	10, 30, 50, 100 , 150, 200
Wind speed(m/s)	1.2, 2,3, 4, 5, 6, 7, 8
Measuring distance(km)	0~10km
Sampling resolution and its error(m)	5~500m, initial integration times t_{int}
Retrieval error(molec.cm ⁻²)	NO ₂ : $\sim 2.5 \times 10^{15}$; SO ₂ : $\sim 4 \times 10^{15}$
Detection limit(molec.cm ⁻²)	NO ₂ : 5×10^{15} ; SO ₂ : 8×10^{15}
Average atmosphere lifetime	NO _x : $5h \pm 1h$; SO ₂ : more than 1 day
R_{NOx}	R_{NOx} inside the plume is calculated by Eqs. (4), (5), (6) and (7). R_{NOx} in steady-state is 1.32.

326

The parameters listed in Table 4 were applied in the forward model in order to perform the

327

simulation. The simulation results are shown in Figures 23 and 24 of the Appendix.

328

4 Analysis of emission flux errors measured by mobile DOAS based on the forward

329

model

330

Figures 23 and 24 in the Appendix show that the modeled relative errors of NO_x and SO₂

331

emission flux varied with sampling resolution and distance from the point source under differ-

332

ent wind speeds and emission rates. Some overall features can be derived from these figures.

333

Therefore, typical cases were selected in order to discuss the overall features based on several

334

key factors.

335

4.1 Sampling resolution and its error

336

Sampling resolution variation impacts on the error combination and propagation and its

337

measuring error is an error source.

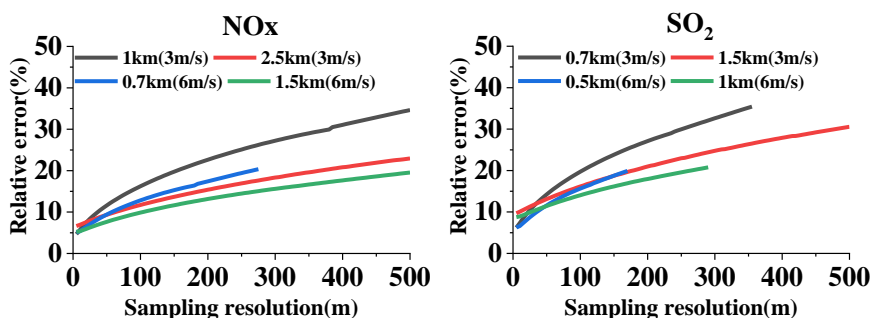

338

The typical uncertainty of the GPS readings is <1.5m. For measurements with small sampling

339 resolutions the GPS error can thus cause relatively large uncertainties for the flux contributions
340 from individual measurements (Eq. 14). However, even for small sampling resolutions the GPS
341 errors of neighboring flux contributions almost completely cancel each other. Thus the contri-
342 bution of the GPS error to the flux calculation (Eq. 16) can be neglected.

343 In order to discuss the dependence of flux error on sampling resolution, some data were ex-
344 tracted from the Appendix and plotted in Figure 5. This figure shows the increase of relative
345 error with increasing sampling resolution. It should be noted that the smaller the sampling res-
346 olution, the more data the mobile DOAS will sample. This directly leads to the inclusion of
347 more data in the emission flux calculations, resulting in the lower emission flux error. However,
348 when far from the source, the plume with narrows quickly (see section 4.2). Applying different
349 sampling resolution is no longer feasible. Therefore, the sampling resolution can only work
350 effectively when the measurements are not far from the source.

351
352 Figure 5. Dependence of relative errors on sampling resolution ($Q = 100 \text{ g/s}$, $u = 3 \text{ m/s}$ and 6 m/s , at
353 different measuring distances)

354 The impact of sampling resolution on emission flux error is noticeable. In terms measurement
355 efficiency, the sampling resolution should be moderate. Therefore, we recommend the proper
356 sampling resolution to be between 5 m and 50 m. Larger resolutions may also be viable, but >
357 100 m is not recommended.

358 4.2 Measuring distance from the source

359 Measuring distance is not an error source, but affects the dispersion and NOx chemical reac-
360 tions, further adding to the emission flux error. Figure 6 presents typical examples of relative
361 errors varying with distance at a resolution of 20 m. Wind speeds of 3 m/s and 6 m/s were

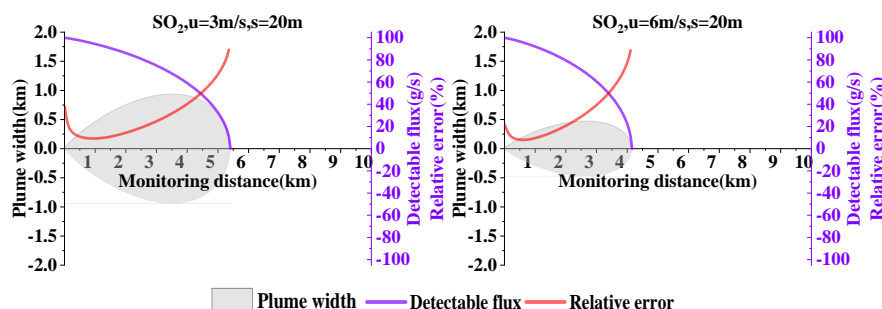

362 utilized in this example. The overall feature shown in all of the sub-figures of Figure 6 is the
363 rapid decrease and then quick increase of the relative error with measuring distance. Different
364 factors lead to the large errors at small and large distances.

365 First, we analyzed NO_x and SO₂ emission flux errors for a large measuring distance. The
366 large distance results in the dramatic decrease of ambient VCDs due to dispersion and decay
367 along the plume transport path. The ambient VCDs can be lower than the detection limit of
368 mobile DOAS measurements, resulting in a portion of the undetectable flux. Because of dis-
369 persion, the plume widths with VCDs above the detection limit and thus the detectable fluxes
370 decrease significantly with distance, even dropping to 0, as shown in Figure 6. This causes the
371 relative error to increase at large measuring distances.

372 Second, we analyzed NO_x and SO₂ emission flux errors in the case of a small measuring
373 distance. Figure 6 indicates that the error is large and decreases rapidly with increasing meas-
374 uring distance when close to the source. As discussed in Section 4.1, if more measurement data
375 are included in the calculations of flux, the relative error can decrease. When the measuring
376 distance is small, the number of samples can dramatically decrease. For SO₂, the relative error
377 can increase significantly when the measurements are close to the point source. For NO_x, the
378 relative error is also affected by chemical reactions, this phenomenon that we will discuss in
379 Section 4.4.

381

382

383 Figure 6. Variation of NO_x and SO₂ relative errors with distance, using Eqs. (18) and (19) ($Q = 100$

384

g/s, setting the sampling resolution $s = 20$ m and the wind speed to 3 m/s and 6 m/s)

385 **4.3 Wind fields and their uncertainty**

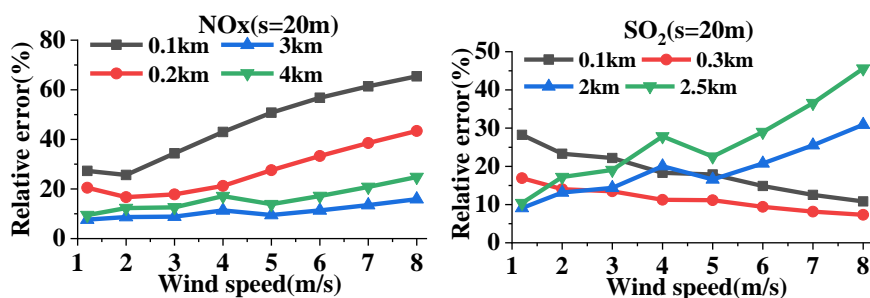

386

Wind fields can impact both the gas dispersion (Eqs. 1, 8, 9) and the calculation of emission flux (Eqs. 16, 17). In terms of dispersion, wind speed affects gas VCD (Eqs. 10, 11, 12). In terms of flux calculation, the temporal and spatial uncertainty of wind fields can contribute to emission flux calculation errors. Therefore, the effects of wind fields are discussed based on these 2 factors in this section.

391

Figure 7 displays the variations of the relative errors of NO_x and SO₂ with wind speed at different distances. The emission rate Q and the sampling resolution are chosen as 100 g/s and 20 m, respectively. Figure 7 indicates the different features of relative error for wind speeds at small and large measurement distances. The relative error of NO_x increases with increasing wind speed at different distances, while the SO₂ relative error for measurements at small distances exhibits a trend opposite that of the large distance measurements. The causes of the different relationships at small and large measurement distances are discussed in subsection 4.3.1.

398

399 Figure 7. Relative errors of NO_x and SO₂ emission flux changes with wind speed at different measure-
400 ment distances (Q = 100 g/s, sampling resolution $s = 20$ m)

401

402 **4.3.1 Effects of different wind speeds on measurements at small and large measurement** 403 **distances**

404 Since the NO_x and SO₂ flux measurement errors of different wind speeds are very different
405 at small and large measurement distances, we discuss them separately.

406 **4.3.1.1 SO₂**

407 We first analyzed the effect of different wind speeds on the SO₂ emission flux error.

408 Since VCDs decrease with increasing wind speed (Eqs. 10, 11, 12), more ambient VCDs
409 would be below the detection limit of mobile DOAS at high wind speeds. Hence, the contribu-
410 tion of undetectable ambient VCDs to the error of flux calculations depends on wind speed. In
411 addition, since wind fields are input into the calculations of emission flux (Eqs. 16, 17), their
412 uncertainties can contribute to the flux measurement error. In order to investigate the contribu-
413 tions of undetectable ambient VCDs and the influence of wind field uncertainties in flux meas-
414 urement, the ratios R_{uf}^2 (R^2 of the undetectable flux) and R_u^2 (R^2 of the wind field uncertainty)
415 calculated using Eq. (20) are shown in Figures 8c and 8d for different wind speeds and meas-
416 urement distances.

417 Again, we first analyzed the measurements at large distances, finding that R_{uf}^2 is greater
418 than R_u^2 for large measurement distances, as shown in Figures 8c and 8d. Therefore, undetect-
419 able VCDs dominate the effect of wind fields on the error of flux calculations when the meas-
420 urement distance is large. Since VCDs decrease with increasing wind speeds, the flux error
421 associated with undetectable VCDs should be increased with wind speed. This relationship ex-
422 plains the phenomenon that the relative error of emission flux increases with increasing wind
423 speed for large measurement distances.

424 Next, the measurements at small distances were analyzed. Figures 8c and 8d indicate that

425 R_{uf}^2 is much lower than R_u^2 for short measurement distances. The wind field uncertainty dom-
426 inates the effect of wind fields on the flux calculation errors. Meanwhile, since the relative
427 uncertainty of the wind field decreases with increasing wind speed, the emission flux error
428 decreases with increasing wind speed for short measurement distances, as shown in Figure 6.

429

430

431 Figure 8. Wind field uncertainty ratio squared R_u^2 and undetectable emission flux ratio squared R_{uf}^2 of

432 NO_2 and SO_2 emission flux measurement error changes with measurement distance for different wind

433 speeds ($Q = 100 \text{ g/s}$, sampling resolution $s = 20\text{m}$)

434

435 4.3.1.2 NO_x

436 We next analyzed the effect of different wind speeds on NO_x emission flux error, as shown

437 in Figures 9a and 9b.

438 The effects of different wind speed dispersions on NO_x emission flux error are similar to

439 SO_2 , i.e., Figures 9b and 9d, indicating that the effects of wind speed dispersion are analogous.

440 The effect of wind field uncertainty is much different from SO_2 , however, especially when the

441 measurements are very close to the source. When very close, wind field uncertainty influence

442 increases and then decreases with distance. Compared with SO_2 , the decreasing trend of NO_x

443 in the case of far measurement distances is also similar, but the increasing trend is very different.

444 This implies that NO_x measurements close to the source have another main potential error

445 source, which we will investigate in Section 4.4.

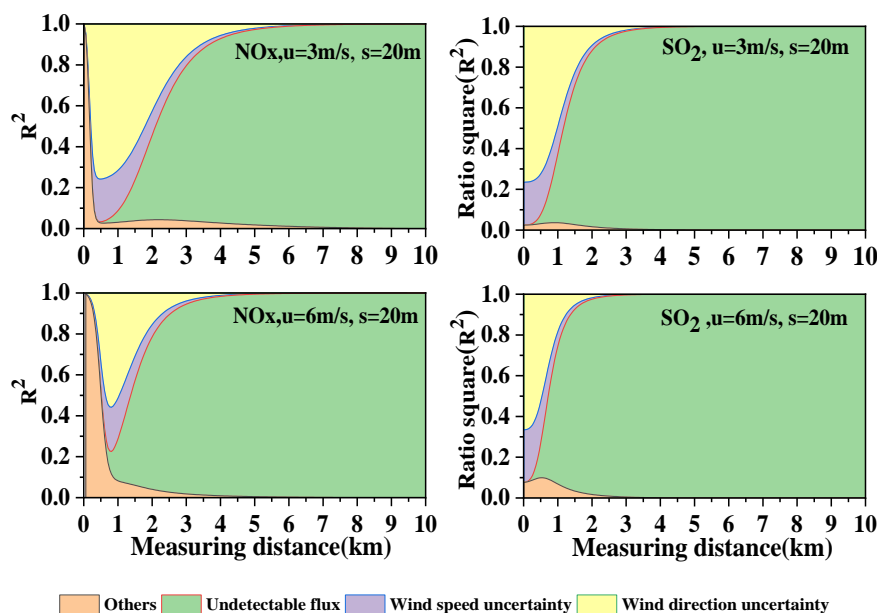

446 The 4 subfigures in Figure 9 share the common characteristic that the R^2 lines have intersec-
447 tions between 4 m/s and 5 m/s. This implies that the wind field uncertainty effect and the wind
448 field dispersion effect are distinguished between 4 m/s and 5 m/s. In actual measurements, un-
449 detectable VCDs cannot be well quantified. Therefore, we recommend the proper wind speed
450 for mobile DOAS to be < 4 m/s. The appropriate lower wind speed in this study was 1.2 m/s,
451 But the Gaussian plume model we used becomes increasingly inaccurate when wind speeds are
452 under 1m/s. Thus, we recommend a proper wind speed of 1–4 m/s.

453 **4.3.2 Error budget of undetectable flux, uncertainties of wind direction and speed**

454 The remaining question is what flux error budget is associated with the wind field. From
455 Section 2.6 we know that R_u^2 (R^2 of wind speed uncertainty) and R_{Dir}^2 (R^2 of wind direction
456 uncertainty) constitute R_{uf}^2 . The R_{uf}^2 value of the undetectable flux is the contribution of the
457 wind field dispersion. Figure 9 presents the changes of R_u^2 , R_{Dir}^2 , and R_{uf}^2 of NOx and SO₂
458 with distance for different wind speeds, 3 m/s and 6 m/s.

459 As for SO₂, the wind field influence contributes most of the emission flux error from wind
460 field uncertainty, in conjunction with wind dispersion. From Figure 9, we can infer that the sum
461 of R_u^2 , R_{Dir}^2 , and R_{uf}^2 is > 0.9 . Furthermore, contributions from wind speed uncertainty and
462 wind direction uncertainty in the emission flux error are also presented in Figure 9. This demon-
463 strates that wind direction uncertainty contributes about 0.78 to the wind field uncertainty when
464 the wind speed is 3 m/s and 0.74 when the wind speed is 6 m/s.

465 With regard to NOx, the wind field influence is similar to SO₂ when measuring far from the
466 source and very different when measuring close to the source. As discussed above, mobile
467 DOAS can only measure the NO₂, as opposed to the NOx. The amount of NO₂ yield determines
468 the mobile DOAS measurement result, and thus that of the NOx flux measurement error, espe-
469 cially when measuring very close to the source.

470

471

472 Figure 9. Changes of R_u^2 , R_{Dir}^2 , and R_{wf}^2 of NOx and SO₂ emission flux measurement errors with
 473 measurement distance for different wind speeds ($Q = 100 \text{ g/s}$)

474 **4.4 NOx chemical reactions**

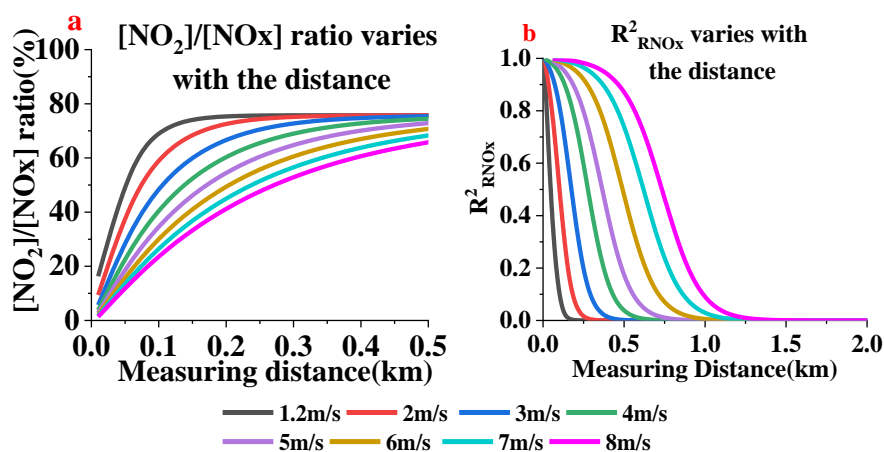

475 In Section 4.2 we left unanswered the question as to why the NOx flux error is very large
 476 when very close to the source (see Figure 6). In this section we will investigate the reason for
 477 this phenomenon.

478 Stacks mainly exhaust NO, which then transforms into NO₂ in a few minutes due to chemical
 479 reactions. Since NOx disperses along the wind direction, this means that the [NO₂]/[NOx] ratio
 480 varies with distance. We calculated the [NO₂]/[NOx] ratio and displayed it in a subfigure of
 481 Figure 10. From Figure 10a we can see that the [NO₂]/[NOx] ratio increases with distance.

482 In actual measurements, especially for elevated point sources, the dependence of the
 483 [NOx]/[NO₂] ratio on the distance from the air parcel of the plume is difficult to measure. Thus
 484 for the NOx flux calculations, a [NOx]/[NO₂] ratio correction factor is applied. However, since
 485 the assumptions for the calculation of this correction factor might be different from the true
 486 conditions, even after the application of the correction factor, substantial flux errors might occur.
 487 Subfigure b in Figure 10 displays the R_{RNOx}^2 value of the [NOx]/[NO₂] ratio correction error.

488 The larger the $[\text{NOx}]/[\text{NO}_2]$ ratio, the larger the R^2_{RNOx} value of the $[\text{NOx}]/[\text{NO}_2]$ ratio correc-
 489 tion. This causes the R^2_{RNOx} to increase, to as high as 1, when near the source. Also, from the
 490 R^2_{RNOx} value we discovered that the $[\text{NOx}]/[\text{NO}_2]$ ratio correction error is the main error source
 491 when close to the emission source. Hence, the main flux error source near the emission source
 492 is the $[\text{NOx}]/[\text{NO}_2]$ ratio correction error.

493

494

495 Figure 10. Variation of $[\text{NO}_2]/[\text{NOx}]$ ratio and R^2_{RNOx} with distance at different wind speeds ($Q = 100 \text{ g/s}$)

496 Since we know that the $[\text{NOx}]/[\text{NO}_2]$ ratio correction error is the main error source near the
 497 emission source, developing ways to avoid or minimize this error is our goal.

498 In real-world experiments, accurately measuring NOx flux requires NOx to reach a steady
 499 state. According to Eq. (4), when time approaches infinity, the NO_2 reaction rate r_{NO_2} ap-
 500 proaches 0, indicating that NOx reaches a steady-state. In theory, steady-state NOx is an ideal
 501 condition for measuring NOx flux. Infinite time, however, is not our expectation. If we regard
 502 $r_{\text{NO}_2} = 0.05r_{\text{max}}$ as the approached steady-state, the approached steady-state time could be at-
 503 tained, as well as the approached steady-state distance. r_{max} is defined as the theoretical NO_2

504 maximal reaction rate, which is $r_{\text{NO}_2} = k_5[\text{NO}]_0[\text{O}_3]$. Figure 11 a displays the variation of $\frac{r_{\text{NO}_2}}{r_{\text{max}}}$

505 with time and Figure 11 b displays the approached steady-state distance.

506 In order to investigate the feasibility of our recommendation, we used the following equation
 507 for analysis:

$$508 \quad E_{RNO_x} = \frac{\Delta F_{RNO_x}}{DQ} \times 100\% \quad (21)$$

509 where ΔF_{RNO_x} is the flux error resulting from the $[NO_x]/[NO_2]$ ratio correction at the ap-
 510 proached steady-state distance. E_{RNO_x} is used rather than R^2 because R^2 only represents the
 511 error source contribution/budget. For example, the R^2 value of the $[NO_x]/[NO_2]$ ratio correction
 512 is 0.9, while the total relative error is only 10%. In this case, it seems that we cannot accept the
 513 high R^2 , although the total relative error is acceptable. Therefore, in our judgment, using E_{RNO_x}
 514 is an advantage.

515 The E_{RNO_x} values at the approached steady-state distance for different wind speeds and
 516 emission rates were calculated, and the results are presented in Figure 11 c. From this figure,
 517 we can infer that E_{RNO_x} is approximately 5%, which is very low. This indicates that the flux
 518 error resulting from the $[NO_x]/[NO_2]$ ratio correction at the approached steady-state distance is
 519 very small and can thus be regarded as negligible.

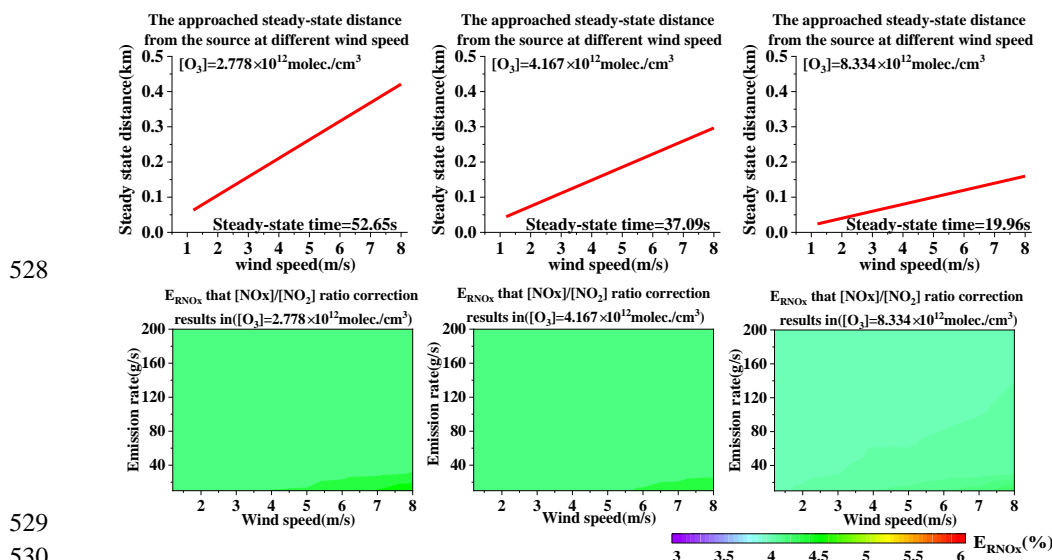

520
 521 Figure 11. NO_x steady-state distance from the source and the E_{RNO_x} values under different emission rates
 522 and wind speeds ($[O_3] = 1.389 \times 10^{12}$ molecules/cm³)

523 According to Eq. (6), r_{NO_2} depends on $[O_3]$. Hence, we also calculated the NO_x steady-state
 524 distance and E_{RNO_x} under different $[O_3]$. The E_{RNO_x} was also approximately 5% under differ-
 525 ent $[O_3]$, as shown in Figure 12. The dependence calculation demonstrates that E_{RNO_x} is also

526 very small under different $[O_3]$. Consequently, regarding $r_{NO_2} = 0.05r_{max}$ as the approached
 527 steady state seems to be acceptable.

529
 530

531 Figure 12. NOx approached steady-state distance from the source and E_{RNOx} values under different emis-
 532 sion rates, different wind speeds, and different $[O_3]$.

533 In summary, when very close to the emission source, the main flux error source is the
 534 $[NO_x]/[NO_2]$ ratio correction error. In order to avoid or minimize this error, we recommend
 535 $r_{NO_2} = 0.05r_{max}$ as the approached steady state, in which case the approached steady-state dis-
 536 tance is the starting measurement distance. The overall distances for different $[O_3]$ concentra-
 537 tions were also simulated as a reference for the DOAS measurement of NOx point source emis-
 538 sions, as shown in Figure 13. In subsection 2.2.2, we assumed that it was reasonable to disregard
 539 VOCs, since NOx, water vapor, and VOCs would generate a more complex reaction that could
 540 produce more O_3 , which in turn would accelerate the NO_2 reaction rate. In other words, what
 541 we assumed is conservative, so the NOx approached steady-state distance in Figure 13 is also
 542 conservative.

543
544 Figure 13. NO_x steady-state distance from the source for different [O₃] concentrations ($r_{NO_2} = 0.05r_{max}$).

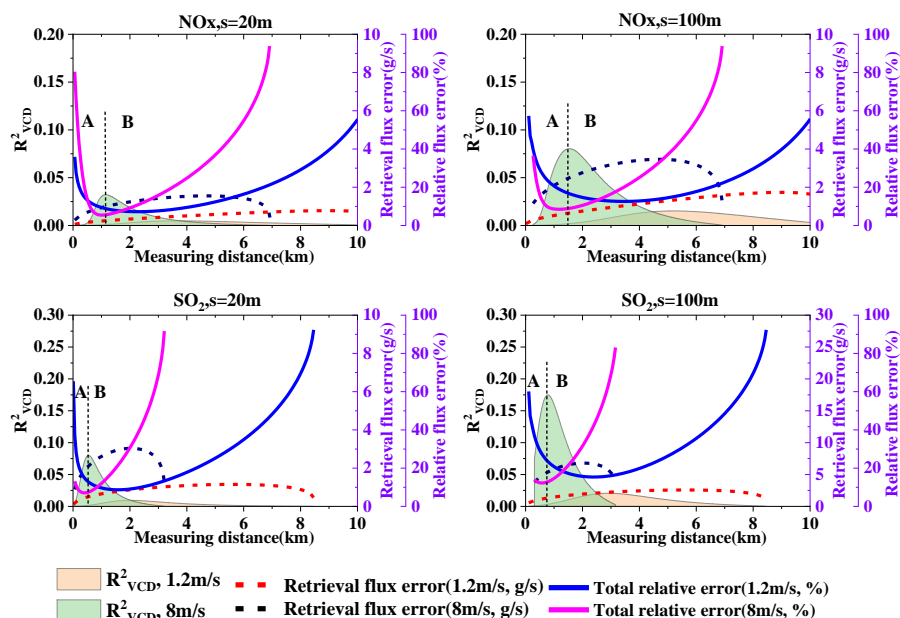

545 4.5 Retrieval error

546 Since the emission flux error due to the VCD retrieval error depends on the plume width and
547 the sampling resolution, typical plume widths and sampling resolutions were selected for this
548 discussion. We set the wind speeds at 1.2 m/s and 8 m/s because, based on the dispersion model,
549 the plume width is a function of the wind speed (Eqs. 1, 8, 9). Sampling resolutions of 20 m
550 and 100 m were chosen. In addition, an emission rate of 100 g/s for the point source Q was set.
551 Figure 14 displays the total relative error, R_{VCD}^2 , and the absolute flux error caused by the re-
552 trieval error. From this figure we could infer that the retrieval error is not the main error source
553 for $R_{VCD}^2 < 0.2$, although the R_{VCD}^2 trend is very interesting.

554 R_{VCD}^2 increases to a peak value and then decreases, while the absolute flux error slowly in-
555 creases at relatively long range measurement distances and then quickly decreases. Meanwhile,
556 the trend of total relative error quickly decreases (stage A in Figure 14) and then slowly increases
557 (stage B in Figure 14). In order to simplify the analysis, we only designated stage A and stage B
558 for the wind speed of 8 m/s. In stage A, the flux error grows while the total relative error de-
559 creases rapidly, resulting in the retrieval error contribution becoming more obvious. In stage B,
560 the flux error slowly grows and then decreases, while the total relative error grows, resulting in
561 the retrieval error contribution becoming less obvious. This results in the observed R_{VCD}^2 trend.

562

563

564

565 Figure 14. Total relative error, absolute flux error, and retrieval error resulting in the R_{VCD}^2 trends
 566 of NO_2 and SO_2 ($Q = 100 \text{ g/s}$)

567 4.6 Effect of number of measurement times

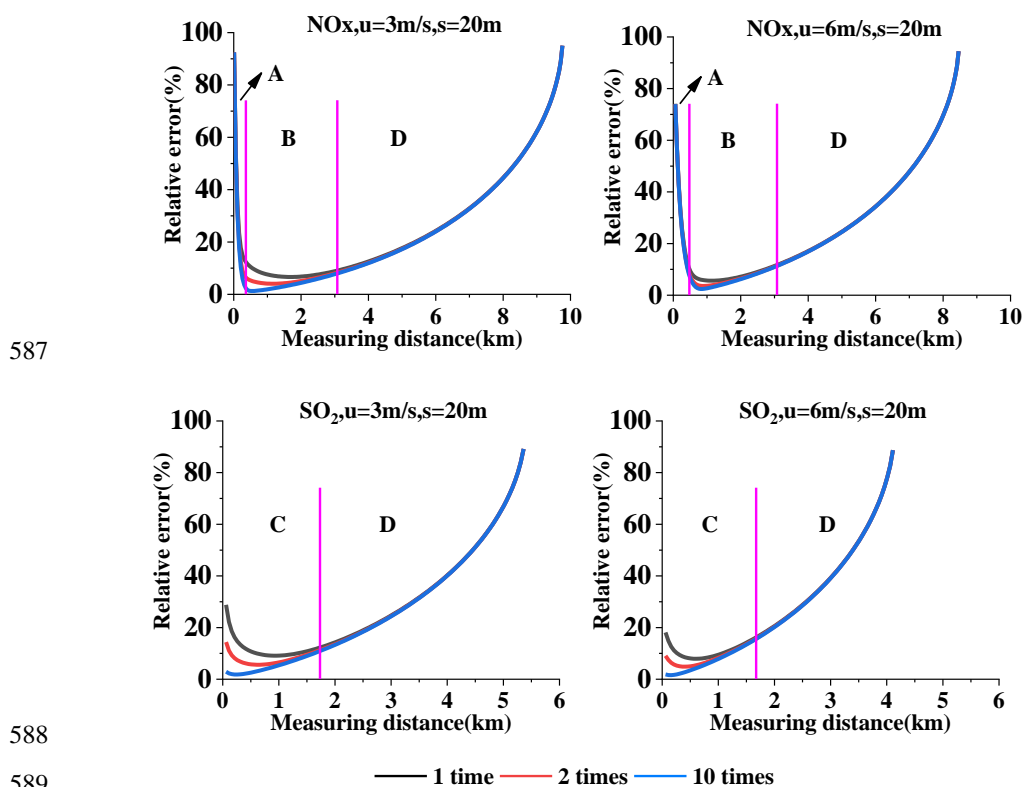

568 In our experiments, we only simulated a single scan of the plume by the mobile DOAS at
 569 each specific distance. In reality, we usually scan the plume cross-section several times in order
 570 to reduce the flux error. Figure 15 displays the simulation example of NO_x and SO_2 flux error
 571 under different measurement times.

572 The error sources of the emission flux can be classified into 2 types. The first is the measur-
 573 able error/uncertainty: wind speed and wind direction uncertainty, and retrieval error. The sec-
 574 ond is: $[\text{NO}_x]/[\text{NO}_2]$ ratio correction error near the source and undetectable flux error. The flux
 575 error resulting from the first type of error source can be lowered by scanning the plume more
 576 times while the second cannot be.

577 According to the analysis in Section 4.3, the undetectable flux is the main error source when
 578 far from the emission source. Consequently, the flux error under different numbers of scans for
 579 both NO_x and SO_2 cannot be significantly lowered when measuring far from the source (range
 580 D in Figure 15). Within the close measurement range (range C in Figure 15), the first type of

581 error source is the predominant source of SO₂ error, and thus the flux error can be lowered by
582 additional plume scans. For NO_x, however, the [NO_x]/[NO₂] ratio correction error is the main
583 error source when very close to the emission source (range A in Figure 15), and thus the effect
584 of additional plume scans is not evident. A little farther from the source, the first type of error
585 source becomes the main error source (range B in Figure 15). Ultimately, the impact of addi-
586 tional plume scans becomes effective.

587

588

589

590 Figure 15. Emission flux error under different numbers of scans. Range A is very close to the source, range
591 B is not too close or too far, range C is close to the source, and D is far from the source ($Q = 100 \text{ g/s}$).
592

592

593 4.7 Effect of spectrometer integration times

594

Spectrometer noise is the main noise source of the mobile DOAS instrument (Platt and Stutz,
595 2008; Danckaert et al., 2015). The noise level varies under different integration times, thereby
596 changing the retrieval error and detection limit, which would then affect the flux measurement
597 error. Therefore, this section is focused on the effect of spectrometer integration times on mobile

598 DOAS flux measurement error.

599 The relationships among retrieval error, detection limit, and noise level are (Kraus, 2006;
600 Platt and Stutz, 2008)

$$601 \quad VCD_{err} \propto Fit_{err} \propto \sigma, \quad D_{lim} \propto \sigma \quad (21)$$

602 where VCD_{err} is the VCD retrieval error, Fit_{err} is the total fitting error in DOAS fitting, D_{lim}
603 is the detection limit, and σ is the noise level. The noise level is approximately inversely
604 proportional to the square root of the integration times.

605 The sampling resolution of mobile DOAS can be expressed as:

$$606 \quad s = v \cdot (t_s \cdot n) = v \cdot t_{int} \quad (22)$$

607 where v is the car speed, t_s is a single integration time of the spectrometer, n is the spec-
608 trometer averaging times, and t_{int} is the spectrometer integration times.

609 According to Eq. (22), the effect of integration times can be investigated in 2 different ways:
610 Varying the car speed and thus fixing the sampling resolution or fixing the car speed and thus
611 varying the sampling resolution. In this study, we simulated the integration times for $0.25 t_{int}$,
612 $0.5 t_{int}$, $1 t_{int}$, $2 t_{int}$ and $4 t_{int}$.

613 4.7.1 Prescribed sampling resolution

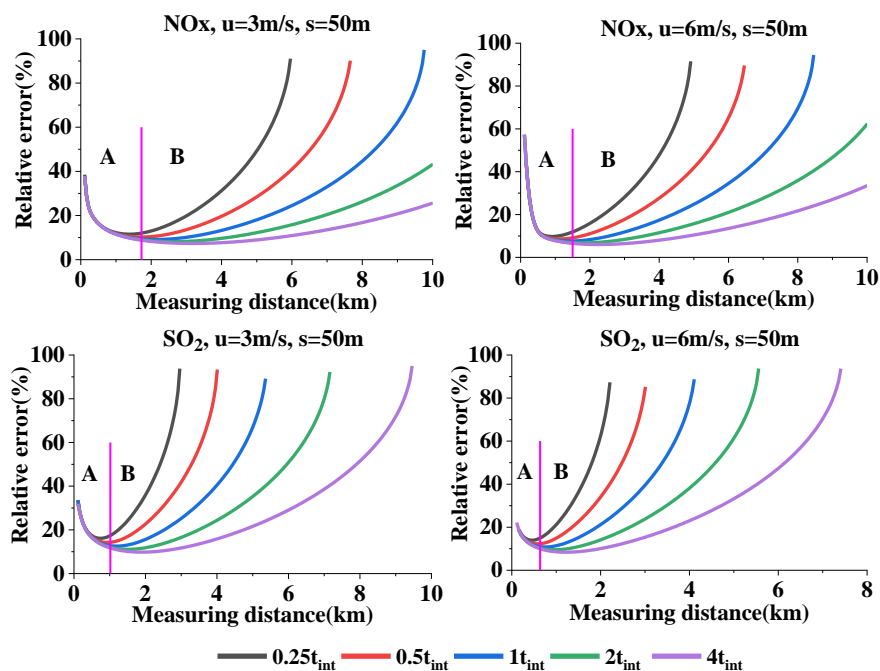

614 Since different integration times results in the car speed varying in a large range that car
615 speed cannot be fully realized in actuality at a given sampling resolution, the sampling resolu-
616 tion cannot be too small. Here, we chose a 50 m sampling resolution as a case study.

617 Figure 16 displays the relative error under different integration times at a given sampling
618 resolution ($Q = 100$ g/s). From Figure 16 we can see the relative error differences resulting from
619 various integration times.

620 Since a larger integration times will directly lead to a lower detection limit and a smaller
621 fitting error, and indirectly to a lower undetectable flux and a lower retrieval error, the relative
622 error nonlinearly decreases with increasing integration times. Since the relative error differ-
623 ences caused by integration times become more evident when far from the source (range B in

624 Figure 16), our analysis focused on this range. This phenomenon is due to that fact that different
625 integration times mainly act on the retrieval error and the detection limit. Therefore, we sepa-
626 rately analyzed these 2 error sources.

627

628

629

630 Figure 16. Relative error under different integration times at a prescribed sampling resolution ($Q = 100 \text{ g/s}$)

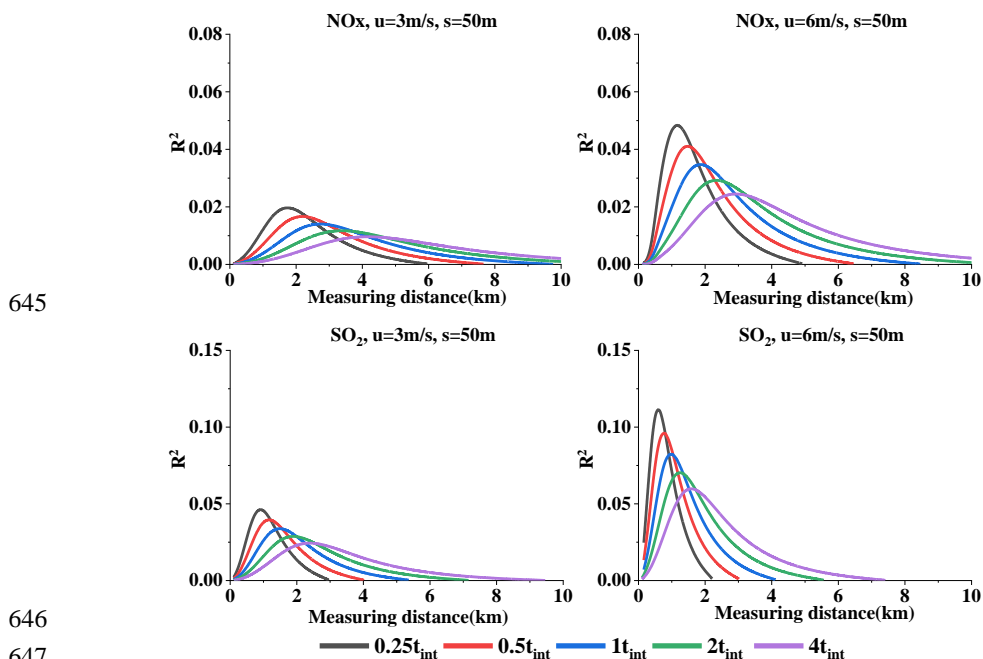

631 First, we analyzed the flux error resulting from the retrieval error. Figure 17 presents the R^2
632 values of the retrieval error. These R^2 values are all < 0.12 , demonstrating that retrieval error is
633 not the main error source and, furthermore, indicating that the main reason for the relative error
634 variation in Figure 16 should not be attributed to retrieval error.

635 Second, we analyzed the undetectable flux differences resulting from different detection lim-
636 its. Figure 18 presents the undetectable flux and its R^2 values. From the R^2 values we could infer
637 that undetectable flux contributes most to the error when far from the source. Especially for
638 smaller integration times, undetectable flux R^2 increases very quickly with distance. In addition,
639 the variation trend of undetectable flux in range B also corresponds to the relative error trend.
640 Therefore, we infer that the relative error trend under different integration times is determined
641 by the undetectable flux.

642 In brief, different integration times significantly impact the relative error at a given sampling

643 resolution in range B, and these error differences are mainly attributed to the undetectable flux
 644 differences resulting from the detection limit.

645

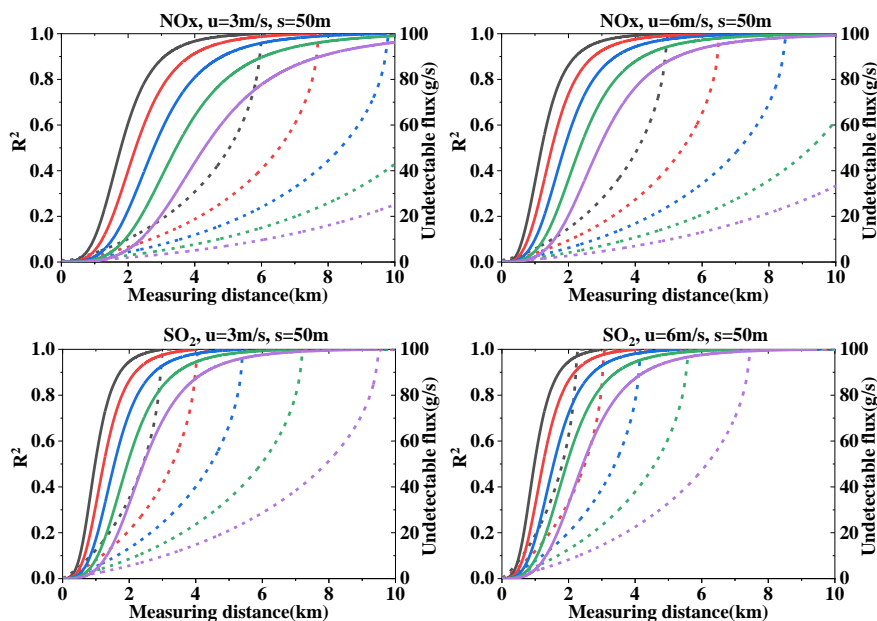

646

647

648

Figure 17. R^2 and flux error resulting from the retrieval error under different integration times.

649

650

651 R^2 — 0.25 t_{int} — 0.5 t_{int} — 1 t_{int} — 2 t_{int} — 4 t_{int}
652 Undetectable flux(g/s) ■ ■ 0.25 t_{int} ■ ■ 0.5 t_{int} ■ ■ 1 t_{int} ■ ■ 2 t_{int} ■ ■ 4 t_{int}
653 Figure 18. Undetectable flux and its R^2 values under wind speeds of 3 m/s and 6 m/s for NO_x and SO₂ un-
654 der different integration times. The sampling resolution is 50 m ($Q = 100$ g/s).

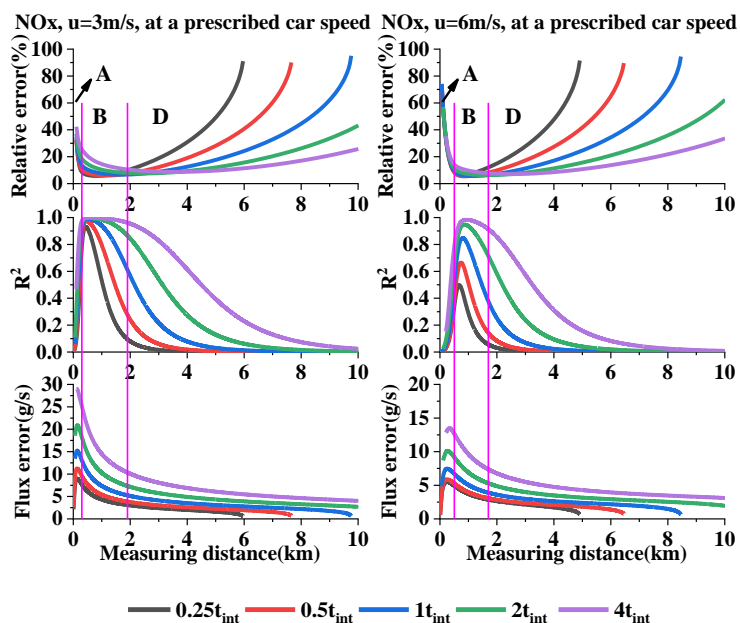

654 4.7.2. Prescribed car speed

655 When the car speed is prescribed, the sampling resolution is determined by the integration
656 times integration times. Therefore, an effect on the error due to the sampling resolution would
657 be introduced (Section 4.1).

658 Figure 19 presents the relative error under different integration times at a given car speed. It
659 is interesting that the relative error differences caused by integration times in ranges B and D
660 (NO_x) are opposite those of ranges C and D (SO₂). We analyzed the causes of the relative error
661 differences in range D, but did not analyze the causes in range B or C.

662 From Section 4.1 we know that, within the proper resolution range, the relative error in-
663 creases with increasing sampling resolution. Moreover, the sampling resolution can only affect
664 the first type of error source mentioned in Section 4.6, i.e., the wind field uncertainty, and re-
665 trieval error. We calculated the sum of the R^2 values for the wind field uncertainty, and retrieval
666 error. In addition, the sum of the absolute flux errors introduced by these error sources is shown
667 in Figure 20. The R^2 values indicate that, in range B or C, these factors are the main error source
668 and thus cause the differences under different t_{int} . The flux error trends do not all correspond
669 to the relative error trend due to the undetectable flux, although it is still the main error source
670 that determines the differences in range B or C.

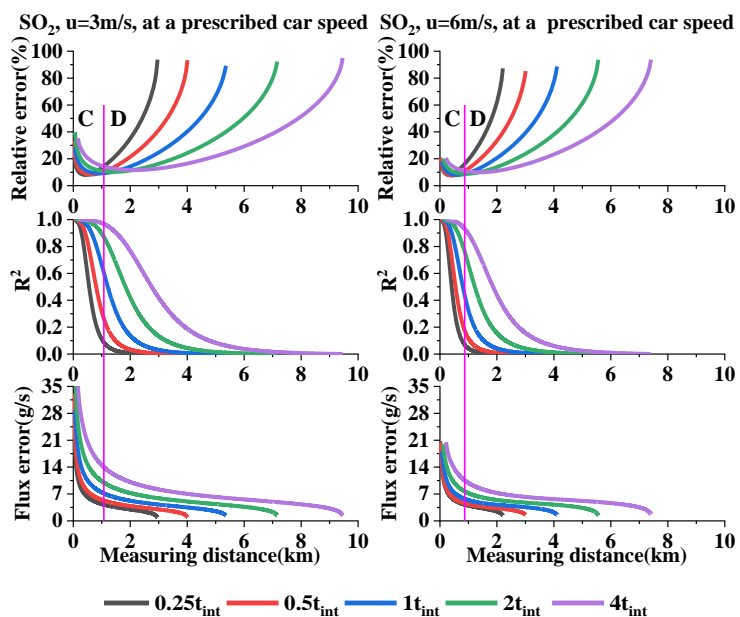

671 Furthermore, we can conclude that the different integration times that significantly affect the
672 relative error at a given car speed can be divided into 2 ranges: B and D for NO_x, and C and D
673 for SO₂. In range B/C, the differences under different t_{int} can be attributed to the sampling
674 resolution effect. In range D, the differences under different t_{int} can be attributed to the unde-
675 tectable flux.

676

677

678 Figure 19. NO_x relative errors, R^2 values, and flux errors introduced by the wind field uncertainty, and re-
 679 trieval error under wind speeds of 3 m/s and 6 m/s ($Q = 100$ g/s)

680

681

682 Figure 20. SO₂ relative errors, R^2 values, and flux errors introduced by the wind field uncertainty, GPS er-
 683 ror, and retrieval error under wind speeds of 3 m/s and 6 m/s ($Q = 100$ g/s)

684

685 Different integration times result in different retrieval errors and different detection limits. The

686 analysis in terms of either a given sampling resolution or a given car speed has significant im-
687 plications. For example, when measuring close to the source, i.e., range B or C in Figures 20
688 and 21, we can fix the car speed within a proper low integration times in order to obtain a higher
689 resolution, which indirectly results in a lower error. When measuring far from the source, proper
690 large sampling resolutions are available since the main error source is the undetectable flux.
691 This further suggests that larger integration times and higher car speeds can be applied in order
692 to increase the efficiency of measuring flux.

693 **4.8 Effects from other factors**

694 Measuring emission flux is extremely complex. It is feasible to analyze the error caused by
695 some key factors, but it is also necessary to study other factors.

696 **4.8.1 Emission rate**

697 Emission rate is an objective factor. The simulation results suggest that the emission rate
698 significantly affects the relative error distribution. Therefore, disregarding the emission rate in
699 order to analyze the error is a less rigorous approach.

700 From Eqs. (10), (11), and (12) we know that $VCD(x,y)$ is proportional to the emission rate,
701 which means that lower emission rates generate lower $VCD(x,y)$ levels, leading to variations
702 of plume width and detectable flux with distance. Ultimately, this results in larger emission flux
703 errors at the same distance when the emission rate is low, even if there is no proper resolution
704 to measure. In order to achieve a low emission flux error, emission rates that are too low are
705 not recommended. We cannot provide a precise lower limit for the emission rate, but can pro-
706 pose a range of values. From the figures in the Appendix, we can see that the red areas (indi-
707 cating large errors) cover nearly all of the figure when the NO_x emission rate is < 30 g/s and
708 the SO_2 emission rate is < 50 g/s. Therefore, emission rates < 30 g/s for NO_x and < 50 g/s for
709 SO_2 are not recommended in mobile DOAS measurements.

710 **4.8.2 Different source heights**

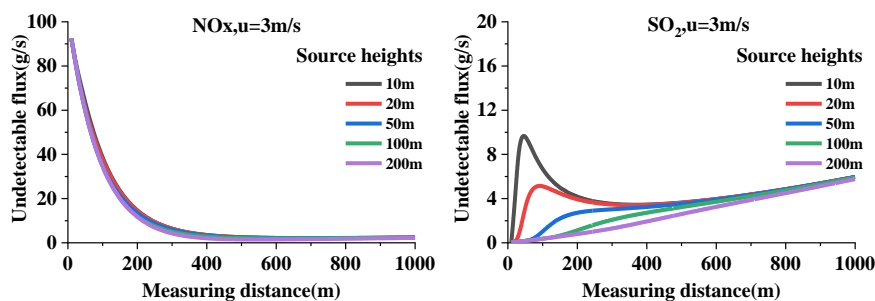

711 The mobile DOAS height, which is approximately 2 m from the ground to the telescope, is
712 usually negligible in actual measurements. When the source is not very high, however, more
713 gas will descend to the ground under the mobile DOAS telescope, where it cannot be measured.

714 Here, we simulated the emission source at heights of 10 m, 20 m, 50 m, 100 m, and 200 m.
715 Since lower wind speeds will lead to gas quickly descending to the ground, we simulated a low
716 wind speed of 3 m/s. The emission rate was set to 100 g/s.

717 The lower the source height, the more gas will descend to the ground, resulting in changes
718 to the undetectable flux. Figure 21 displays the undetectable flux of NO_x and SO₂ for the wind
719 speed of 3 m/s. From this figure we can see that the undetectable flux of NO_x exhibits little
720 variation, while obvious variations occur in the SO₂ flux when close to the source. The unde-
721 tectable flux variation may impact the flux relative error.

722 Figure 22 presents the flux relative error at different heights. These results show that the
723 relative errors of NO_x and SO₂ exhibit little variation. This is because, compared to the flux
724 error resulting from other main error sources, the undetectable flux variation with height is
725 negligible.

726
727 Figure 21. NO_x and SO₂ undetectable flux values at different source heights ($Q = 100$ g/s, $u = 3$ m/s)

728
729 Figure 22. NO_x and SO₂ flux relative errors at different source heights ($Q = 100$ g/s, $u = 3$ m/s, $s = 20$ m)

730 4.8.3 Uncertainties of the Gaussian dispersion model

731 The Gaussian dispersion model was assumed in the forward model during our discussion of
732 the emission flux error budget. The dispersion in actual measurements, however, depends on

733 meteorological conditions and surrounding terrain. Differences in the Gaussian dispersion
734 model from reality could have resulted in a bias of the error budget presented in this study from
735 reality. The investigation of the detailed of the dispersion model is outside the scope of this
736 investigation.

737 **5 Conclusions**

738 In this study, we used a Gaussian dispersion model to quantify the NO_x and SO₂ point source
739 emission flux errors of mobile DOAS.

740 We first established a forward model for the simulation.

741 In the forward model, we modified the Gaussian dispersion model in order to make it appro-
742 priate for the DOAS technique, i.e., the SO₂ and NO_x VCD dispersion model. The NO_x VCD
743 dispersion model also took NO_x atmospheric chemical reactions into consideration.

744 Second, we analyzed the simulation data, reaching the following conclusions:

745 **(1)** The impact of sampling resolution on emission flux error is noticeable. Smaller resolution
746 can lower the flux error. In terms of measurement efficiency, the sampling resolution should be
747 moderate. Therefore, we recommended the proper sampling resolution to range from 5–50 m.
748 Larger resolutions could also be applied, but > 100 m is not recommended.

749 **(2)** Measuring distance significantly affects the flux measurement error. When far from the
750 source, undetectable flux from the wind dispersion effect, which results in large errors, will be
751 noticeable. When close to the emission source, a low number of sampling data leads to large
752 flux errors. The proper measuring distance is not too far or too close to the source. Due to the
753 complex situation, the proper distance is difficult to quantify. It should be noted that undetect-
754 able flux is the error source which was not considered in (Johansson et al., 2008, 2009; Rivera
755 et al., 2009, 2012; Ibrahim et al., 2010; Shaiganfar et al., 2011, 2017; Berg, et al., 2012; Walter,
756 2012 et al.; Wu et al., 2013, 2017; Frins et al., 2014; Merlaud et al., 2018).

757 **(3)** The wind field influence could be classified into 2 parts: uncertainty and dispersion. Dis-
758 persion is more evident when far from the emission source; thus, undetectable flux is the main
759 error source for both SO₂ and NO_x. When measuring close to the emission source, wind field
760 uncertainty is the main error source of SO₂ flux measurements, but not of NO_x. For higher wind

761 speeds the dispersion effect is more distinct, thereby directly leading to more undetectable flux.

762 We recommended a wind speed of 1–4 m/s for accurate mobile DOAS measurements.

763 **(4)** NO converts to NO₂ upon exhaust from a stack and reaches the NO_x steady state within
764 a few minutes. During this time period the [NO_x]/[NO₂] ratio decreases continuously with dis-
765 tance, resulting in a flux error due to [NO_x]/[NO₂] ratio correction. Our simulation indicates
766 that [NO_x]/[NO₂] ratio correction is the main error source when measuring very close to the
767 emission source. To minimize the large [NO_x]/[NO₂] ratio correction error, we recommended
768 $r_{NO_2} = 0.05r_{max}$ as the NO_x steady state. Therefore, the proper starting measurement distance
769 for NO_x could be determined, which we displayed in Figure 13.

770 **(5)** Retrieval error is not a dominant error source and its error budget varies with the meas-
771 uring distance.

772 **(6)** Repeating the measurements several times can only affect the measurable error source,
773 and do not affect the unmeasurable. This causes the SO₂ flux error to decrease when not very
774 far from the emission source. As for NO_x, increasing the number of measurement times could
775 become effective when not very close to the source but not too far away.

776 **(7)** Different integration times result in different retrieval errors and detection limits. For a
777 prescribed sampling resolution, relative error differences under different integration times are
778 attributed to undetectable flux differences caused by the detection limit, especially for distant
779 measurements. For a prescribed car speed, the sampling resolution effect is introduced. When
780 measuring not very far from the emission source, the relative error differences are attributed to
781 the sampling resolution effect from the first type of error source. Far from the source, the de-
782 tection limit applies.

783 **(8)** Other studies have indicated that emission rates < 30 g/s for NO_x and < 50 g/s for SO₂
784 are not recommended in mobile DOAS measurements. The source height exerts an impact on
785 the undetectable flux, but has little impact on the total error.

786 The advantage of the method put forth in this study is that many scenarios can be simulated.
787 Through this simulation method, we discovered a missing error source, and were able to exam-
788 ine the error sources and influence factors affecting flux error in more detail. Also important is

789 that the $[\text{NO}_x]/[\text{NO}_2]$ ratio correction effect of flux measurement was clarified.

790

791 *Data availability.* The data used in this analysis are available from the authors upon request.

792 *Author contributions.* Ang Li, Thomas Wagner and Yeyuan Huang developed the simulation
793 method. Yeyuan Huang, Yang Wang and Zhaokun Hu designed the forward model. Hongmei
794 Ren and Bing Dang processed the wind data. Pinhua Xie, Thomas Wagner, Jin Xu and Xiaoyi
795 Fang supervised this study. Yeyuan Huang analyzed the data and wrote the paper. Yang Wang
796 revised this paper preliminarily.

910 Appendix

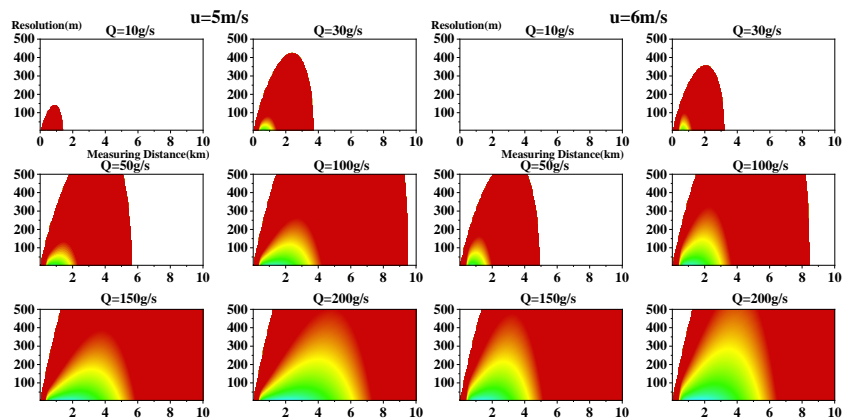

911 1. NO_x simulation results (relative error)

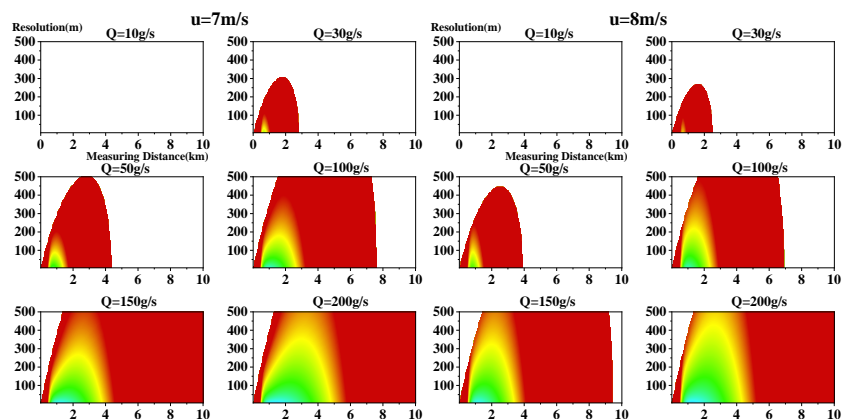

912

913

914

915

916

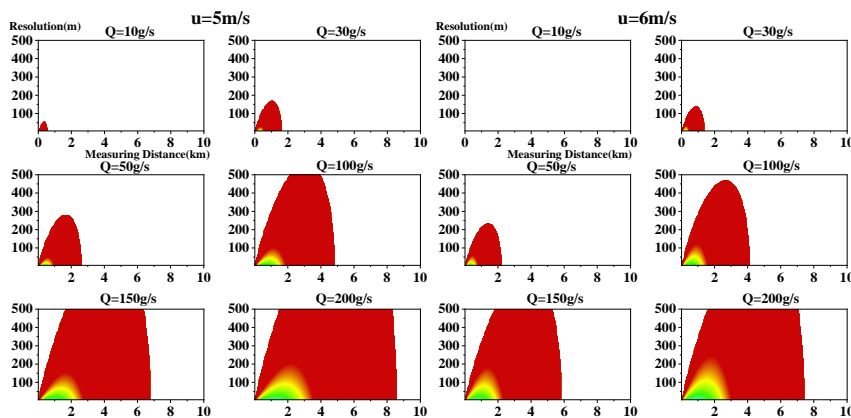

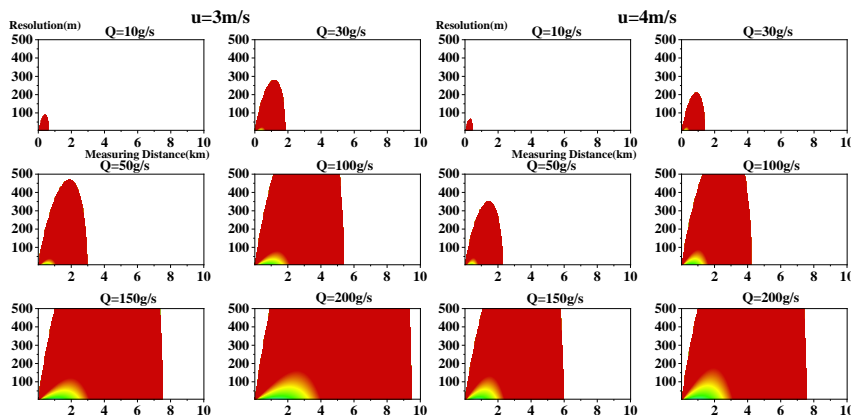

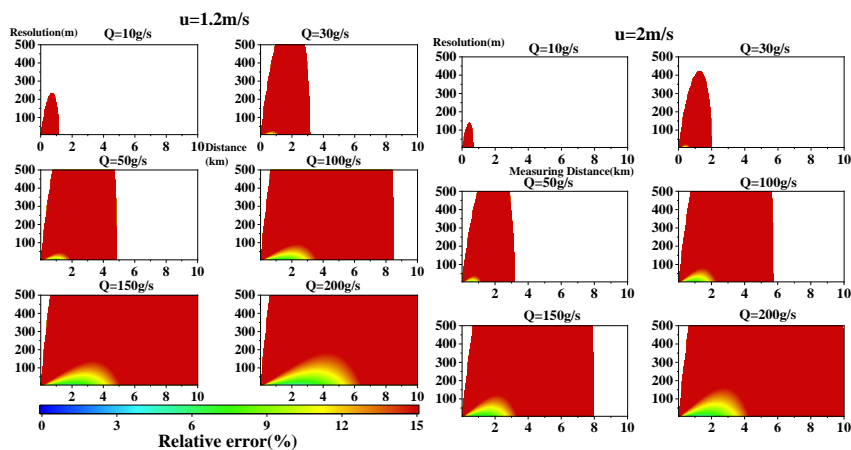

917 Figure 23. Relative errors (using Eq. 19) of NO_x as a function of the measurement distance from the source

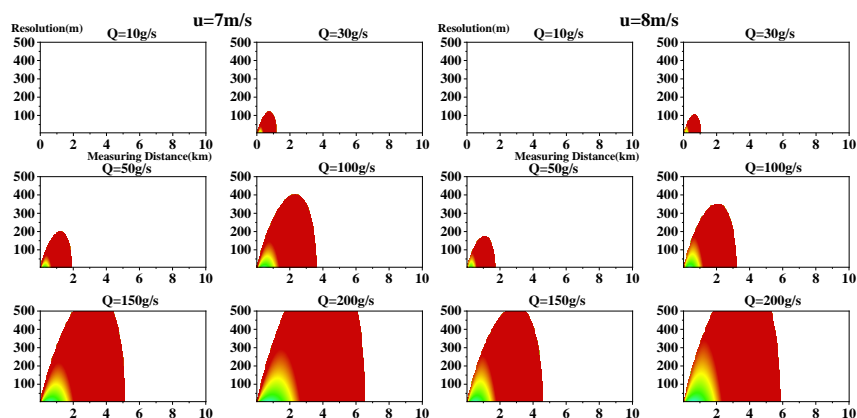

918 (*x*-axis) and the sampling resolution (*y*-axis). The different subfigures show the results for different wind

919 speeds and different emission rates. The color map indicates the relative errors.

920 **2. SO₂ simulation results (relative error)**

924

925 Figure 24. Relative error (using Eq. 18) of the distribution of SO₂ for different wind fields of different

926 emission rates. The unit of all abscissas is the measurement distance from the source (km), while that

927 of the ordinate is the sampling resolution (m). The color map indicates the relative errors.
