Abstract. We present first eddy covariance flux measurements with the PTR3-TOF-MS, a novel proton-transfer-reaction mass-spectrometer. During three weeks in spring 2016 the instrument recorded 10 Hz data of biogenic volatile organic compounds above a boreal forest, on top of a measurement tower at the SMEAR II station in Hyytiälä, Finland. Flux and concentration data of isoprene, monoterpenes and sesquiterpenes were compared to the literature. Due to the improved instrument sensitivity and a customized “wall less” inlet design we could detect fluxes of semi-volatile and low volatile organic compounds with less than single digit picomol/m²/s values for the first time. These compounds include sesquiterpene oxidation products and diterpenes. Daytime diterpene fluxes were in the range of 0.05 to 0.15 picomol/m²/s, which amounts to about 0.25% to 0.5% of the daytime sesquiterpene flux above canopy.

1 Introduction

More than 1000 teragrams (Tg) organic carbon excluding methane is emitted from terrestrial ecosystems into the atmosphere per year as biogenic volatile organic compounds (BVOC) (Guenther et al., 2012). All anthropogenic VOC emissions together account for another 200 Tg yr⁻¹ of carbon flux into the atmosphere (Huang et al., 2017). Once in the atmosphere, these VOC react with the hydroxyl radical (OH), ozone (O₃), or nitrate (NO₃) radicals and subsequent O₂ addition generates peroxy (RO₂) radicals as intermediates. Further oxidative steps depending on the availability of NO_x (NO + NO₂) lead to oxidized volatile organic compounds (OVOC) (Seinfeld and Pandis, 2016). These OVOC could degrade further through photooxidation reactions becoming less volatile and condense onto aerosol particles, contributing to secondary organic aerosol (SOA) or deposit to surfaces (Nguyen et al., 2015). Highly oxidized RO₂ resulting from monoterpene oxidation with subsequent H-shifts and O₂ addition were also found to produce accretion products having a remarkably low vapor pressure. These dimers are likely able to initiate new particle formation (NPF) (Ehn et al., 2012, Kulmala et al. 2013, Ehn et al. 2014, Kirkby et al., 2016, Tröstl et al. 2016, Berndt et al., 2018a). Resulting aerosol can act as cloud condensation nuclei and impact global climate as well as air quality (Pöschl, 2005). Molecular understanding of NPF and early growth is critically for climate modeling (Lee et al., 2019, Gordon et al., 2016). A recent global model by Zhu et al., (2019) shows a decrease in total aerosol direct and indirect

35 radiative forcing of 12.5% compared to previous models when including organic nucleation. Their calculations were based on
an explicit chemical mechanism coupling emissions from the Community Earth System Model (CESM) with the IMPACT
aerosol model. CESM itself uses global inventories of precursor emissions models like MEGAN (Guenther et al., 2012),
extrapolated from local observations. These observations were gathered from numerous field-measurements that are limited
to VOC fluxes, which are detectable with current analytical devices. Proton transfer reaction mass spectrometry (PTR-MS)
40 (Hansel et al., 1995) can detect the majority of volatile organic carbon in ambient air (Hunter et al., 2017). It is a well-
established technique for direct emission measurements of VOC (Karl et al., 2001; Müller et al., 2010) and was used
successfully in gradient and eddy covariance flux measurements (e.g., B. Millet et al., 2018; Karl et al., 2018; Rinne et al.,
2007; Ruuskanen et al., 2011). VOC including methanol, isoprene and monoterpenes comprise the largest fraction of emissions
and can be detected fast enough for eddy covariance flux analysis by existing PTR-MS instruments. Still, Guenther et al.
45 (2012) stresses the need for instrumentation able to measure BVOC with low vapor pressures and semi-volatile organic
compounds (SVOC), in order to refine current emission models. This aim goes in line with monitoring highly oxidized organic
molecules (HOM) important for NPF and SOA formation.

A group of compounds challenging current instrumentation are sesquiterpenes (SQT; $C_{15}H_{24}$), which can be highly reactive.
Despite their lower emission rates, the importance of sesquiterpenes for NPF was postulated long ago (Bonn and Moortgat,
50 2003), but emission estimates are still based mainly on enclosure measurements (Bourtsoukidis et al., 2018; Hakola et al.,
2006; Helmig et al., 2007). At the boreal forest site at Hyytiälä, Finland, Rinne et al. (2007) predicted, that sesquiterpene
emissions are as high as 20% of monoterpene emissions at the leaf level (based on enclosure measurements) and that thereof
30-40% are chemical degraded on the way from emission to instrument inlets at tower height. These sesquiterpene fluxes were
below limit of detection (LoD) of the state-of-the-art instruments at that time when considering reactivity, adhesion to surfaces
55 and inlet damping (Bourtsoukidis et al., 2018; Rinne et al., 2007). Recent particle phase measurements at a hemi boreal forest
site in Estonia suggest that sesquiterpene oxidation products can substantially contribute to secondary organic aerosol mass
(Barreira et al., 2021, under review).

Here, we present our technical approach and first results of eddy covariance flux measurements of VOC and SVOC with the
recently developed PTR3-TOF-MS (PTR3) (Breitenlechner et al., 2017). The instrument features a greatly improved
60 sensitivity compared to standard PTR-TOF-MS devices, a prerequisite for measuring the lower ambient concentrations of
SVOC.

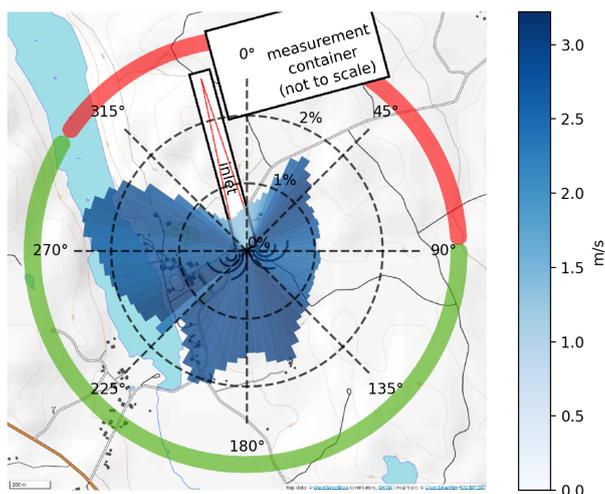

2 Experimental

2.1 Site

65 Measurements were conducted at the SMEAR II station (Station for Measuring Ecosystem – Atmosphere Relations) in
Hyytiälä, Finland (61°51'N, 24°17'E, 181 m above sea level; Hari and Kulmala, 2005; Kulmala et al., 2001) during April and
May 2016. The surrounding managed stand is predominated by 50-year-old Scots Pines (*Pinus sylvestris*), with less than 1%
other species like downy birch (*Betula pubescens*), grey alder (*Alnus incana*) and aspen (*Populus tremula*). Ground vegetation
includes heather (*Calluna vulgaris*), lingonberry (*Vaccinium vitis-idaea*) and blueberry (*V. myrtillus*) and the dominating moss
70 species *Dicranum undulatum*. Similar boreal coniferous forests represent 8% of the Earth's surface. The PTR3 mass
spectrometer was placed inside a measurement container on top of a tower, 35 m above ground, overtopping the canopy by
about 15 m. Local winds were originating from all directions with no clear prevailing direction during the whole campaign as
shown in the directional histogram in Figure 1. Wind speeds with an average magnitude of 2.5 m/s were observed. The inlet
was oriented horizontally, pointing in southeast direction (165°). In close proximity of the flux measurement tower (150 m

75 away), various parameters such as temperature, humidity, photosynthetically active radiation, wind, trace gas concentrations, such as ozone, NO_x etc. are routinely recorded at different heights of a second tower. These datasets are publicly available through the online Smart SMEAR service (Junninen et al., 2009).

80 **Figure 1: Prevailing winds from April 26th to May 16th in 2016. The orientation of the air inlet required filtering out data originating from the wind sector shown in red: Length of the histogram bars equals occurrence frequency in the corresponding sector, average wind speed is indicated in blue. Data with wind directions within the green sector are considered undisturbed, the red sector is influenced by the container on top of the tower structure. Wind data were recorded from a sonic anemometer located at the air intake point. Map: © OpenStreetMap contributors 2020, Distributed under a Creative Commons BY-SA License.**

85 2.2 Wind and humidity data

Horizontal and vertical wind components as well as virtual temperature were measured by a sonic anemometer (Metek USA-1) at 10Hz. The sensor was mounted 0.5 m above our air inlet, a trade-off between sensor separation and minimal disturbance by the high inlet flow. An infrared gas analyzer (IRGA) from LI-COR Inc. (LI-840A) recorded water vapor concentration at a sampling frequency of 1Hz in the excess sample air of the core sampling flow. Synchronous recording of concentrations and
90 wind data was assured by running the acquisition applications on the same computer and using the system clock for time stamps.

2.3 PTR3-TOF Mass Spectrometer (PTR3)

Highly time resolved VOC and SVOC volume mixing ratios were measured by the novel PTR3-TOF mass spectrometer described in detail by Breitenlechner et al. (2017). The PTR3 has a highly improved sensitivity and a special inlet design
95 reducing wall losses for low volatility compounds compared to standard PTR-TOF instruments. In field calibrations were performed regularly by dynamic dilution of a gas standard (Apel Riemer) containing known amounts of different VOC in dry

and humidified synthetic air. Impurities in the synthetic air were removed by a catalytic scrubber. We varied the water vapor concentration in the diluted calibration standard and in zero air by humidifying the synthetic air before entering the catalyst. In this way the calibration gas humidity was buffered and slowly changed from dry to humid conditions resulting in smooth ramps covering the whole humidity range. Absolute humidity was monitored simultaneously by the same infrared gas analyzer used for the ambient measurements. The measured dependence of the sensitivity for the calibration compounds on humidity was fitted by an empiric model, later used for calibration of the ambient measurements. The instrument operated with $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ($n=0-3$) primary ions at a reduced electric field strength E/N of 80 Townsend in the reaction region. PTR3 sensitivities are highest for ketones and almost humidity independent as was shown by Breitenlechner et al. (2017). The ketones present in our calibration standard are therefore used as a measure for the maximum expectable sensitivity for unknown compounds assuming fast reactions close to the collisional limit value with all $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ primary ions. To account for the mass dependent duty cycle of the TOF analyzer we normalized sensitivities to m/z 100. Hexanone and methyl ethyl ketone both showed a sensitivity of 16 ± 2 dcps/pptv (duty cycle corrected counts per second, per pptv) independent of humidity. With these settings, α -pinene could be ionized reasonably well with a sensitivity of 6.8 ± 1.5 dcps/pptv at dry and 3.8 ± 0.9 dcps/pptv at humid conditions (8 parts per thousand of H_2O). Isoprene sensitivities were 5.4 ± 0.9 dcps/pptv at dry and 2.4 ± 0.5 dcps/pptv at humid conditions. Fragmentation was kept low as indicated by α -pinene fragmentation, m/z 81 to m/z 137 was 32% on average. β -caryophyllene was not available as on-site gas standard, but it was calibrated in the laboratory at the same instrument settings and a sensitivity of 7 ± 3 dcps/pptv was found independent of the humidity. The respective limits of detection (LoD) were 12 pptv for isoprene, 7.5 pptv for α -pinene and 1.7 pptv for β -caryophyllene at 1s integration time based on the 2σ standard deviation of the chemical background during calibration divided by the measured sensitivity. The measured LoD was mainly limited by the background in the available VOC free zero air. Mass spectra were recorded at 10 Hz up to m/z 610, mass scale calibration during data acquisition was done based on known primary ions and a diffusion source constantly adding D_6 -siloxane to the reaction chamber of the PTR3.

The strength of the PTR3 lies in detecting VOC, OVOC, and HOM with concentrations at sub pptv level by a single instrument. The PTR3 bridges the gap between previous PTR instruments and the atmospheric pressure chemical ionization techniques such as Nitrate-CIMS or Iodide-CIMS (Riva et al., 2019).

2.4 Inlet design

Low volatility species are most affected by inlet line losses hence a more sophisticated inlet concept is required. Accurate eddy covariance flux measurements require air velocity, temperature, humidity and SVOC concentrations to be sampled co-located and synchronized without disturbing the natural air flow (Aubinet et al., 2012, p.45ff., 72). Chemical ionization mass spectrometers are by design closed path analyzers and too bulky to be deployed within the preferable sensor separation distance of < 50 cm (Massman, 2000) to the sonic anemometer. Most previously reported tower flux measurement campaigns using mass spectrometers (B. Millet et al., 2018; Fulgham et al., 2019; Karl et al., 2018; Schallhart et al., 2017) extended the inlet lines from the top of the measurement tower down to the instruments placed in a container at ground level. In such setups, well known limitations caused by long inlet lines (~ 50 m) of closed path analyzers have to be tackled. While high frequency attenuation of fluctuations created by these long inlet lines is sufficiently small for highly volatile compounds (Lenschow and Raupach, 1991), surface interacting molecules like SVOC are affected substantially (Massman, 1991). In order to avoid these drawbacks, we place the PTR3 on top of the measurement tower and deployed a new inlet concept for the remaining ~ 4 m. We sampled air as far away from the container as possible to reduce influences of the container structure on the wind flow field while keeping wall contact of the sample air as low as possible. We have chosen the sampling line inner diameter (ID) and the air flow rate in such a way that the hydrodynamic entrance length is longer than the sampling line itself. That way we avoid that turbulence - developing at the shear regions close to the tubing wall - reaching the center of the tube where the core

sampling is located as illustrated in Figure 2. The entrance length was calculated as $L_{h,turbulent} = 1.359DRe^{1/4}$ as described by Zhi-qing (1982). Despite operating in highly turbulent conditions at Reynolds numbers (Re) above 42000, there is still an undisturbed laminar cone stretching from the entrance of the tube down to the intake point of our core sampling line. By sampling from the center at the end of the tube, only the central portions of the flow, which have not contacted the inlet line wall, are analysed by the mass spectrometer. Our choice was a 20 cm ID pipe at a flow velocity of 3 m/s, resulting in a theoretical entrance length of 3.9 m. The sampling tube had to be mounted horizontally due to constraints imposed by other instruments. Anemometer deviation caused by the suction of the air intake are estimated to be below 2 cm/s at a sensor separation distance of 0.5 m.

The 20cm ID pipe consisted of double walled stainless steel with mineral wool insulation in between. While wall contact is already minimized by core sampling, the reflective metal surface and thermal insulation reduce heating of the exposed inlet walls by sunlight and additionally avoid SVOC partitioning effects inside the inlet due to temperature changes. The sample flow of 3 m/s was generated by a blower mounted at the end of the tube, 1 m downstream of the core sampling (see Figure 2).

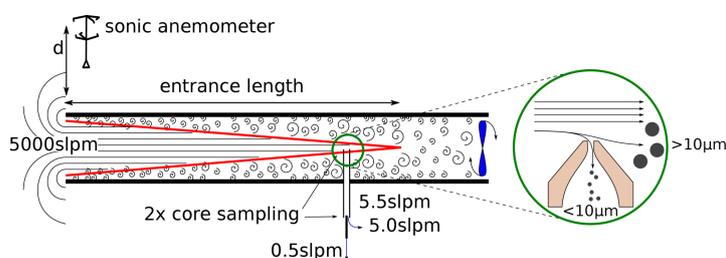

Figure 2: Inlet concept. A high flow of ambient air is sucked through a tube by a blower. The air inside the entrance cone (red) is mostly free of wall contacts and can be sampled from the center of the tube several meters away from the opening. Sampling perpendicular to the high inlet flow through a small nozzle creates a cut-off for particles $>10\mu\text{m}$. The sonic anemometer is placed at distance $d=0.5\text{ m}$ above the air inlet.

The remaining inlet of 0.4 m length from the center of the 20 cm ID tube through the container wall to the PTR3 consisted of a virtual particle impactor and a second center sampling setup. Through a critical orifice of 0.8 mm diameter, 5.5 slpm of ambient air was sampled perpendicular to the flow inside the large tube (see Figure 2, detail), resulting in an aerodynamic particle cutoff diameter of about $8\mu\text{m}$. This way we avoid clogging of the inlet and contamination of the ion source by larger particles like pollen and dust. Sampling efficiency for the second core sampling section was calculated to be larger than 93% for compounds which are completely lost at the wall surface according to Fu et al. (2019). For the calculation, we used the diffusion coefficient of α -pinene.

3 Data Processing

The analysis of raw data consisted of separate tasks described in the following section: reducing the raw TOF spectra to mass specific time traces, calculating concentrations from ion count rates and deriving eddy covariance flux from wind and concentration data.

3.1 Time trace calculation from mass spectra

Similar to Müller et al. (2010), data reduction of the raw time bin based TOF spectral data was performed in order to reduce cross talk of neighboring masses and speed up eddy covariance calculations. We used our Julia based analysis scripts

(<https://github.com/lukasfischer83/TOF-Tracer>) already mentioned in previous work (Breitenlechner et al., 2017; Stolzenburg et al., 2018). Spectra were mass scale calibrated every 5 minutes and long term averaged for TOF peak shape analysis. For peak fitting and identification, we developed an interactive software with live visual feedback on the resulting fit quality, automatic isotope pattern calculation and molecular composition proposition and assignment (<https://github.com/lukasfischer83/peakFit>). This program was used on the averaged spectrum with the calculated peak shapes to create an optimized mass list of more than 1800 identified isobaric compounds with different sum formulas, excluding isotopes. Based on the resulting mass list, 10 Hz time traces were obtained by integration of non-overlapping intervals around each mass followed by deconvolution of cross talk caused by contributions of neighboring masses and isotopes in each spectrum. The script run time on an Intel Core i7 quad core processor system with SSD and 32GB of RAM is about 1 hour for 10 hours of 10 Hz data. The recorded amount of raw data in native HDF5 format was more than 30GB per day.

3.2 Humidity dependent calibration

It is extremely important to characterize the humidity dependent sensitivity of the PTR3 for different compounds. The new key features improving the PTR3-TOF sensitivity have been achieved with a 30 times longer reaction time and a 20 times higher pressure in the chemical ionization region. This means that the number of ion molecule collisions in the reaction zone has strongly increased compared to normal PTR-TOF-MS. Under these conditions, equilibria between forward and reverse reactions involving collisions between ions and water molecules have to be considered even at humidity levels in the single digit parts per thousand range (Breitenlechner et al., 2017). While H_3O^+ is the most prominent primary ion in standard PTR-TOF-MS (at 2 mbar and 80 Td) the primary ions in the PTR3 consist of a distribution of $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ cluster ions ($n=0-3$) that change as a function of humidity. In contrast to PTR-MS where proton transfer between H_3O^+ and VOC was the major ionization process, in the PTR3 ligand switching between $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ cluster ions and organic compounds becomes important. Many oxidized VOC (OVOC) react fast (i.e., reaction occurs with the collisional reaction rate) with all $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ions ($n=0-3$), resulting in a rather small humidity dependence and a high sensitivity. This is particularly the case for compounds with high proton affinities and strong bond energies between the ligand and the (hydrated) hydronium ions like ketones as shown in Breitenlechner et al. (2017). In contrast, pure hydrocarbons react compound specific with individual $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ions. Isoprene, for example, reacts with $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ions $n=0-1$, while α -pinene reacts with ions $n=0-2$. This leads to a reduction of sensitivity and a moderate humidity dependence of typically a factor of two under ambient humidity. A factor of two in sensitivity change (less sensitivity at higher humidity) can cause an artificial deposition flux signal of such a compound even with an actually stable ambient concentration, modulated by water vapor emission fluxes. This potential error source in flux measurements was also discussed by B. Millet et al. (2018), who additionally compared errors resulting from different normalization methods to the primary ion signal. We chose to employ no normalization to the primary ion signal of the $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ions and directly calibrate the individual product ion signals as a function of humidity.

Humidity dependent calibrations of the PTR3 for a set of individual compounds were done in the field at regular time intervals. Since the humidity of the ambient air sample changes at eddy frequency, calibrations had to be applied sample by sample at the recorded frequency of 10 Hz, before calculating the eddy covariance and performing an averaging. Each calibration measurement was parametrized as a function of sample humidity by fitting an empiric curve to calibration data (see Appendix A). For every 10 Hz ambient sample data point, a corresponding sensitivity was calculated and applied which requires fast humidity sampling. This fast humidity signal was reconstructed from a proxy ion signal reflecting the sample humidity. The relation between our proxy signal and the slower IRGA humidity time trace was calibrated regularly. A similar approach was demonstrated by Ammann et al. (2006), who used the $\text{H}_3\text{O}^+(\text{H}_2\text{O})$ ion signal as proxy. In PTR3, the signal of N_2H^+ showed a much better correlation to the humidity measurement of the IRGA. N_2H^+ is created in the PTR3 by endothermic proton transfer from H_3O^+ ions in collisions with N_2 at low pressure in the transition region to the TOF quadrupole interface. Exothermic

210 proton transfer from N_2H^+ to H_2O in the sample gas is the predominating loss reaction. Consequently, the N_2H^+ signal depends
inversely on the absolute humidity. Results are shown in figure A2.

For compounds present in the calibration gas standard, the corresponding calibration was applied directly. A total calibration
error of $\pm 30\%$ including uncertainties of the gas standard mixing ratio, dilution errors and sensitivity drifts of the instrument
between calibration intervals was estimated. For the other compounds a best estimate, an upper and a lower limit for sensitivity
215 were assigned. The upper limit corresponds to an ionization at the collisional limit in the reaction region. It was derived from
the calibrations of 2-hexanone with a safety margin of $+30\%$, the lower limit was chosen depending on the sum formula of the
uncalibrated compound. We assumed at least 50% of the 2-hexanone sensitivity for compounds containing at least ten carbon
atoms and one or more oxygen atoms, as well as for compounds with at least five carbon atoms and more than two oxygen
atoms. Compounds with a) at least two oxygens or b) at least five carbon atoms and one oxygen atom or c) more than ten
220 carbon atoms and no functional group were treated similar to α -pinene. All remaining compounds were treated similar to the
compound in our gas standard showing the least favorable water dependence: acetonitrile. However, in this publication, we
only discuss two compounds quantitatively using estimated sensitivities: $\text{C}_{15}\text{H}_{24}\text{O}_3$ and $\text{C}_{20}\text{H}_{32}$.

Therefore, our data usually represent the lower limit of concentrations or emissions, with a positive estimated uncertainty
based on composition. Artificial flux contributions from water vapor emission due to humidity dependent ionization efficiency
225 would cause a deposition flux bias. This means that for uncalibrated compounds, an observed emission flux can be
underestimated at worst, while observed small deposition fluxes could in principle be caused entirely by a humidity dependent
sensitivity.

3.3 Eddy covariance flux calculations

Eddy covariance flux calculations are based on the innFLUX code (Striednig et al., 2020). The calibrated concentration data
230 were exported together with wind and IRGA data to conform to the necessary input format of innFLUX. Three similar data
sets were exported for the different sensitivity estimates mentioned earlier and analyzed separately in order to study the effects
of calibration uncertainties. The analysis routines of the innFLUX code include sector dependent tilt correction for wind data,
lag time determination and calculation of several quality test parameters that are described in detail by Striednig et al. (2020).
An ensemble average of 30 min was selected as a compromise between data loss due to non-stationary conditions and artificial
235 low frequency attenuation (Lee et al., 2005, p.20). No spectral corrections were applied, but cospectra are compared to the
sonic anemometer sensible heat flux in the discussion section.

4 Results and Discussion

4.1 Campaign overview

In the time period from April 25th to May 16th 2016 we were able to record flux and volume mixing ratio data during 97% of
240 the time. Exemplary data are shown in Figure 3, accompanied by the SMEAR II station data for ozone (O_3), nitrogen oxides
(NO_x), temperature (T) and photosynthetically active radiation (PAR) at 36 m. We filtered these data for a minimal friction
velocity ($u^* > 0.3$ m/s) to assure turbulent conditions discarding about 30% of potential flux data, mostly during nighttime
hours. Additionally, we tested stationarity for each compound individually as proposed by Foken and Wichura (1996).
Measurements with wind coming from the sector between 300° and 90° were rejected, because they might have been
245 influenced by the tower structure (see Figure 1). This sector was identified based on wind inclination deviation from the
horizontal plane shown by the results of the tilt correction calculation. After filtering, 60-70% of recorded data remain as

indicated by the dark-colored periods of the overall time traces shown in Figure 3. Validity of data based on u^* and wind direction is indicated on top of the flux data plot by the red and black bars, respectively. Recorded ion signals were assigned to most likely compounds according to the identified sum formula of protonated species.

250

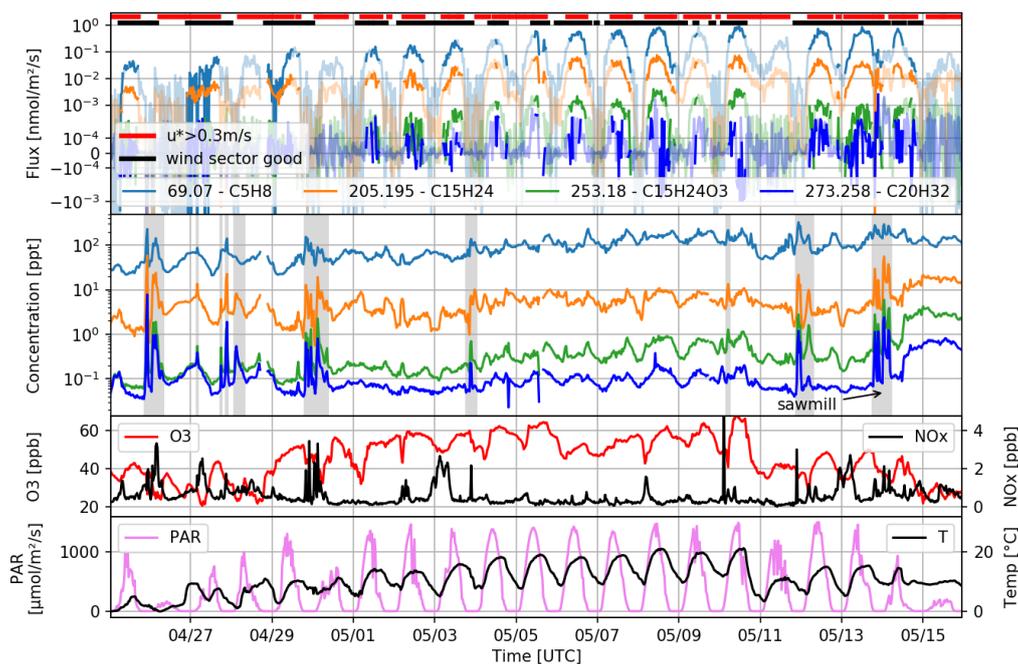

Figure 3: Campaign overview. Eddy covariance flux and concentration data of isoprene (C_5H_8), sum of sesquiterpenes ($C_{15}H_{24}$), sesquiterpene oxidation products ($C_{15}H_{24}O_3$) and sum of diterpenes ($C_{20}H_{32}$) Data filtering based on friction velocity, direction and stationarity is indicated by light colors of the flux traces, filtering on friction velocity and wind sector are indicated independently on top by red and black bars. Periods with concentrations influenced by local sawmill emissions are marked in grey. O_3 , NO_x and temperature recorded at 36m height as well as light are shown in the two bottom panels.

255

We observed periods showing highly elevated concentrations of isoprene (C_5H_8 ; protonated exact mass 69.070 Da), the sum of sesquiterpenes ($C_{15}H_{24}$, protonated exact mass 205.195 Da) and the ozonolysis products of sesquiterpenes ($C_{15}H_{24}O_3$; exact mass 253.180 Da) and diterpenes ($C_{20}H_{32}$; exact mass 273.258 Da) together with numerous other molecules (not shown in Figure 3). Wind back trajectories during these events calculated from our sonic anemometer readings enabled us to pinpoint the emission source to the nearby sawmill facilities in Juupajoki located 6,4 km southeast of the Hyytiälä flux tower. Such events are indicated by grey areas in the concentration time trace in Figure 3. Eerdekens et al. (2009) also observed increased concentrations of certain compounds measured in Hyytiälä originating from the sawmill. Flux footprint contributions were calculated with the method published in Kljun et al. (2015). We see that the forestry field station 400m west-southwest of measurement tower can contribute to our flux measurements at corresponding wind directions. Depending on wind conditions, the station lies within an area which contributes 60% to 80% to the total measured flux.

260

265

270 About 200 further compounds excluding isotopes show covariance with the vertical wind component in our dataset. While two
previous publications report even higher numbers (B. Millet et al., 2018; Park et al., 2013), ambient temperatures during their
measurement periods varied between 15°C (Night) and 40°C (Day) and were substantially higher compared to our site and
season (0°C-20°C). More comparable: measured in Hyytiälä and also in May, but in 2013, Schallhart et al. (2017) reported
270 only 12 compounds above flux detection limit using the same generation of PTR-TOF as Park et al., 2013.

4.1 Isoprene

275 The largest non-methane biogenic precursor emission is isoprene (C_5H_8), emitted from broadleaf trees with high emission rates
($\sim 550 \text{ Tg yr}^{-1}$) (Saunois et al., 2016). It shows a fast reactivity and contributes to SOA and ozone formation (Carlton et al.,
2009; Mao et al., 2013). Isoprene photooxidation products also deposit to terrestrial plants initiating plant stress triggering
enzymatic detoxification processes within the leaves which lead to re-emission of less toxic OVOC such as methyl ethyl ketone
(MEK) (Canaval et al., 2020). Isoprene is a VOC with well characterized sensitivity due to frequent calibrations. We provide
isoprene as a reference for comparison to more challenging compounds. Its atmospheric lifetime is long enough that chemical
280 degradation during turbulent vertical transport from the source to our measurement tower height is negligible (Rinne et al.,
2007). During daylight hours, isoprene emissions are compensated by its main oxidation sink, the reaction with OH radicals,
and an increased dilution rate due to the elevated boundary layer mixing height. Therefore, measured isoprene concentrations
exhibit no distinct diurnal pattern. In contrast, isoprene fluxes increase during the day following light and temperature peaking
at around noon. Isoprene emissions decrease by one and a half orders of magnitude during sunset before eddy covariant flux
285 conditions are no longer met due to low turbulence. Daily flux maxima are increasing from $0.045 \pm 0.025 \text{ nmol/m}^2/\text{s}$ in late
April to $0.94 \pm 0.44 \text{ nmol/m}^2/\text{s}$ in May. This rise, which can be attributed to the onset of the growing season, nicely follows the
increasing maximum temperatures during the first weeks in May. Measurement error contributions are dominated by the
assumed calibration uncertainties ($\pm 0.41 \text{ nmol/m}^2/\text{s}$), while flux calculation error based on the method of Finkelstein and Sims
(2001) is smaller ($\pm 0.14 \text{ nmol/m}^2/\text{s}$).

290 Schallhart et al. (2017) classified the month of May as start of the growing season and reported an average isoprene flux of
 $0.030 \text{ nmol/m}^2/\text{s}$ in 2013. We observed a higher average flux of $0.146 \pm 0.089 \text{ nmol/m}^2/\text{s}$ already during the first half of May in
2016. The average temperature during the first two weeks of May was more than three degrees higher than in 2013, which
likely lead to an earlier onset of the growing season. This could explain the higher isoprene emissions during our measurements.

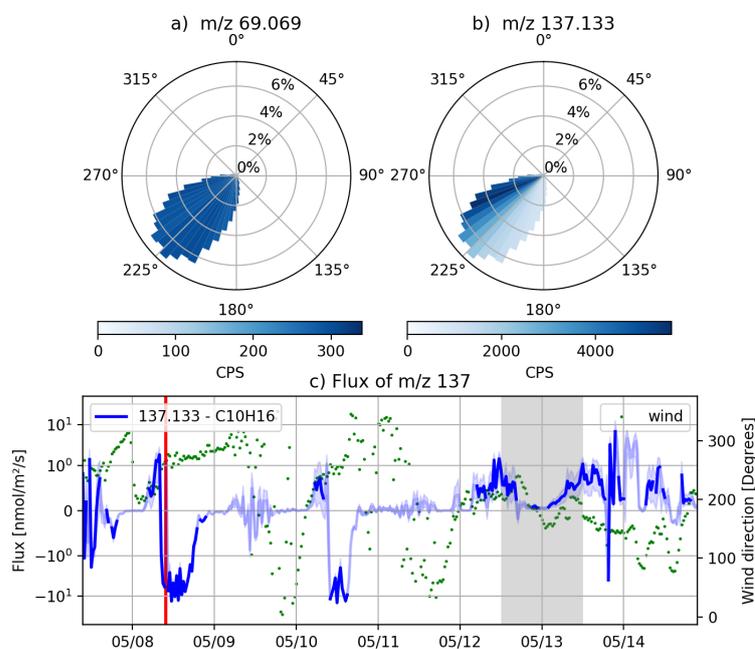

4.2 Monoterpenes

295 Needle trees emit large amounts ($\sim 100 \text{ Tg yr}^{-1}$) of monoterpenes ($C_{10}H_{16}$) into the atmosphere (Guenther et al., 2012).
Atmospheric degradation of monoterpenes as described above generates various RO_2 radicals, which can undergo
isomerization reactions involving intramolecular H-shifts, resulting in highly oxidized RO_2 radicals after subsequent O_2
addition. Highly functionalized RO_2 radicals produced in self and cross reactions efficiently create accretion products
composed of the carbon backbone of both RO_2 reactants (Berndt et al., 2018a). The vapor pressure of these highly oxidized
300 “dimers” containing more than 18 carbon atoms are remarkably low, making them important precursors for gas-to-particle
conversion (Berndt et al., 2018b). However, the larger fraction of RO_2 radicals is terminated by HOx, NOx and smaller ROx
radicals, forming highly oxidized organic molecules (HOM) which contribute substantially to particle growth (Stolzenburg et
al., 2018; Lehtipalo et al., 2018; Tröstl et al., 2016).

305 Previously reported monoterpene ($C_{10}H_{16}$; protonated exact mass 137.133 Da) emission fluxes by Hakola et al. (2006), Rinne
et al. (2007) and Schallhart et al. (2017) obtained at the same measurement site are only partially reproduced by our data. Our
monoterpene flux data show sudden changes from emission to deposition most of the time, even when comparing two
consecutive flux values. Each flux value is an ensemble average of a 30 min interval and is validity checked concerning u^*
and wind direction. Only for monoterpenes we observe a strong directional concentration gradient during many averaging
intervals. A comparison of monoterpenes and isoprene is shown in figure 4 panel a) and b). The plots represent the 30 min
310 time interval highlighted in red in panel c). The length of the bars in the wind rose plot show the percentage of time the wind
is coming from the respective sector. Average concentrations within the sectors are encoded in blue. Such gradients in the
monoterpene data suggests that emissions/depositions show strong inhomogeneities within the footprint at this time of the year
in 2016. These unknown inhomogeneities cause monoterpene data to show high correlation with horizontal wind components
at lower frequencies similar to data reported earlier by Yang et al. (2013) for OVOC measured at a coastal site. The steady
315 state test fails for most averaging intervals reducing our data coverage for monoterpenes to less than 32%. Figure 4 panel c)
shows validity checked monoterpene flux data colored in solid blue, while rejected data are shown in light blue. Errors
calculated analogous to the isoprene data are represented by the blue shades. Even during periods which passed the steady
state test, the discussed inhomogeneities exist. The time trace in panel c) shows a time period on May 8th, capturing a deposition
event. Monoterpene data are still passing the steady state test, with the directional histogram in panel b) clearly including the
320 aforementioned monoterpene source. Unfortunately, the prevailing wind direction included similar sources from several
directions on most days of the campaign. The direction of the highest monoterpene concentrations seen in figure 4, panel b)
and our calculated footprint extent (not shown) suggest that the forestry field station could be a local source of monoterpene
flux. Further analysis is needed to characterize the composition of emissions from the station, which is likely coupled to daily
routines such as cooking or woodworking.

325 Nevertheless, there remains a period from 05/12 noon to 05/13 noon with almost continuous valid data. During these two days,
the wind direction was stable between 150° and 200° and no directional gradients in monoterpene concentrations were
observed. Ambient temperature had dropped by 5 degrees compared to previous days. We measured a 24h average
monoterpene flux of 0.29 ± 0.19 nmol/m²/s, which is in agreement with 0.32 nmol/m²/s reported by Schallhart et al. (2017)
during the start of the growing season. While isoprene emissions were affected by a seasonally different start of the growing
330 season during the compared observation periods, monoterpene seems less influenced. This is attributed to the lower
temperature during the two days used for monoterpene analysis. Rinne et al. (2007) also provides monoterpene flux data,
although measured later during summer. After normalizing their monoterpene fluxes to the known temperature dependence
during the afternoon hours of 5/13, we obtain an emission flux of 0.62 nmol/m²/s at 15.2°C, which is comparable to our
measured flux of 0.74 ± 0.49 nmol/m²/s.

335

Figure 4: Isoprene (C_5H_8 , panel a) and monoterpene ($\text{C}_{10}\text{H}_{16}$, panel b) concentrations in counts per second (cps; blue color coded) as a function of occurrence frequency (represented by sector length). The monoterpene flux signal (panel c) is strongly fluctuating with wind direction. The red line indicates the 30 min interval shown in the directional histograms a) and b). Only the grey period is used for comparison with literature monoterpene flux values. The periods colored in light blue do not pass our quality checks for wind direction and friction velocity or the steady state test.

340

4.3 Sesquiterpenes

Hakola et al. (2006) and Rinne et al. (2007) estimated sesquiterpene emissions to be 20% of that of monoterpene emissions based on enclosure measurements, with monoterpenes peaking earlier in June and sesquiterpenes were dominated by β -caryophyllene in July. Due to the fast ozonolysis rate of β -caryophyllene, stochastic Lagrangian transport model calculations by Rinne et al. (2007) predict that only 30-40% of β -caryophyllene leaf level emissions reach the intake point on top of the measurement tower. Direct eddy covariance flux measurements with previous PTR-MS instruments did not show flux values even during highest emissions in summer due to instrumental constraints (LoD and sensitivity). Due to the high sensitivity of the PTR3 instrument we are able to report first eddy covariance fluxes of sesquiterpenes and sesquiterpene oxidation products at this site. Figure 5 shows diurnal sesquiterpene concentrations and fluxes. Concentrations are in the range of 1 to 10 pptv slightly increasing during the campaign, matching data presented by Hellén et al. (2018). Fluxes show a pronounced diurnal pattern peaking in the early afternoon (local time) with maximum values rising from $0.004[+0.007,-0.003]$ $\text{nmol}/\text{m}^2/\text{s}$ at the end of April to $0.054[+0.078,-0.040]$ $\text{nmol}/\text{m}^2/\text{s}$ in mid of May. The eddy covariance flux analysis errors based on the method of Finkelstein and Sims (2001) are ± 0.0009 $\text{nmol}/\text{m}^2/\text{s}$ for the lower and 0.0049 $\text{nmol}/\text{m}^2/\text{s}$ for the higher flux value. Again, the majority of the measurement error is originating from the sensitivity uncertainty. Since the isomeric composition

345

350

355 contributing to the PTR3 sesquiterpene ion signal is not known, we rely on calibrations obtained for β -caryophyllene after the campaign in the laboratory with the same PTR3 settings.

The chemical structures of the observed sesquiterpenes cannot be identified by PTR-MS. Previous enclosure measurements in Hyytiälä (Hakola et al., 2006) and in situ gas chromatography measurements (Hellén et al., 2018) reported, that β -caryophyllene is the most abundant sesquiterpene species emitted by Scots Pine. Hellén et al. (2018) claim that due to the short atmospheric lifetime of β -caryophyllene, O_3 reactivity and secondary organic aerosol production rates are dominated by sesquiterpenes in Hyytiälä during summer. In hemi boreal forests similar findings are reported from recent particle phase measurements (Barreira et al., 2021, under review).

Our eddy covariance flux measurements give additional insight in the local emission rates and chemistry of sesquiterpenes. These measurements show a substantial contribution of $C_{15}H_{24}O_3$ which was attributed to sesquiterpene ozonolysis products. β -Caryophyllene is known to have one of the highest sesquiterpene emission rates (Hakola et al., 2006; Hellén et al., 2018; Rinne et al., 2007) and is also very reactive (Richters et al., 2015), so it is presumably the predominant source of $C_{15}H_{24}O_3$. We suspect this signal to represent several isomeric first-generation ozonolysis products of β -caryophyllene based on published laboratory measurement results by Winterhalter et al. (2009). According to their findings, the products still contain an exocyclic double bond, resulting in atmospheric lifetimes shorter than those of for example α -pinene. Starting with a 1.5 times longer carbon backbone and a higher oxidation state compared to monoterpene, their oxidation products contribute substantially to aerosol particle growth (Li et al., 2011).

We can give an estimate of the emission rate of β -caryophyllene at the top of the canopy by modeling the potential reacted fraction, which is converted during transport from canopy to the measurement tower due to ozonolysis and assuming that our measured signal on $C_{15}H_{24}O_3$ is dominated by β -caryophyllene oxidation products:

$$375 \quad F_{BCY,cpy} = \frac{F_{BCYO_3,tower}}{y} \frac{1}{1 - \exp(-k \cdot [O_3] \cdot t_{react})}$$

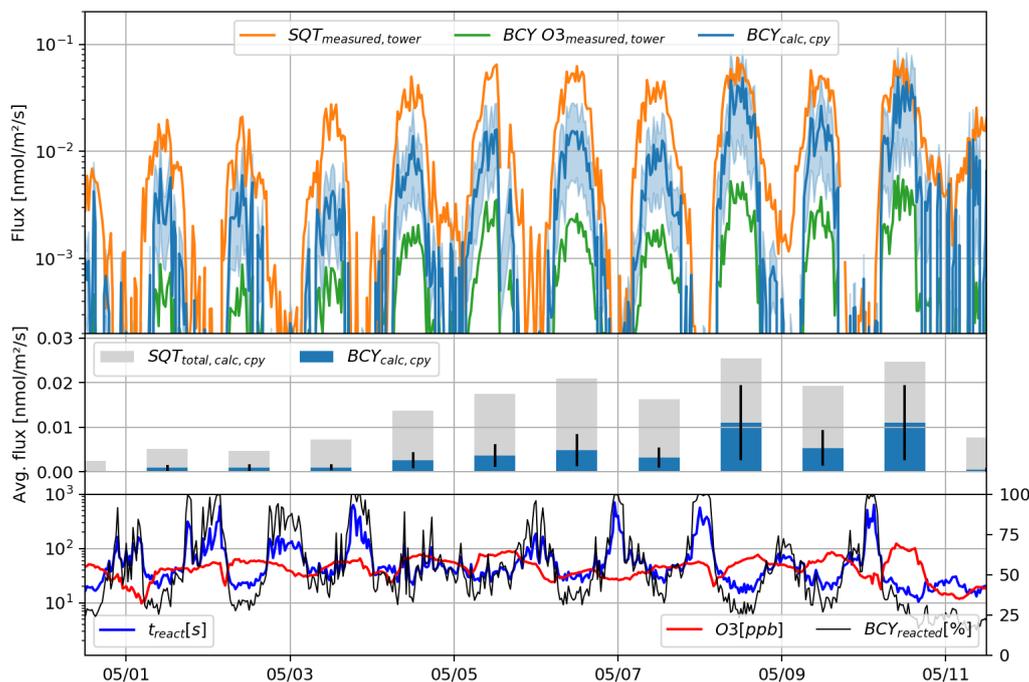

Here $F_{BCY,cpy}$ is the calculated canopy level flux of β -caryophyllene, $F_{BCYO_3,tower}$ our β -caryophyllene oxidation product flux measured at tower level after reaction time t_{react} , y the yield of the β -caryophyllene oxidation product, k the ozonolysis rate of β -caryophyllene and $[O_3]$ the ozone concentration.

The yield of $C_{15}H_{24}O_3$ from β -caryophyllene ozonolysis for the calculation was experimentally determined in a flow reactor experiment in our laboratory, using the same instrument at similar settings and conditions. Details on the measurement can be found in Appendix B. The yield of $C_{15}H_{24}O_3$ plus its most abundant fragments found after a reaction time of 12 seconds was 43 ± 10 percent of the reacted β -caryophyllene. In the flow reactor experiments a similar fragmentation pattern of the ozonolysis products as in the ambient air measurements was observed. For a mixing distance H from the top of the canopy up to the inlet, vertical mixing times are estimated based on the scaling parameter of H/u^* (Karl et al., 2018). An ozonolysis rate of $1.1 \times 10^{14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Richters et al., 2015) and the measured ambient ozone concentration were used to calculate which emission rate of β -caryophyllene was necessary to explain the measured product emission flux at our inlet height.

The measured flux values of sesquiterpene and $C_{15}H_{24}O_3$ at the tower are plotted in orange and green in figure 5, top panel. Calculated canopy level β -caryophyllene flux is indicated in blue. The error shows the sensitivity of the calculation to upper and lower limit assumptions on reaction times of 400% and 66% of the calculated $t=H/u^*$. Daily averages are shown in the middle panel. The grey bars correspond to the total sesquiterpene emission at canopy level which is calculated by the remaining tower sesquiterpene flux plus the missing reacted fraction. This missing fraction is calculated from the product $C_{15}H_{24}O_3$ and its fragments flux divided by their yield. The blue bars show the calculated canopy level β -caryophyllene. During the warmer days towards the end of the campaign, our canopy level calculations show that β -caryophyllene can make up as much as 50%

of the total sesquiterpene emissions. The fraction of reacted β -caryophyllene is shown in the bottom panel. The changes in
395 ozone concentration show minor contributions to the reacted fraction, which is dominated by the reaction time governed by
friction velocity u^* . The ability to follow oxidation processes by monitoring precursor as well as product fluxes directly with
one single instrument at these low emission rates is unprecedented and could help to solve questions on sesquiterpene in- and
above-canopy chemistry. Jardine et al. (2011) and Bourtsoukidis et al. (2018) for example emphasize the influence of
sesquiterpenes on the oxidative capacity of the atmosphere but also struggle with technical limitations measuring
400 sesquiterpenes and rely on enclosure measurements for emission estimates.

405 **Figure 5:** Upper panel: Calculated β -caryophyllene flux ($BCY_{calc,cpy}$) at the top of the canopy derived from measured oxidation products ($BCYO_3_{measured,tower}$) compared to tower level sesquiterpene ($SQT_{measured,tower}$) and calculated total sesquiterpene fluxes ($SQT_{total,calc,cpy}$) at the leaf level. Bottom panel: O_3 concentration, reaction time based on u^* and the calculated reacted fraction of β -caryophyllene.

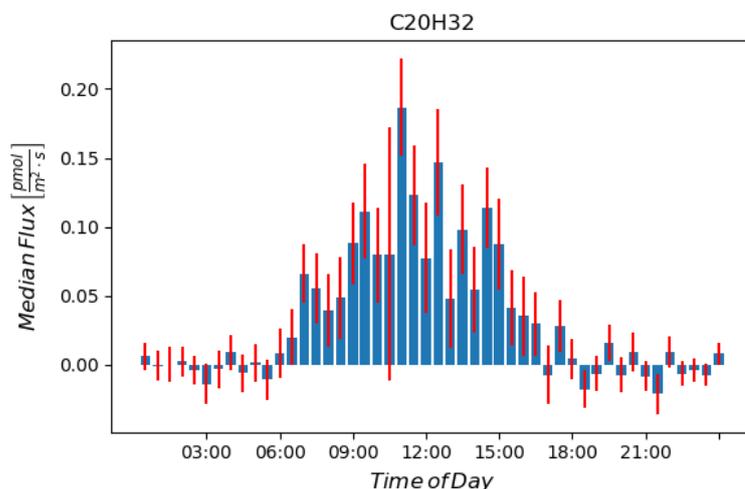

4.4 Diterpenes

To the best of our knowledge, we can report the first direct eddy covariance flux measurements of diterpenes using mass spectrometry. We measured diterpene concentrations on $C_{20}H_{32} \cdot H^+$ in the order of 100 ppqv, which was below the limit of

410 detection of previous PTR mass spectrometers. Complementary technologies capable of measuring such low VOC
concentrations like Acetate-, Iodide- or Nitrate-CIMS are lacking ionization efficiency for pure hydrocarbon compounds (Riva
et al., 2019).

We aggregated two weeks of flux measurements and calculated an average diurnal pattern of diterpene emissions shown in
figure 6. Similar to sesquiterpenes, the diterpene flux shows its peak in the early afternoon at an average of 0.15 pmol/m²/s
415 with vanishing emissions during night time. Since no calibration data or proton affinity data was available for the unidentified
diterpenes, we assume ionization at the kinetic limit and thus give a lower estimate of the diterpene emission flux. This seems
justified, if we extrapolate the increasing trend in measured ionization efficiency from isoprene via α -pinene to β -
caryophyllene, probably due to the longer carbon backbone and thus higher proton affinity.

420 **Figure 6: Diurnal cycle of diterpene emissions. Red lines indicate the random error as described by Finkelstein and Sims (2001) divided by the square root of the averaged samples.**

The role of diterpenes in new particle formation and early growth has not yet been thoroughly studied. Atmospheric
degradation of monoterpenes (C_{10}) generates different RO_2 radicals, which can undergo isomerization reactions involving
intramolecular H shifts resulting in highly oxidized RO_2 radicals after subsequent O_2 addition. Highly functionalized RO_2
425 radicals efficiently produce accretion products in self and cross reactions composed of the carbon backbone of both C_{10} - RO_2
reactants (Berndt et al., 2018a; Berndt et al., 2018b). The vapor pressures of these highly oxidized C_{20} dimers are remarkably
low. Ambient measurements report concentrations of C_{16-20} HOM in the order of 10^{-2} to 10^{-3} $\mu\text{g}/\text{m}^3$ (Mohr et al., 2017). A
substantial fraction of these HOM could also originate from diterpene ($C_{20}H_{32}$) oxidation. Giving an estimate on the diterpene
emissions could help to investigate their importance for aerosol formation and necessitate further laboratory and field studies
430 on their role in the initial steps as well as subsequent growth into CCN sizes.

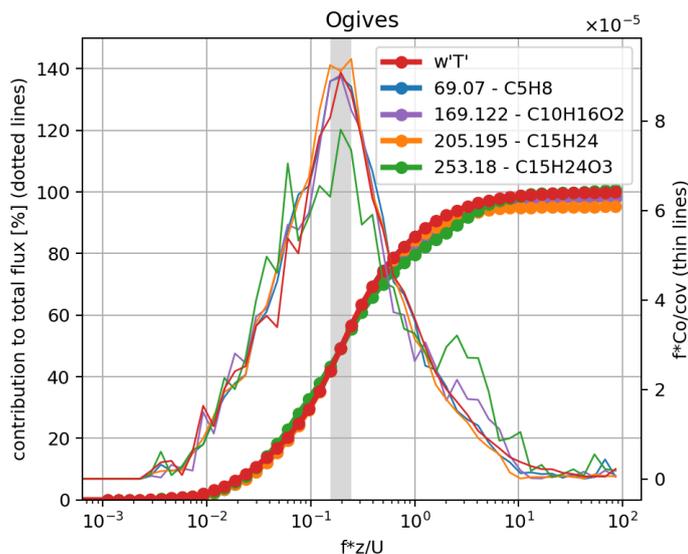

4.5 Frequency Response

Inlet performance can be assessed by comparing the high frequency attenuation in the spectrum of the eddy covariance flux contributions to those of sensible heat (Aubinet et al., 2012, p.93ff.). While Millet et al. (2018) was using an improved PTR-QiTOF-MS having sensitivities closer to the PTR3, both, Park et al. (2013) and Millet present sesquiterpene ($C_{15}H_{24}$) fluxes that can be compared to our results. Millet estimates <25% high frequency damping for sesquiterpenes and monoterpene oxidation products based on cospectral similarity with sensible heat flux $w'T'$. Our system allows to measure sesquiterpene and probably the monoterpene oxidation product pinaldehyde ($C_{10}H_{16}O_3$; exact mass 169.122 Da) virtually as good as the volatile precursors like isoprene demonstrated in the ogive analysis in figure 7. Ogives represent the relative cumulative contribution of all measured eddies up to a certain frequency. At the frequency range carrying most of the eddy covariance flux, our setup shows no visible damping compared to $w'T'$ directly measured with the sonic anemometer. This indicates the effectiveness of our wall contact reduced inlet concept and the overall fast time response of our setup and the PTR3. Ogives were calculated by cumulative numerical integration of the scaled, averaged cospectra passing the basic quality tests mentioned earlier and exceeding a signal to noise ratio of three. The resulting ogives were scaled to match at the frequency of the maximum covariance of $w'T'$ indicated by the grey bar.

435

440

445

Figure 7: Ogives (dotted lines) showing the cumulative flux contribution by frequency in percent, covariances $f*Co/cov$ (thin lines) scaled to show spectral contributions. Red trace shows sensible heat flux $w'T'$ as best reference, no high frequency damping is visible for all compounds including also semi volatile $C_{15}H_{24}O_3$.

4.6 Uncertainties

450 The compounds presented here have been chosen to cover a wide range in concentration, volatility and flux. Different sources of uncertainty dominate the individual compounds. While monoterpene and isoprene show decent signal-to-noise ratios in concentration data, their main source of uncertainty results from water dependent sensitivities, which was taken into account by frequent calibration. For the low concentrations that are typical for sesquiterpenes and sesquiterpene oxidation products, lag times between the sonic anemometer data and the mass spectrometer data become harder to determine. Striednig et al. (2020) proposed to ensure consistent lag times by experimental design, so covariances of individual ensemble average intervals can be accumulated for a sharper maximum. Their routines in innFLUX already provide lag time determination from accumulated covariances, which were used in our analysis. Figure 8 shows an example, which was obtained averaging over a period of eight hours on May 13th. The presented compounds differ greatly in volatility, and their very similar lag times indicate an efficient wall contact reduction of our inlet design. The lag time of isoprene throughout the campaign during times with valid flux conditions was 2.34 ± 0.36 seconds.

460

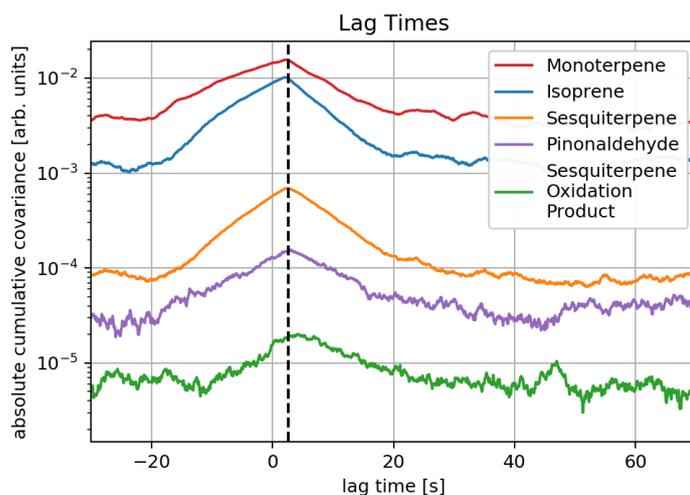

Figure 8: Lag times calculated from absolute covariances averaged over a period of 8 hours on May 13th. The black vertical line illustrates the very similar lag time of all compounds having different volatility.

Flux calculation noise estimates given in the discussion of the individual compounds were also computed by innFLUX, which implements several different estimates proposed in the literature. We chose the method by Finkelstein and Sims (2001), which seemed to give the most conservative error estimate on our dataset. Nevertheless, only for the very low fluxes of diterpenes, the flux noise contributes significantly compared to the instrument sensitivity uncertainty.

465

5 Conclusions

470 Accurate quantification of concentrations and fluxes of VOC and SVOC is a crucial component for understanding the formation and evolution of SOA. While conventional methods for measuring VOC composition based on GC-MS sampling are typically available during atmospheric field measurement campaigns, a critical research need is the quantification of concentrations as well as fluxes of all VOCs and SVOCs closely linked to SOA formation. Fluxes of BVOC and their oxidation products exhibiting reduced volatility such as SVOC or low volatile organic compounds can only be measured with rather short inlets to avoid wall losses during sampling. Here we explored the possibility of using a PTR3 instrument on top of the
475 SMEAR II tower in Hyytiälä, Finland. We recorded data at 36 m above a forested ecosystem dominated by terpenoid emitters. We designed and tested a virtually wall less inlet that allows undisturbed gas sampling approximately 4 m away from the tower structure.

480 At the beginning of the growing season during several warm days in May 2016 we recorded isoprene and monoterpene fluxes supporting previous results measured at the same site. In addition, we report sesquiterpene emission fluxes as low as single digit picomol/m²/s. For the first time, we present emission fluxes of sesquiterpene ozonolysis products ranging from 0.2 to 2 picomol/m²/s. With this setup most suitable for direct eddy covariance flux measurements we were able to detect diterpene emissions lower than 0.15 picomol/m²/s. With the large reserves in flux signal to noise ratio achieved with the new PTR3, fast processes can be tracked virtually in real time and clear diurnal patterns can now be studied even for smallest emission rates.
485 Ogive analysis suggests that the new inlet design allows an almost contact free transfer of sample air to the PTR3 over several meters.

Appendix A

Humidity dependent in field calibration

490 In field calibrations were performed regularly by dynamic dilution of a gas standard (Apel Riemer) containing known amounts of different VOC in dry and humidified synthetic air. Figure A1 shows calibration results for α -pinene at two different days.

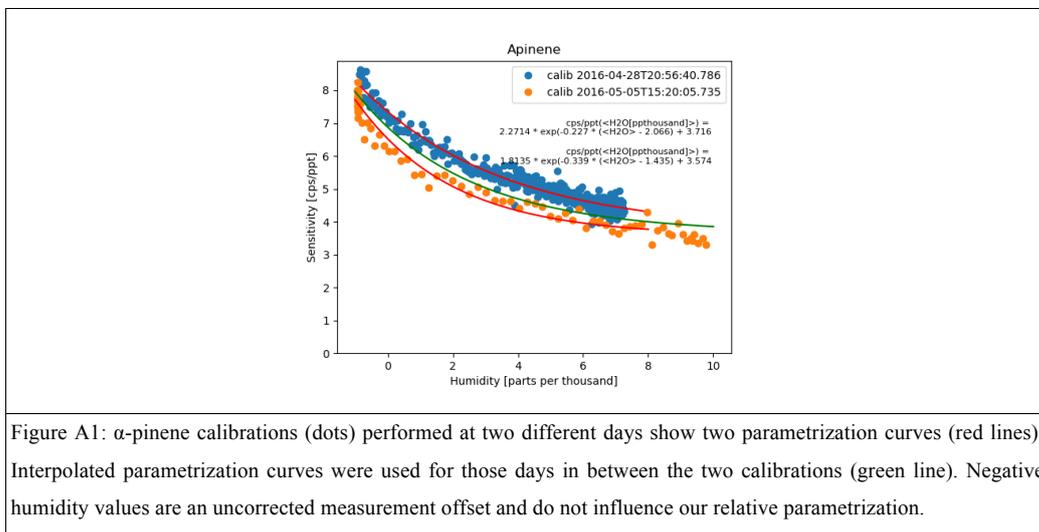

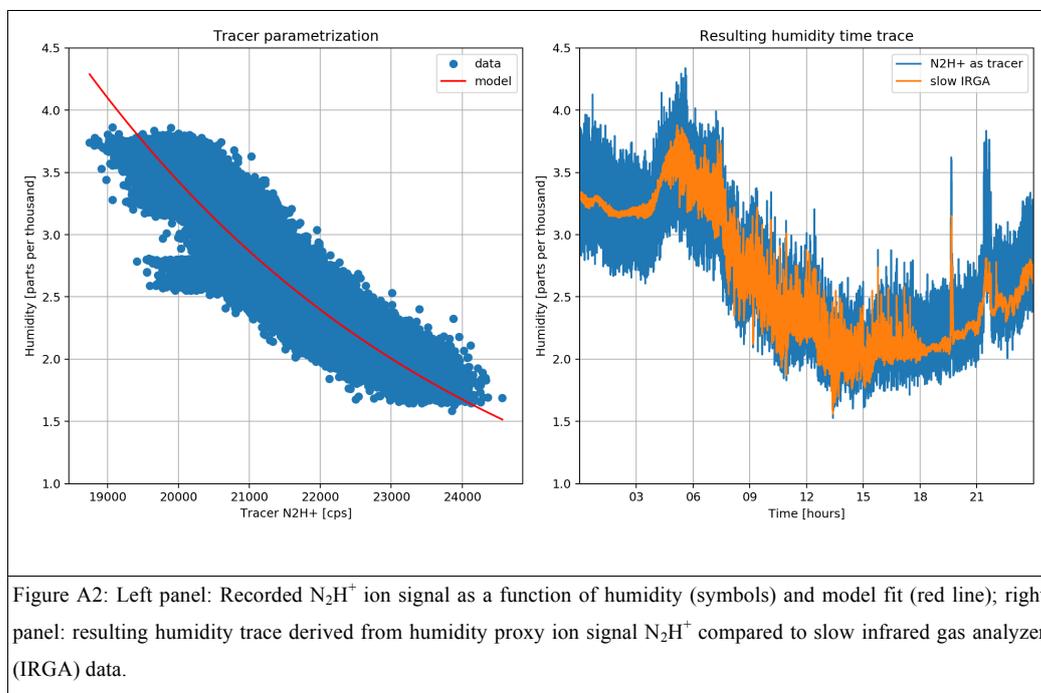

Figure A1: α -pinene calibrations (dots) performed at two different days show two parametrization curves (red lines). Interpolated parametrization curves were used for those days in between the two calibrations (green line). Negative humidity values are an uncorrected measurement offset and do not influence our relative parametrization.

Fast humidity signal from tracer (N_2H^+):

The recorded ion signal N_2H^+ was fitted to the slower infrared gas analyzer signal to derive a fast humidity trace. The advantage of this method is, that the humidity signal is affected by inlet line delays and frequency damping in the same way as the other concentration signals used for eddy covariance analysis. Exemplary results of the method are shown in figure A2.

495

Appendix B

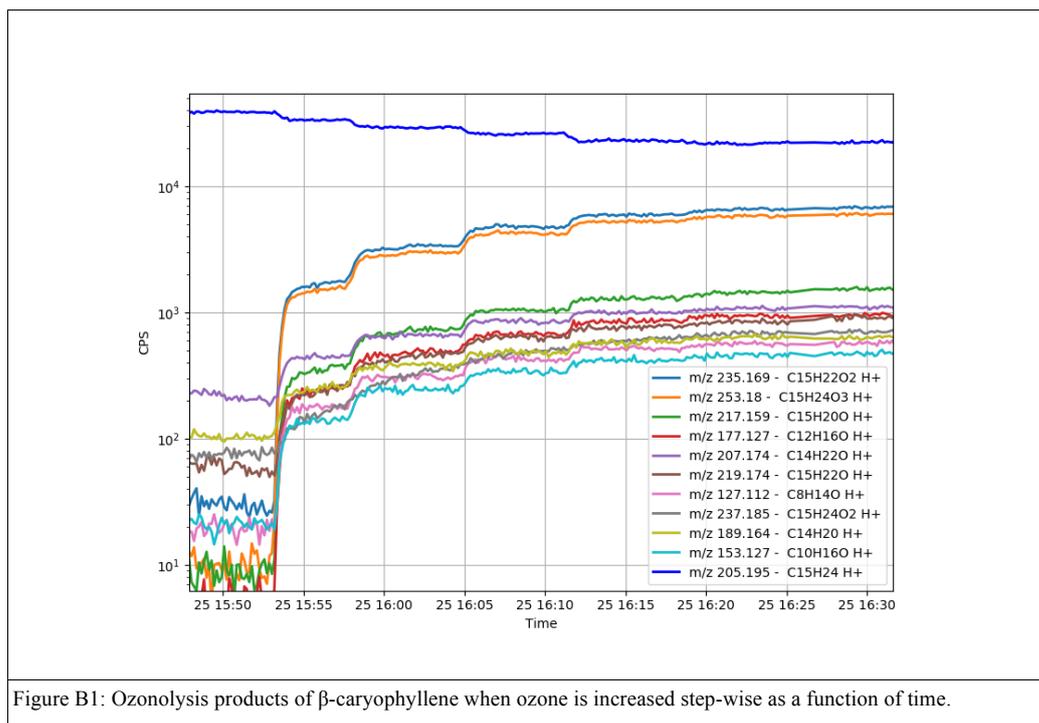

β -caryophyllene ozonolysis product yield determined in flow reactor measurements:

PTR3 eddy covariance flux measurements revealed an ion signal of protonated $\text{C}_{15}\text{H}_{24}\text{O}_3$, which we attributed to sesquiterpene ozonolysis products. β -caryophyllene is one of the most prominently emitted sesquiterpenes in Hyttiälä (Hakola 2006, Rinne 2007, Helen 2018). β -caryophyllene reacts very fast with ozone (Richters 2015), so it is presumable the predominant precursor of $\text{C}_{15}\text{H}_{24}\text{O}_3$. To support this assumption and quantitatively relate the amount measured with PTR3 to the reacted precursor, we performed ozonolysis experiments with the flow reactor in our laboratory. A reaction time of 12 seconds without substantial wall contact is achieved in the Innsbruck flow reactor, which is similar as described in Hansel et al. (2018).

505 We could add up to 130 ppbv ozone (utilizing an UVP Ozone Generator from Analytik Jena) to a laminar flow of purified air (33 SLM). 2 SLM purified air with 2 ppbv of β -caryophyllene was injected via four impinging jets further down-streams initiating quick local mixing. At the end of the flow reactor ozone as well as β -caryophyllene and corresponding ozonolysis products were monitored with an ozone monitor (Thermo Environmental Instruments 49 C) and a PTR3, respectively. When

switching on ozone β -caryophyllene is consumed during a reaction time of 9.4 seconds. More than 40 ion signals corresponding to ozonolysis products could be measured with PTR3. On a carbon basis we detected at least $82 \pm 17\%$ of the amount of reacted β -caryophyllene with PTR3. The ten most prominent product ion signals are shown in figure B1, which correspond to $67 \pm 14\%$ of total reacted β -caryophyllene.

515 The three most prominent peaks are $C_{15}H_{24}O_3 \cdot H^+$ and two corresponding fragment ions losing one or two H_2O molecules have been recorded. The intensity of the fragment ions was increased when collision induced dissociation experiments were performed. Yields were calculated from the quotient of product concentration and the reacted β -caryophyllene concentration. The PTR3 sensitivity for β -caryophyllene was calibrated. Sensitivities for product ions were assumed to be similar to ketones which have highest ionization efficiencies (upper estimate). The yield of $C_{15}H_{24}O_3 \cdot H^+$ was $23 \pm 5\%$, the two fragments

520 $C_{15}H_{22}O_2 \cdot H^+$ and $C_{15}H_{20}O \cdot H^+$ had a yield of $20 \pm 4\%$ and $5.2 \pm 1\%$, respectively.

Data Availability

Processed data of eddy covariance flux and concentrations are provided online by Fischer et al., (2021) at <https://hdl.handle.net/20.500.11756/d025b0bb>. Data recorded by the SMEAR II station can be found at <https://smear.avaa.csc.fi/>. The scripts used to process raw TOF spectral data are hosted at <https://github.com/lukasfischer83/TOF-Tracer> and <https://github.com/lukasfischer83/peakFit>. The eddy covariance flux routines by Marcus Striednig can be downloaded from <https://www.atm-phys-chem.at/innflux> (Thomas G. Karl, 2020).

Author Contribution

LF, MB and EC performed the field measurements. WS assisted LF during the flow reactor measurements. MS provided the flux analysis routines. LF, MB, MG, TGK and AH designed the flux measurement approach. AH, TP and MK acquired funding and supervised the project. LF analyzed the flux and concentration data and drafted the paper. All authors read the paper and provided feedback that led to improvements.

Competing interests

The authors declare that they have no conflict of interest.

Financial support

This research has been supported by the Austrian Research Promotion Agency (FFG) under project no. 846050. The field campaign in Hyytiälä was financially supported by ACTRIS-2 TNA project: “Emissions of BVOC and their oxidation products contributing to New Particle Formation (BVOC-NPF)”.
