**Abstract.** In this study we focus on the retrieval of aerosol and trace gas vertical profiles from Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) observations for the first time over Thessaloniki, Greece. We use two independent inversion algorithms for the profile retrievals: The Mexican MAX-DOAS Fit (MMF) and the Mainz Profile Algorithm (MAPA). The former is based on the Optimal Estimation Method (OEM), while the latter follows a parameterization approach. We evaluate the performance of MMF and MAPA and we validate their retrieved products with ancillary data measured by other co-located reference instruments. We find an excellent agreement between the tropospheric column densities of NO<sub>2</sub> retrieved by MMF and MAPA (Slope = 1.009, Pearson's correlation coefficient  $R = 0.982$ ) and a good correlation for the case of HCHO ( $R = 0.927$ ). For aerosols, we find better agreement for the aerosol optical depths (AODs) in the visible (i.e., at 477 nm), compared to the UV (360 nm) and we show that the agreement strongly depends on the O<sub>4</sub> scaling factor that is used in the analysis. The trace gas differential slant column densities (dSCDs), simulated by the forward models, are also in good agreement, except for HCHO, where larger scatter is observed due to the increased spectral noise of the measurements in the UV. The agreement for NO<sub>2</sub> and HCHO surface concentrations is similar to the comparison of the integrated columns with slightly decreased correlation coefficients. The AODs retrieved by the MAX-DOAS are validated by comparing them with AOD values measured by a CIMEL sun-photometer and a Brewer spectrophotometer. Four different flagging schemes were applied to the data in order to evaluate their performance. Qualitatively, a generally good agreement is observed for both wavelengths, but we find a systematic bias from the CIMEL and Brewer measurements, due to the limited sensitivity of the MAX-DOAS in retrieving information at higher altitudes, especially in the UV. An in-depth validation of the aerosol vertical profiles retrieved by the MAX-DOAS is not possible since only in very few cases the true aerosol profile is known during the period of study. However, we examine four cases, where the MAX-DOAS provided a generally good estimation of the shape

20 of the profiles retrieved by a co-located multi-wavelength lidar system. The  $\text{NO}_2$  surface concentrations are validated against in situ observations and the comparison of both MMF and MAPA revealed good agreement with correlation coefficients of  $R = 0.78$  and  $R = 0.73$ , respectively. Finally, the effect of the  $\text{O}_4$  scaling factor is investigated by intercomparing the integrated columns retrieved by the two algorithms and also by comparing the AODs derived by MAPA for different values of the scaling factor with AODs measured by the CIMEL and the Brewer.

## 25 1 Introduction

The planetary boundary layer (PBL), also called atmospheric boundary layer, is defined as the lowermost layer of the troposphere that is directly influenced by the terrestrial surface. The PBL height, at mid-latitudes, expands typically up to 1 – 2 km during daytime (von Engelmann and Teixeira, 2013) and its composition has a strong impact on weather, climate and air quality. The increasing interest of understanding the PBL's structure and dynamics is apparent in various research fields, from air pol-  
30 lution analysis to weather prediction and thus, continuous ground-based monitoring of both chemical composition and aerosol content of the PBL with high temporal resolution is of great importance.

Thessaloniki is a Mediterranean city and it is the second largest city of Greece, located in the northern part of the country. Thessaloniki hosts approximately 10% of the country's total population with more than 1 million inhabitants (Resident Population Census, 2011) and with approximately 20% of the country's industrial activity, it is considered one of the largest urban  
35 agglomerations in the Balkans (Moussiopoulos et al., 2009). The air pollution sources in Thessaloniki are mainly industrial activities in the western part of the city, road transport and domestic heating during the cold period of the year, while the air quality of the city is affected by local topographic and meteorological characteristics (Poupkou et al., 2011; Kassomenos et al., 2011). Nitrogen oxides ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ), formaldehyde (HCHO) and aerosols are considered major atmospheric pollutants contained in the PBL of the city.

40 Nitrogen dioxide ( $\text{NO}_2$ ) and HCHO are two important trace gas species of the atmosphere that play a critical role in tropospheric photochemistry (Seinfeld et al., 1998), participating in the formation of tropospheric ozone ( $\text{O}_3$ ), while aerosols can have a strong influence on air quality and climate through effects on radiation (IPCC, 2007). Both  $\text{NO}_2$  and HCHO are toxic to humans in high concentrations and can lead to or deteriorate severe health conditions. HCHO is a short-lived product derived by the oxidation of volatile organic compounds (VOCs). Its sources are both natural (i.e., oxidation of VOCs emitted  
45 from plants), as well as anthropogenic (i.e., biomass burning, industrial-related emissions and road transport) (De Smedt et al., 2008; Chan et al., 2020).  $\text{NO}_2$  is mainly produced by the oxidation of nitrogen monoxide (NO) and in most urban areas its sources include fossil fuel combustion, biomass burning, soil emissions and lightning (Lee et al., 1997; Zhang et al., 2003). Moreover, under certain meteorological conditions,  $\text{NO}_2$  may participate in the formation of secondary aerosols (Jang and Kamens, 2001). Given the influence of  $\text{NO}_2$ , HCHO and aerosols on air quality and climate, it is of high environmental and  
50 research importance to monitor accurately and continuously their spatio-temporal distribution in the troposphere.

Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) is a well-established ground-based passive remote sensing technique that received considerable attention during the past decades (Hönninger and Platt, 2002; Hönninger et al.,

2004; Wagner et al., 2004; Wittrock et al., 2004; Frieß et al., 2006; Irie et al., 2008) and is nowadays widely used in many studies in order to simultaneously detect trace gases and aerosols mainly in the PBL and in the lowermost free troposphere (e.g., Clémer et al. (2010); Irie et al. (2011); Ma et al. (2013); Pinardi et al. (2013); Vlemmix et al. (2015a, b); Wang et al. (2017b); Chan et al. (2019) and references therein). Such trace gases include NO<sub>2</sub>, HCHO, sulfur dioxide (SO<sub>2</sub>), water vapour (H<sub>2</sub>O), ozone (O<sub>3</sub>), nitrous acid (HONO), iodine oxide (IO), glyoxal (CHOCHO) and bromine oxide (BrO). The MAX-DOAS measurement technique utilizes scattered sunlight in the ultraviolet (UV) and visible (VIS) part of the electromagnetic spectrum received from different elevation angles and the measured spectra are analyzed by Differential Optical Absorption Spectroscopy (DOAS) (Platt and Stutz, 2008) for the determination of the differential Slant Column Densities (dSCDs). Information about the vertical distribution of aerosols and trace gases can be retrieved from a single elevation sequence (i.e., spectra recorded at different elevation angles that belong to the same azimuthal direction) using suitable inversion algorithms. The products retrieved by the inversion algorithms include, among others, estimates of the profile shape, tropospheric Vertical Column Densities (VCDs) and near-surface concentrations.

Nowadays, there is a variety of such inversion algorithms for the retrieval of vertical profiles from MAX-DOAS measurements using different techniques. These algorithms are mainly separated into those that retrieve the profiles based on the optimal estimation method (OEM) (Rodgers, 2000) and into those that rely on a few parameters to characterize the atmospheric profile (parameterization approach). Both OEM-based and parameterized inversion algorithms have been tested and intercompared so far in many studies using either synthetic data (e.g., Frieß et al., 2019) or actual MAX-DOAS measurements, as for example, during the Cabauw Intercomparison of Nitrogen Dioxide Measuring Instruments 2 (CINDI-2) campaign (Wang et al., 2020; Tirpitz et al., 2021). Here, we use two of the already tested inversion algorithms to analyze MAX-DOAS measurements conducted at Thessaloniki, Greece, for the retrieval of aerosol, NO<sub>2</sub> and HCHO vertical profiles and column densities. These algorithms are the Mexican MAX-DOAS Fit (MMF) v2020\_04 (Friedrich et al., 2019) and the Mainz Profile Algorithm (MAPA) v0.98 (Beirle et al., 2019). The former is based on the OEM, while the latter follows the parameterization approach and are both adopted by the Fiducial Reference Measurements for Ground-Based DOAS Air-Quality Observations (FRM<sub>4</sub>DOAS) project (<https://frm4doas.aeronomie.be/>, last access: 05 March 2021). In this work we evaluate the performance of the two algorithms, we validate their results with reference datasets and we investigate the effect of applying different flagging schemes to the retrieved products. Additionally, by using two independent inversion algorithms, we aim at producing a reference MAX-DOAS dataset of higher quality for further research activities in Thessaloniki (e.g., validation of satellite-retrieved tropospheric products). Thessaloniki is also part of the FRM<sub>4</sub>DOAS project, which aims at the development of the first central processing system for MAX-DOAS observations. Even though the measured spectra are regularly submitted and analyzed on a near-real-time basis, in this work both MMF and MAPA runs are performed offline in order to obtain more flexibility in the analysis and also to investigate and optimize the retrieval settings particularly for Thessaloniki.

The article is structured as follows. In Sect. 2 the instrumentation, the MAX-DOAS retrieval settings and a brief description of the profiling algorithms are reported, along with the methodology used in this analysis. In Sect. 3 we present the results of the comparison between different products retrieved by MMF and MAPA. In Sect. 4 the validation results of the retrieved products with ancillary data are presented and in Sect. 5 the main conclusions of this article are summarized.

## 2 Data and Methodology

### 2.1 Instrumentation

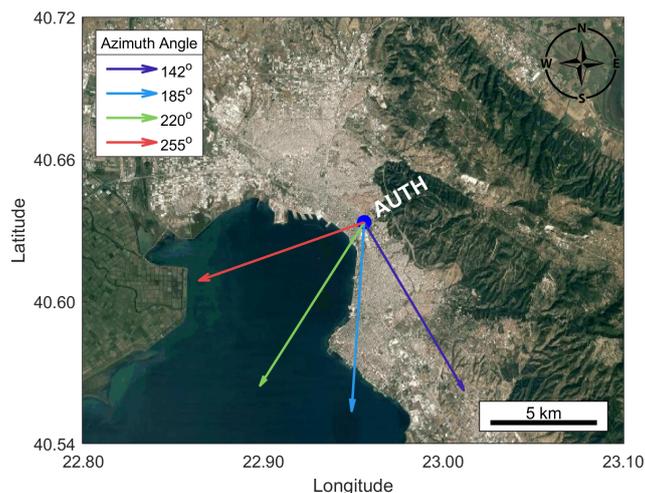

90 A 2D MAX-DOAS system (Phaethon) operates regularly on the rooftop of the Physics Department of the Aristotle University of Thessaloniki (40.634° N, 22.956° E), about 80 m above sea level. The measurement site is located near the city center of Thessaloniki (Figure 1). The prototype system was developed in 2006 at the Laboratory of Atmospheric Physics (LAP) (Kouremeti et al., 2008, 2013) and has been upgraded ever since for the retrieval of tropospheric NO<sub>2</sub> VCDs (Drosoglou et al., 2017, 2018) and total ozone columns (Gkertsis et al., 2018). The current version of the system comprises a single channel  
95 ultra-low stray-light AvaSpec-ULS2048x64-EVO ( $f = 75$  mm) spectrometer by Avantes, the entrance optics and a two-axes tracker. The spectrometer's detector is a back-thinned Hamamatsu charge-coupled device (CCD) array of 2048 pixels with Signal to Noise Ratio (SNR) 450:1 for a single measurement at full signal. The spectrometer covers the spectral range 280 – 539 nm and uses a 50  $\mu$ m wide entrance slit. Mercury discharge lamp spectra were recorded to determine the instrument's slit function and the spectral resolution was found  $\sim 0.55$  nm full width at half maximum (FWHM) at 436 nm. The spectrometer  
100 is positioned inside a thermally isolated box, where the temperature is maintained at +10 °C using a thermoelectric Peltier system. The entrance optics are mounted on a two-axes tracker with two stepper motors controlling the azimuth viewing angle ( $0^\circ \leq \phi \leq 360^\circ$ ) and the elevation viewing angle ( $0^\circ \leq \alpha \leq 90^\circ$ ) with pointing resolution of 0.125°, allowing both direct-sun and off-axis observations. A third motor rotates a filter-wheel of 8 positions with different optical components (diffuser, attenuation and band-pass filters), used for the measurement of direct-sun and scattered radiation spectra and an opaque position  
105 for the measurement of the dark signal. The instrument operates automatically and is controlled by a custom-made software, developed at LAP. The entrance comprises also a telescope with a plano-convex lens that focuses the collected solar radiation onto one end of an optical fiber. The system's field of view (FOV) was characterized using a distant light source and was found  $\sim 1^\circ$ . Simultaneous azimuth and elevation angle calibration is regularly performed by sighting the sun, so no horizon scans are necessary for the elevation angle calibration.

**Figure 1.** The Phaethon MAX-DOAS system in the middle and a panoramic view (East - South - West) of the measurement site.

110 A routine MAX-DOAS measurement cycle starts by orienting the optics at a certain azimuth viewing direction followed  
by the measurement of scattered radiation spectra at the elevation angles: 90 (zenith), 30, 15, 12, 10, 8, 6, 5, 4, 3, 2 and 1°  
in this order. For this study, the system was configured to measure at four consecutive azimuth angles of 142, 185, 220 and  
255°, illustrated in Figure 2 with arrows of different colors. Based on the intensity of the measured spectra during an elevation  
scan at 142° azimuth, the viewing direction of 1° elevation angle was found to be partly blocked by obstacles, such as trees  
115 and buildings in the campus. Thus,  $\alpha = 1^\circ$  in this particular direction was excluded from the profiling analysis. In order to  
achieve high SNR values and to avoid saturated spectra, the number of scans of each individual measurement and the exposure  
time of the CCD are automatically adjusted by the operating software according to the received intensity by the detector. The  
integration time at each elevation angle is  $\sim 60$  sec and a full measurement sequence for all azimuth directions lasts about one  
hour.

**Figure 2.** Location of the MAX-DOAS measurement site (blue dot). The arrows in different colors represent the azimuth viewing directions,  $\phi$ , of the MAX-DOAS observations (i.e., purple: 142°, blue: 185°, green: 220° and red: 255°). The base map is taken from © Google Maps, <https://www.google.com/maps/> (last access: 05 March 2021).

## 120 2.2 MAX-DOAS measurements and slant column retrieval settings

The primary retrieved product from the analysis of the measured MAX-DOAS spectra is the dSCD of several trace gases at different elevation angles. The dSCD of a trace gas at an elevation angle  $\alpha$  ( $dSCD_\alpha$ ) can be calculated as the difference between the Slant Column Density (i.e., its concentration integrated along the light path) ( $SCD_\alpha$ ) and the SCD of a Fraunhofer reference spectrum (FRS), usually measured at the zenith ( $SCD_{ref}$ ):

$$125 \quad dSCD_\alpha = SCD_\alpha - SCD_{ref} \quad (1)$$

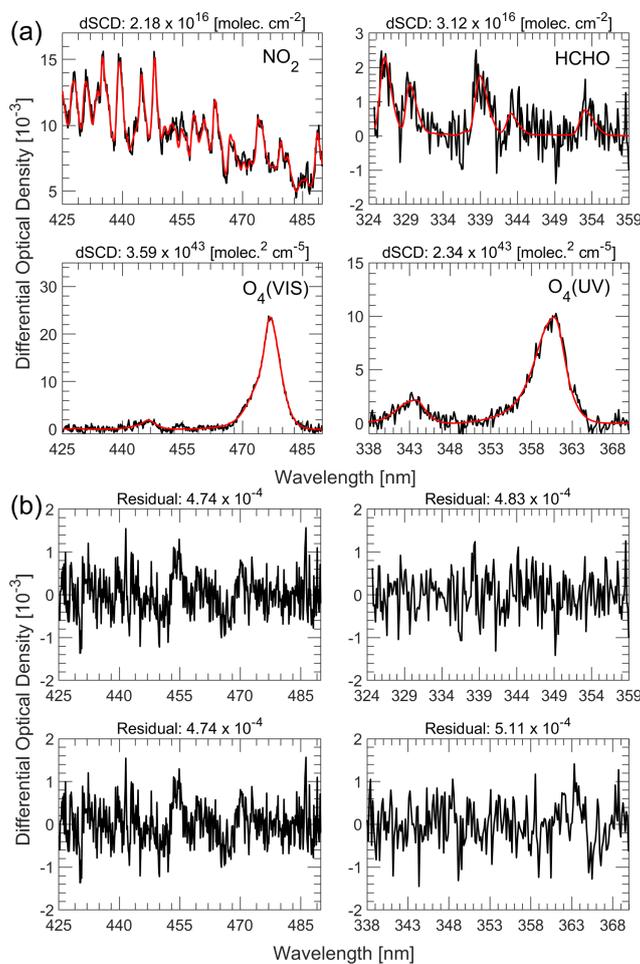

The MAX-DOAS spectra that are used in this study have been recorded for 1 year (from May 2020 through May 2021) and a zenith spectrum is selected as the FRS in order to account for the Fraunhofer lines and the stratospheric contribution of the absorbers (Hönninger et al., 2004). Since the system is scheduled to perform both direct-sun and MAX-DOAS observations during the day, the zenith spectra of two consecutive elevation sequences may have a large time difference (duration of the first sequence plus the duration of two direct-sun measurements). So, in this study, the zenith spectrum of each sequence was selected as the FRS for the DOAS-based retrieval of the collision-induced oxygen complex ( $O_2-O_2$  or  $O_4$ ) and the trace gas dSCDs and not the average or the time interpolated spectrum between the zenith spectra of the two consecutive sequences. The dSCDs of  $O_4$  and trace gases are derived from the recorded spectra by applying the DOAS technique (Platt and Stutz, 2008), while the measured spectra are analyzed using the QDOAS (version 3.2, September 2017) spectral fitting software suite developed by BIRA-IASB (<http://uv-vis.aeronomie.be/software/QDOAS/>) (Danckaert et al., 2013). The retrieval settings are based on results from the CINDI-2 campaign (<http://www.tropomi.eu/data-products/cindi-2/>, last access: 05 March 2021) (e.g., Kreher et al., 2020), the Quality Assurance for Essential Climate Variables (QA4ECV) project (<http://www.qa4ecv.eu/>, last access: 05 March 2021) and the Network for Detection of Atmospheric Composition Change (NDACC) protocol for UV – VIS measurements (<http://www.ndaccdemo.org/data/protocols/>, last access: 05 March 2021). The spectral retrieval settings and the trace gas absorption cross sections that are included in the DOAS fit are listed in Table 1. The wavelength calibration of the measured spectra is achieved by shifting and stretching them against a highly resolved solar reference spectrum (Chance and Kurucz, 2010). Even though the spectrometer is operating in a temperature controlled environment, small diurnal temperature variations may occur. Thus, dark spectra are measured after each elevation sequence for all of the exposure times that were used during the sequence. This procedure might be time-consuming, but assures that the solar and dark spectra are measured at the same temperature. The dark spectra are then subtracted from the scattered radiation spectra prior to the DOAS analysis. Figure 3 shows a typical example of the DOAS analysis of a spectrum recorded on 9 July 2020 at 07:50 UTC at  $3^\circ$  elevation angle. During the whole period of study no apparent system-related issue or instrument degradation is observed.

### 2.3 Retrieval of the vertical profile

The retrieval of vertical profiles (extinction and concentration profiles for aerosols and trace gases, respectively) from MAX-DOAS measurements typically involves three major steps (Irie et al., 2011; Hendrick et al., 2014; Vlemmix et al., 2015b), independent of the retrieval approach. In the first step, the  $O_4$  dSCDs and the trace gas dSCDs (in this case  $NO_2$  and HCHO) are derived by applying the DOAS fitting technique to the measured spectra, as described in Sect. 2.2. Next, the  $O_4$  dSCDs retrieved for each elevation angle of the same sequence are used as input to the algorithm for the retrieval of the aerosol extinction vertical profile. In the end, the trace gas dSCDs are used as input to the algorithm for the retrieval of the trace gas vertical profile, along with the aerosol extinction profile, calculated in the previous step.

As mentioned already, the profiling algorithms that have been developed so far and are commonly used within the MAX-DOAS community are either based on the OEM or follow the parameterization approach. How the  $O_4$  and trace gas dSCDs are handled for the retrieval of the vertical profiles depends on each algorithm's approach. However, the principal idea of both OEM and parameterized inversion algorithms is the same: A layered model atmosphere with defined parameters is assumed in

**Figure 3.** A typical example of the DOAS retrieval of NO<sub>2</sub>, HCHO, O<sub>4</sub> (VIS) and O<sub>4</sub> (UV) dSCDs derived from a MAX-DOAS measurement on 9 July 2020 at 07:50 UTC (SZA = 38.85°) at 3° viewing elevation angle. The DOAS fits are presented in the figures of panel a. The black lines represent the measured spectra and red lines are the fitted O<sub>4</sub> and trace gas cross sections. The figures of panel b show the residual of the DOAS fits.

160 a forward Radiative Transfer Model (RTM) and it is used in order to simulate the O<sub>4</sub> and trace gas dSCDs, taking into account the viewing geometry, i.e., the solar zenith angle (SZA), the elevation angle and the relative azimuth angle. The forward models and how the dSCDs are simulated are described in Beirle et al. (2019) for MAPA and in Friedrich et al. (2019) for MMF. The extinction and concentration vertical profiles are derived by inverting the forward model, i.e., by finding the model parameters, for which the difference between the simulated and the measured dSCDs is minimized, based on a cost function.

**Table 1.** DOAS fit settings for NO<sub>2</sub>, HCHO, O<sub>4</sub> (VIS) and O<sub>4</sub> (UV).

Parameter	Data Source	trace gas		
		NO <sub>2</sub> and O <sub>4</sub> (VIS)	HCHO	O <sub>4</sub> (UV)
Spectral range		425 – 490 nm	324.5 – 359 nm	338 – 370 nm
NO <sub>2</sub> (298 K)	Vandaele et al. (1998), $I_0$ -corrected (SCD in 10 <sup>17</sup> molecules cm <sup>-2</sup> )	✓	✓	✓
NO <sub>2</sub> (220 K)	Vandaele et al. (1998), $I_0$ -corrected (SCD in 10 <sup>17</sup> molecules cm <sup>-2</sup> )	✓		✓
O <sub>3</sub> (223 K)	Serdyuchenko et al. (2014), $I_0$ -corrected (SCD in 10 <sup>20</sup> molecules cm <sup>-2</sup> )	✓	✓	✓
O <sub>3</sub> (243 K)	Serdyuchenko et al. (2014), $I_0$ -corrected (SCD in 10 <sup>20</sup> molecules cm <sup>-2</sup> )		✓	✓
O <sub>4</sub> (293 K)	Thalman and Volkamer (2013)	✓	✓	✓
BrO (223 K)	Fleischmann et al. (2004)		✓	✓

Polynomial degree		5	5	5
Intensity offset		Constant	Order 1	Constant
Wavelength Calibration	Based on a high-resolution solar reference spectrum (Chance and Kurucz, 2010)			

## 165 2.4 MMF

The Mexican MAX-DOAS Fit (MMF) v2020\_04 (Friedrich et al., 2019) is an OEM-based profiling algorithm that relies on online RTM simulations using VLIDORT version 2.7 (Spurr, 2006) as forward model. The input parameters for each atmospheric layer are calculated from temperature and pressure profiles, the trace gas concentration in each layer and the aerosol properties. The aerosol properties, which are the same for all layers, are the single scattering albedo (SSA) and the asymmetry parameter (using the Henyey–Greenstein phase function, Henyey and Greenstein (1941), to calculate the phase function moments). Furthermore, the wavelength of the retrieval and the surface albedo need to be specified as additional input parameters. The retrieval algorithm comprises an aerosol extinction profile retrieval and a trace gas profile retrieval. The former constrains the aerosol extinction profile in the forward model of the trace gas retrieval. The inversion uses constrained damped least-square fitting with an optimal estimation regularization. In the used version, both the a priori and the covariance matrix are constructed. More details about the a priori settings and the input parameters can be found in Sect. 2.6. The retrieval algorithm provides the aerosol extinction profiles, trace gas partial column profiles, their integrated quantities, the corresponding noise and smoothing errors, as well as the averaging kernel, the degrees of freedom and a quality flag of the retrieval.

## 2.5 MAPA

The Mainz Profile Algorithm (MAPA) v0.98 (Beirle et al., 2019) is a profiling algorithm developed by the Max Planck Institute  
180 for Chemistry (MPIC) that is based on a parameterization approach. MAPA does not rely on online RTM simulations, but its  
forward model is provided as pre-calculated differential Air Mass Factor (dAMF) look-up tables (LUTs) at multiple wave-  
lengths. These LUTs have been calculated offline by a full spherical RTM, McArtim (Deutschmann et al., 2011), following a  
backward Monte Carlo approach. Just like MMF, MAPA is based on a two-step process in order to retrieve the aerosol and  
trace gas vertical profiles. It uses three main parameters to characterize the atmospheric profile: The column parameter,  $c$  (i.e.,  
185 AOD for aerosols and VCD for trace gases), the layer height,  $h$  and the shape parameter,  $s$ . Additionally, a fourth optional  
parameter can be included, the  $O_4$  scaling factor, which was initially introduced by Wagner et al. (2009) in order to achieve  
agreement between the measured dSCDs and the forward model simulations. Unlike MMF, MAPA is not based on the OEM,  
so no a priori assumption of the vertical profile is required. In some cases this can be an advantage since a priori information  
and constraints are usually difficult to estimate. MAPA also provides a detailed flagging algorithm that is based on thresholding  
190 techniques applied to different parameters. More details about MAPA can be found in Beirle et al. (2019).

## 2.6 Input parameters and settings

During MAPA calculations, depending on the aerosol or trace gas retrieval, a LUT corresponding to the central wavelength of  
the  $O_4$  or trace gas fitting window is selected (i.e., 360 nm for  $O_4$  in the UV, 343 nm for HCHO, 460 nm for  $NO_2$  and 477  
nm for  $O_4$  in the VIS). These wavelengths are also used in the RTM simulations of MMF. For the calculation of the dAMF  
195 LUTs, MAPA's radiative transfer simulations were performed with a typical fixed set of parameters for all wavelengths (Beirle  
et al., 2019), which can describe the majority of all potential measurement sites. MMF, on the other hand, relies on online RTM  
simulations and so the aerosol and surface parameters can be adjusted to the most suitable values. In this study, the aerosol  
optical properties that are used as input for the simulations of MMF are based on 15 years climatological data measured by  
a co-located CIMEL sun-photometer. Figure 4 shows the frequency distribution of the Ångström exponent, AOD, asymmetry  
200 factor and SSA in Thessaloniki, while their values that are used as input to each inversion algorithm are listed in Table 2.  
Discrepancies between MMF and MAPA due to small differences in these selected parameters are expected to be minor.

**Table 2.** The RTM settings that were used in MMF and MAPA for Thessaloniki.

Parameter	Inversion algorithm	
	MAPA	MMF
Aerosol single-scattering albedo	0.95	0.95
Aerosol asymmetry parameter	0.68	0.69
Surface albedo	0.05	0.06
Ångström exponent	1.4	1.4

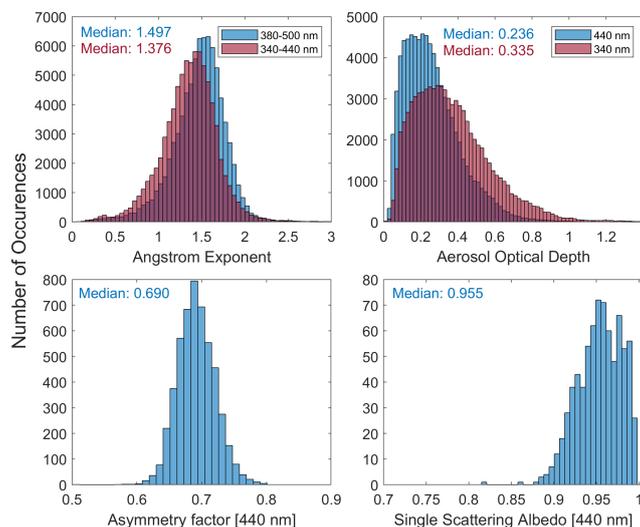

MMF requires a priori profile and covariance matrix information for the profile retrievals. The “a priori” term represents knowledge of the true state before the measurement is performed. However, the true shape of the trace gas vertical profiles at Thessaloniki is generally not known, while the true state of the aerosol profiles is known only in certain cases during the period  
205 of study. Thus, the retrieval is based on constructed exponentially decreasing a priori profiles with scale height of 1 km, which are considered a reasonable estimate of the true profiles. Since no covariance matrix information is available, the covariance matrix is also constructed from the a priori profile. The AOD as well as the trace gas VCDs in Thessaloniki vary substantially throughout the year. In order to take into account the annual variability, we use the square of 50% of the a priori on the diagonal elements of the covariance matrix for aerosols and 100% for NO<sub>2</sub> and HCHO. The loose constraint of the latter is due to the  
210 higher variability of the trace gas vertical columns over the course of the year. Both for aerosols and trace gases, the off-axis elements of the covariance matrix were constructed by assuming a correlation length of 200 m, as described in Clémer et al. (2010). Additionally, the progress of the convergence is faster when using an a priori VCD or AOD below the true value. Thus, the a priori AODs were set to 0.25 and 0.15 for the aerosol retrievals at 360 and 477 nm, respectively. For the trace gas retrievals we have used a priori VCDs of  $4 \times 10^{15}$  and  $6 \times 10^{15}$  molecules cm<sup>-2</sup> for NO<sub>2</sub> and HCHO, respectively, based on data derived  
215 from the MAX-DOAS by applying the geometrical approximation (Hönninger et al., 2004) to the dSCDs measured at 30° and 15° elevation angles. The LUTs used in MAPA cover the following ranges: 0 – 5 for the AOD, 0.02 – 5 km for the layer height and 0.2 – 1.8 for the profile shape parameter (Beirle et al., 2019).

The temperature and pressure vertical profiles that are used as input in this study are identical for both MMF and MAPA. We have used climatological profiles for Thessaloniki produced by MPIC that are based on ~ 16 years re-analysis data from  
220 the European Centre for Medium-Range Weather Forecasts (ECMWF). The temperature and pressure profiles are interpolated to the day and time of each elevation sequence. We have also tried to use temperature and pressure profiles measured by radiosondes, launched on a daily basis at Thessaloniki Airport (~ 13 km away from the measurement site), as input, but since no major effect is observed on the retrieved products, these results are not presented. Both algorithms are configured to export the retrieved vertical profiles to the same output grid ranging from the ground up to 4 km with 200 m vertical resolution.

## 225 2.7 Ancillary data

### 2.7.1 CIMEL sun-photometer

Since 2003 a Sun Sky photometer (CIMEL) provides spectral measurements of the AOD at Thessaloniki as part of the NASA’s Aerosol Robotic Network (AERONET) (<https://aeronet.gsfc.nasa.gov/>). CIMEL is an automated, well-calibrated scanning filter radiometer specifically developed for the retrieval of the AOD at 7 wavelengths (i.e., 340, 380, 440, 500, 670, 870 and  
230 1020 nm) by using direct-sun observations. The technical specifications of the instrument are given in Holben et al. (1998). The instrument is calibrated regularly following the procedures and the guidelines of AERONET. The AERONET database provides three distinct levels for data quality. Level 1.0 is defined as pre-screened data (i.e., no quality assurance criteria are applied). The Version 3 (Sinyuk et al., 2020) of Level 1.5 represents near-real-time automatic cloud screened data, while Level 2.0 applies additional pre- and post-field calibrations. In this paper, we use the AERONET Level 1.5 data, since the Level 2.0

**Figure 4.** Frequency distribution of the Ångström exponent, AOD, asymmetry factor and SSA measured by a CIMEL sun-photometer in Thessaloniki for the period 2005 – 2021.

235 data for the period of study is not yet published. In order to compare with the AOD retrieved by the MAX-DOAS, the AODs at 360 and 477 nm have been calculated using the Ångström exponent between the standard spectral bands of the instrument.

### 2.7.2 Brewer spectrophotometer

The Brewer spectrophotometer with serial number 086 (B086) is a double monochromator that performs spectrally resolved measurements of the direct and global solar irradiance at Thessaloniki since 1993 (Bais et al., 1996; Fountoulakis et al., 2016).  
240 The wavelength range of B086 is 290 – 365 nm and its spectral resolution is 0.55 nm at full width at half maximum (FWHM). The wavelength calibration is performed by scanning the emission lines of spectral discharge lamps, while maintenance of the absolute calibration is achieved by regularly scanning the spectral irradiance of a calibrated 1000-W quartz–halogen tungsten lamp (Garane et al., 2006).

Although the Brewer’s initial purpose was the retrieval of total ozone columns, research activities have shown that the  
245 spectral AOD can be calculated from direct irradiance measurements by following two main approaches: The first is based on the absolute calibration of the direct-sun spectra measured by the Brewer (Kazadzis et al., 2005), while the second uses the Langley extrapolation method (relative calibration) (Gröbner and Meleti, 2004). In both cases the spectral AOD is calculated as the residual optical depth after subtracting from the total atmospheric optical depth the optical depths due to molecular scattering and the O<sub>3</sub> and SO<sub>2</sub> absorption (Kazadzis et al., 2007). Since 1997, the direct solar irradiance spectra measured by  
250 the Brewer are calibrated (Bais, 1997), so in this study we use the former approach (i.e., absolute calibration) for the retrieval of the spectral AOD. In order to compare with the AOD retrieved by the MAX-DOAS, the AOD at 477 nm is calculated using climatological monthly mean values of the extinction Ångström exponent derived from measurements of the CIMEL

sun-photometer in Thessaloniki. Details on the procedure of Brewer's direct solar irradiance spectra absolute calibration, as well as the spectral AOD retrieval methodology can be found in Bais (1997); Kazadzis et al. (2005, 2007); Fountoulakis et al. (2019).

### 2.7.3 Lidar

Thessaloniki is a member station of the European Lidar Aerosol Network (EARLINET, <https://www.earlinet.org>) since 2000, providing regular aerosol profile measurements, following the EARLINET's schedule (Monday morning, Monday and Thursday evening), during extreme events and at satellite overpasses (e.g., AEOLUS, OMI).

260 THEssaloniki LIdar SYStem (THELISYS) is a multi-wavelength Raman/depolarization lidar system, which has been gradually upgraded regarding its operational wavelengths and the detection configuration. All the quality standards, established within EARLINET, are followed in order to assure the high quality of the THELISYS products, which are publicly available in the EARLINET database (<https://www.earlinet.org/index.php?id=125>). A detailed description of THELISYS technical specifications and algorithm can be found in Voudouri et al. (2020).

265 The final products derived from the raw lidar data processing are: the aerosol backscatter coefficient at 355, 532 and 1064 nm, the aerosol extinction coefficient at 355 and 532 nm and the linear particle/volume depolarization ratio at 532 nm. During the day, the data acquisition is limited to the signals that arise from the elastic scattering of the laser beam by the air molecules and the atmospheric aerosol. The Klett-Fernald algorithm in backward integration mode is applied (Klett, 1981) and the backscatter coefficient profiles are produced. Constant a priori climatological values of the ratio between the extinction and the backscatter coefficient (Lidar Ratio) were assumed in this daytime method. Values of 60, 50 and 40 were used for 355, 532 and 1064 nm, respectively, given the atmospheric situations that occur over Thessaloniki (Voudouri et al., 2020). The resulting uncertainties are discussed in depth by Böckmann et al. (2004) and can be as high as 50% if there is no information about the actual Lidar Ratio, during extreme atmospheric conditions.

275 Another source of uncertainty during the lidar signals processing is the system's overlap function, which determines the altitude, above which a profile contains trustworthy values. In our analysis, the correction is not available for the daytime retrievals. Thus, an overlap function from the previous nighttime measurement or a mean overlap profile is applied. The starting height is set to the full overlap height (approximately 0.6 km), assuming height-independent backscatter below 0.6 km, equal to the backscatter measured at this height, to account for both the incomplete overlap within the lidar profile and atmospheric variability in the lowermost tropospheric part. This overlap effect generally introduces uncertainties in the calculation of the columnar products (e.g., AOD). However, long term comparisons (Siomos et al., 2018) have shown similar decreasing trends of the AOD at 355 nm between the EARLINET and the AERONET datasets (-23.2% and -22.3% per decade, respectively).

### 2.7.4 In situ

285 Near-surface concentrations of different air pollutants, including NO<sub>2</sub>, NO, SO<sub>2</sub>, CO and O<sub>3</sub> are measured in Thessaloniki by in situ instruments as part of the Network for Air Quality Monitoring of the Municipality of Thessaloniki. NO<sub>2</sub> is being monitored by chemiluminescence detectors that are mainly distributed around the city center. In this study, we use hourly mean

in situ NO<sub>2</sub> concentrations measured at the “Eftapyrgion” site (40.644° N, 22.957° E, 174 m a.s.l.), which is located in an urban background area at a distance of ~ 1.2 km from the MAX-DOAS system to the North. The in situ measurements, spanning from May 2020 to March 2021, are used in order to validate the MAX-DOAS-derived NO<sub>2</sub> near-surface concentrations. Even though this site is located opposite to the MAX-DOAS system’s azimuth viewing directions, it has been selected because the vertical and horizontal displacement of the two instruments is small, but also because it is the only site of the network almost unaffected by local traffic emissions and therefore can be considered more representative of the average NO<sub>2</sub> concentrations in the local boundary layer.

### 3 Results and discussion

In this section, we present results of the trace gas and aerosol quantities retrieved by the two inversion algorithms. We intercompare the integrated columns (i.e., VCDs and AODs for trace gases and aerosols, respectively), the dSCDs simulated by the RTMs, the retrieved vertical profiles and the surface concentrations between MMF and MAPA. Since MAPA is based on a parameterization approach, no information about averaging kernels is provided; hence, results on averaging kernels are presented only for MMF.

The MAX-DOAS system operates at a site where the northern viewing directions are blocked by buildings of the campus and the city, so the system is configured to perform sequences of elevation scans at azimuth directions in the southern sector, as illustrated in Figure 2. As a result, scattered radiation spectra may be measured during the day at azimuths close to the solar azimuth angle. In such cases, RTM simulations might face difficulties in calculating properly the dAMF due to increased aerosol forward scattering, leading usually to underestimation of the true dAMF. Therefore, the elevation sequences measured at azimuth angles relative to the sun of less than 5° are excluded from the analysis. In addition, the elevation sequences, for which the retrieved AOD from the MAX-DOAS inversion algorithms is greater than 1.5 are filtered-out, since such high aerosol loads are unrealistic for Thessaloniki (Figure 4). Negative columns can occur in the trace gas retrievals of MAPA within the Monte Carlo ensemble and they are intentionally not removed, but this is not possible for MMF retrievals since, in its current version, MMF operates in logarithmic state vector space. For NO<sub>2</sub>, no valid negative columns are retrieved, but for HCHO, MAPA reports negative columns for ~ 8.5% of the valid data. In order to compare meaningful results between the two algorithms, the negative columns are removed from the initial dataset.

The individual flagging schemes of MMF and MAPA have been discussed elsewhere. Based on synthetic data, Frieß et al. (2019) reported that the quality flagging criteria of MAPA might be too strict, since a large fraction of data was flagged as invalid, even though the algorithm successfully removed almost all outliers. In our study, MAPA flags a larger fraction of data as invalid, compared to MMF, for all the retrieved species. The percentage of the valid data flagged individually by MAPA and MMF is presented in Table 3. The retrieval results are sensitive to the validity flagging approach, which is further investigated in the next section. In order to achieve retrievals of high quality and to ensure that the MAX-DOAS measurements performed under broken cloud conditions are filtered-out, an elevation sequence is considered valid as long as it is flagged as valid by both MMF and MAPA. This is the default flagging scheme for NO<sub>2</sub>, HCHO and AOD at 477 nm and all the results shown

in the next sections follow this flagging approach unless stated otherwise. For AOD at 360 nm the flags reported by MAPA  
320 are considered as default, since this approach performs better when comparing the MAX-DOAS results with other reference  
instruments (Sect. 4), although the reason for this behavior has not yet been identified. Also, since the issue for selecting the  
optimum  $O_4$  scaling factor remains unresolved (Beirle et al., 2019; Wagner et al., 2019, 2021), we let MAPA determine an  
optimum  $O_4$  scaling factor (variable) for each elevation sequence and this option is selected as the default for the retrievals.

It should be noted that in the following sections an Orthogonal Distance Regression (ODR or bivariate least-squares) has  
325 been used instead of an Ordinary Linear Regression (OLR or standard least-squares) for the comparison of the retrieved  
products derived by MMF and MAPA, in order to treat equally the two algorithms since none of them depends on the other.  
The discrepancies in the regression slopes and intercepts arising in the OLR when comparing independent variables, and the  
appropriateness of ODR, are discussed in Cantrell (2008). The ODR results are also sensitive to the assumed errors of the two  
variables. The uncertainty contained in the MAX-DOAS measurements may be difficult to assess, but, since both MMF and  
330 MAPA retrievals are based on the same input data, the associated errors are assumed the same and equal to the mean error  
provided by MMF and MAPA for each data point.

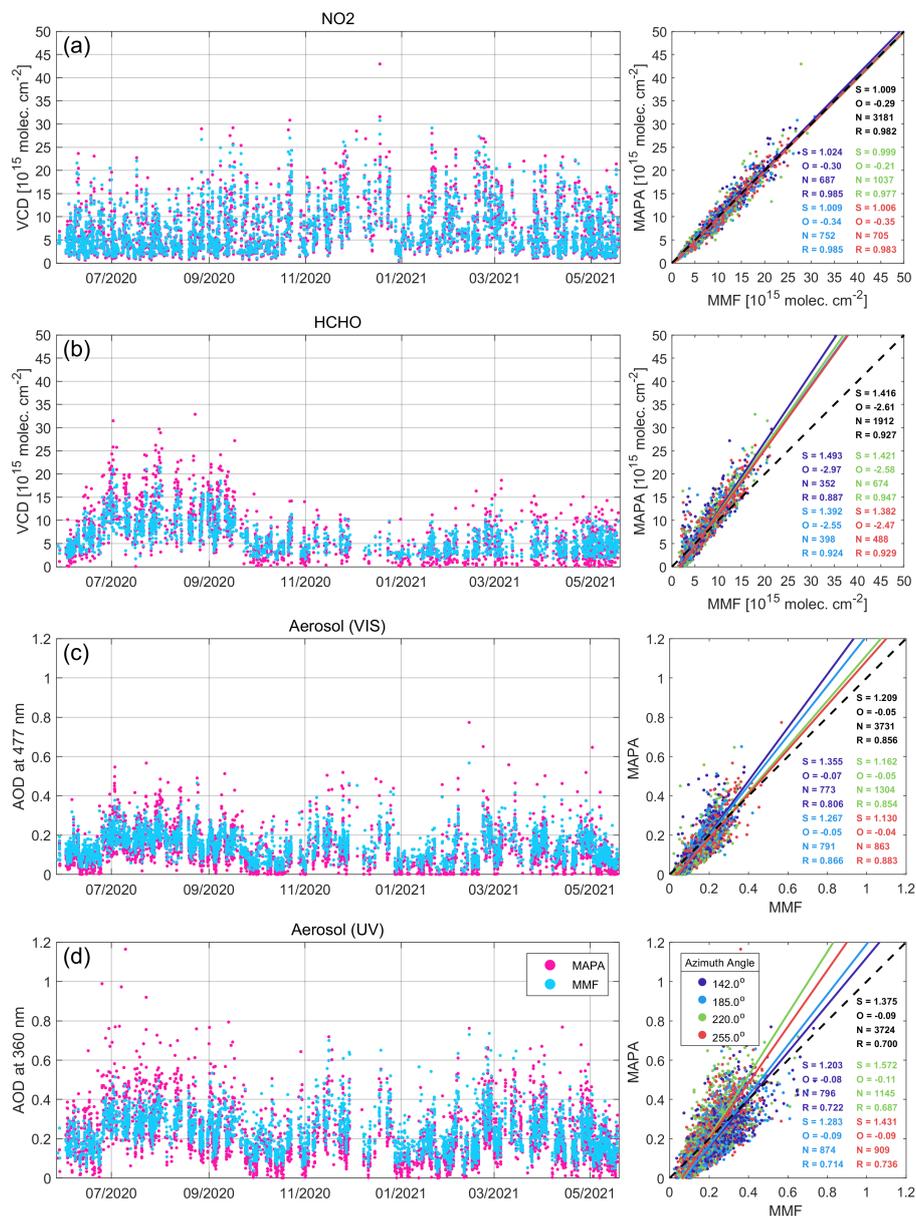

**Table 3.** The fraction of the data (%) that are individually flagged as valid by MMF and MAPA for each species.

Species	Inversion Algorithm	
	MAPA	MMF
NO <sub>2</sub>	29.0	62.4
HCHO	18.0	82.6
Aerosols (VIS)	47.6	57.4
Aerosols (UV)	38.3	54.8

### 3.1 Integrated Columns

In the past, the trace gas VCDs measured by our MAX-DOAS systems have been derived by dividing the measured dSCDs,  
only at two elevation angles, 30° and 15°, or the mean of the two, with appropriate dAMFs. The dAMFs have been calculated  
335 either following the geometrical approximation approach or by deploying RTM simulations taking into account the viewing  
geometry, the aerosol optical properties and the instrument's viewing direction relative to the sun (Drosoglou et al., 2017).  
However, in both cases, the actual trace gas profile has not been taken into consideration introducing, possibly, an additional  
uncertainty to the measured VCD. This is the first time during the Phaethon's operation that the whole elevation sequence is  
being used in order to derive the tropospheric VCDs more accurately.

340 In Figure 5 the time series of the integrated columns of all retrieved species (i.e., AODs for aerosols and VCDs for trace  
gases) are presented, as well as comparisons between MMF and MAPA. The statistics of the comparisons, i.e., slope ( $S$ ),  
offset ( $O$ ), number of points ( $N$ ) and Pearson's correlation coefficient ( $R$ ) are shown in different colors for each azimuth

**Figure 5.** Time series and scatter plots of the integrated columns for all species retrieved by MMF and MAPA (panel **a** refers to NO<sub>2</sub>, **b** to HCHO, **c** to aerosols in the visible range and **d** to aerosols in the UV). The parameters of the linear regression, i.e., slope ( $S$ ), offset ( $O$ ), number of points ( $N$ ) and Pearson’s correlation coefficient ( $R$ ) are shown in different colors for each azimuth viewing direction. The text in black color represents the consolidated statistics for all azimuth directions. The dashed black line represents the 1:1 line.

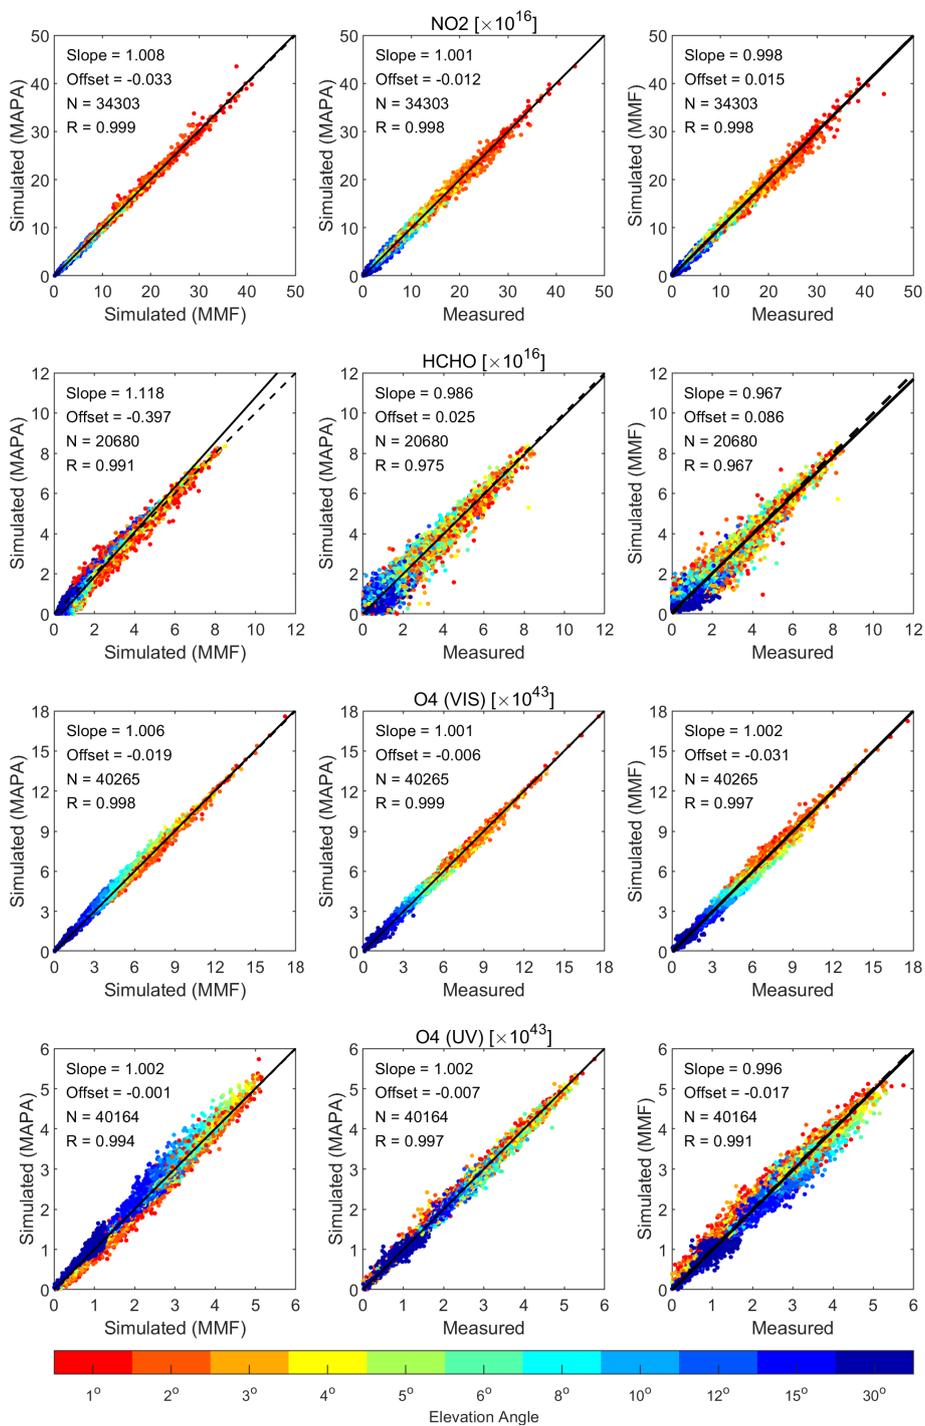

viewing direction. The text in black color represents the consolidated statistics for all azimuth directions. No clear azimuth dependence of the retrieved columns is observed for the trace gases. However, for aerosols, especially in the UV, significant

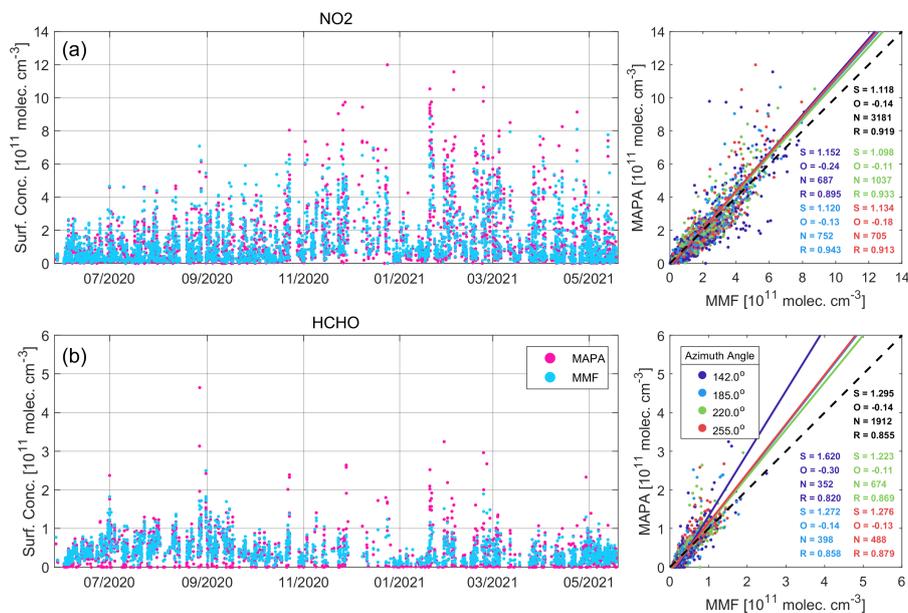

345 differences in the regression slopes appear for the different azimuths. It should be noted that in these comparisons a variable  
O<sub>4</sub> scaling factor has been used for the MAPA retrievals, and since no scaling factor has been applied to the MMF retrievals,  
differences in the AODs between the two algorithms are expected. The number of elevation sequences for 220° azimuth  
is always larger compared to the other azimuth directions, because the instrument was configured to record spectra only  
at this particular direction for approximately one month in the beginning of its operation. The comparison shows that the  
350 NO<sub>2</sub> VCDs derived by MMF and MAPA are in very good agreement, with slopes and correlation coefficients close to unity  
(ranges:  $0.999 \leq S \leq 1.024$  and  $0.977 \leq R \leq 0.985$ ). Similar results were obtained for all azimuth directions with  $S = 1.009$   
and  $R = 0.982$ . In the case of HCHO, despite the good correlation ( $R = 0.927$ ), notable deviations from unity in the slope are  
observed for all azimuth directions. MAPA systematically reports larger VCDs than MMF for higher HCHO concentrations,  
while the opposite behavior is observed for low HCHO loads, indicating that further investigation is required. This behavior  
355 could be explained by the increased spectral noise in the UV that leads to discrepancies between the HCHO dSCDs simulated  
by the forward models of MMF and MAPA (see discussion in Sect. 3.2) and due to invariant a priori profile during the year.  
Concerning aerosols, the comparison of the retrieved AODs reveals better agreement at 477 nm ( $R = 0.856$ ) than at 360 nm  
( $R = 0.700$ ), with larger scatter and more outliers compared to the trace gas VCDs. As already mentioned, this is mainly  
attributed to the O<sub>4</sub> scaling factors that are used in MAPA retrievals. More details about the effect of the O<sub>4</sub> scaling factor on  
360 the retrieved AODs and the trace gas VCDs can be found in the Appendix.

### 3.2 Simulated dSCDs

In this section we evaluate the performance of the forward models of MMF and MAPA by intercomparing the simulated trace  
gas dSCDs of the four species for the entire period. Also, we assess their ability to successfully simulate the slant column  
densities under different atmospheric (pollution and meteorological) conditions and viewing geometries by comparing the  
365 modeled with the measured dSCDs (Figure 6). Each row corresponds to a different trace gas, with the left column presenting  
the intercomparison results of the modeled dSCDs, while the middle and right columns show the comparison results between  
the measured dSCDs and the dSCDs simulated by MAPA and MMF, respectively. The data points are colored by the elevation  
angle and hotter colors represent dSCDs close to the horizon. A generally better performance of both algorithms is observed  
for the species retrieved in the VIS range compared to those retrieved in the UV. The modeled slant columns agree well, with  
370 Pearson's correlation coefficients and slopes close to unity ( $R = 0.999$ , Slope = 1.008 for NO<sub>2</sub> and  $R = 0.998$ , Slope = 1.006  
for O<sub>4</sub> VIS). Additionally, the simulated dSCDs are in good agreement with the measured dSCDs, which is a good indicator for  
successful profile retrievals. In the case of O<sub>4</sub> (UV), even though the slope and correlation coefficient are similar to O<sub>4</sub> (VIS),  
a larger scatter is evident, while for HCHO larger deviations from unity in the slopes and correlation coefficients are observed,  
especially at higher elevation angles. This can probably be explained by the increased noise in the UV spectra compared to  
375 the VIS range and also due to the fact that at higher elevation angles the measured differential optical densities are very low,  
reaching the spectrometer's detection limit. For aerosols in both spectral ranges, discrepancies between the simulated dSCDs  
of MMF and MAPA may also arise due to the variable O<sub>4</sub> scaling factor that is included in MAPA retrievals.

**Figure 6.** Intercomparison of the dSCDs simulated by MMF and MAPA (left column) and comparison of the dSCDs simulated by MAPA (center column) and MMF (right column) against the measured dSCDs. The elevation angles are denoted by different colors (see scale at the bottom).

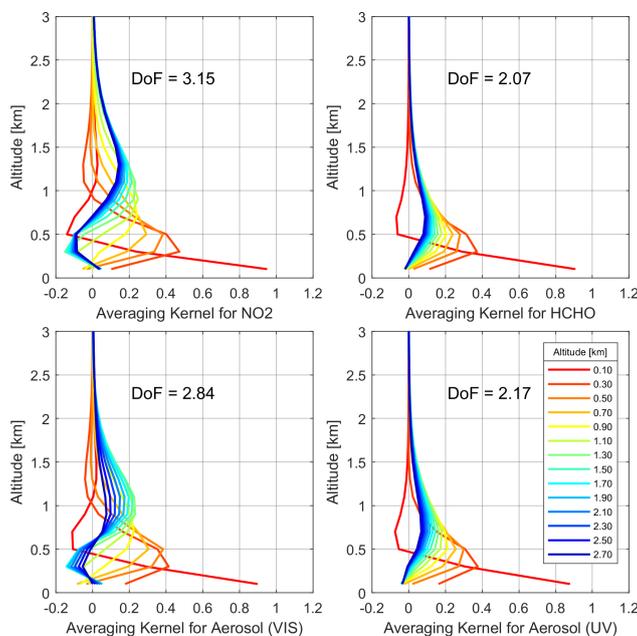

**Figure 7.** Time series and scatter plots of the near-surface concentrations of NO<sub>2</sub> (a) and HCHO (b) derived by MMF and MAPA. The parameters of the linear regressions are presented as in Figure 5.

### 3.3 Surface concentrations

The surface concentration is defined as the trace gas amount at ground level. However, in MAPA’s configuration the algorithm  
 380 allows for the retrieval of lifted trace gas layers for a shape parameter greater than 1, which leads to a zero value for the surface concentration. For these cases, the comparison of the lowermost concentrations with in situ measurements or surface concentrations retrieved by an OEM-based algorithm will be biased. Thus, in the following sections, the term “surface concentration” will refer to the concentration reported for the lowermost layer of the MAX-DOAS profile for both MMF and MAPA, rather than the concentration at the ground. Figure 7 shows the time series of the near-surface NO<sub>2</sub> and HCHO concentrations derived  
 385 by MMF and MAPA and the corresponding scatter plots. The comparisons of the surface values are similar to the comparisons of the tropospheric VCDs (shown in Figure 5) with Slope = 1.118,  $R = 0.919$  for NO<sub>2</sub> and Slope = 1.295,  $R = 0.855$  for HCHO, but more outliers are present. In the case of HCHO, the surface concentrations derived for the 142° azimuth show larger differences compared to the other directions, while this is not clear for NO<sub>2</sub>. These discrepancies are possibly related to the fact that for this azimuth, the elevation angle of 1° was not included in the analysis (see Sect. 2.1), which may have  
 390 influenced the retrieved surface concentrations.

### 3.4 Averaging Kernels

The averaging kernels (AVKs) of a profile retrieval describe the sensitivity of the retrieved state to the true atmospheric state for each altitude layer. The degrees of freedom (DoF) are mathematically derived as the trace (or sum of the diagonal elements) of

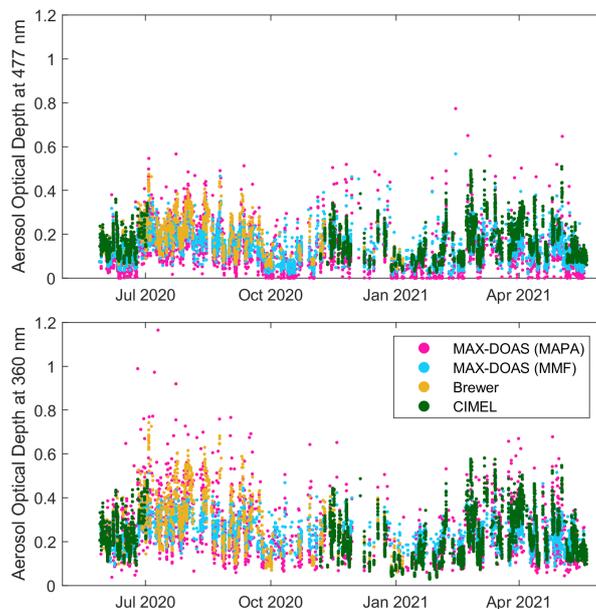

**Figure 8.** A typical example of the retrieved averaging kernels for different altitudes of each species. Hotter colors correspond to altitudes closer to the ground.

the AVK matrix and quantify the number of independent pieces of information gained from the measurements compared to the a priori knowledge (Rodgers, 2000). Both the AVKs and the DoF can be used to characterize the quality of the retrieved profile. Since only OEM-based inversion algorithms are capable of providing AVKs, the results shown here are derived only by MMF. Figure 8 shows a typical example of the calculated AVKs for each of the retrieved species. The DoF of this example retrieval are shown for each species. The median DoF retrieved by MMF are:  $3.13 \pm 0.32$  for  $\text{NO}_2$ ,  $2.22 \pm 0.34$  for HCHO,  $2.73 \pm 0.28$  for aerosols in the VIS and  $2.02 \pm 0.32$  for aerosols in the UV. The averaging kernels verify that MAX-DOAS measurements are typically less sensitive for altitudes greater than  $\sim 2$  km, as a result of the viewing geometry, and thus, altitudes greater than 3 km are not presented here. That means that the MAX-DOAS measurements under these viewing geometries and with the a priori profiles and covariance matrices used in this study (Sect. 2.6) are adequate for retrieving the extinction and concentration profiles only up to the lowermost  $\sim 1.5 - 2$  km of the atmosphere with highest sensitivity closer to the ground. Also, since the photon path increases with wavelength, the MAX-DOAS technique shows higher sensitivity for the species retrieved in the VIS range than in the UV.

#### 4 Validation

In this section we present the validation results of the products retrieved by the MAX-DOAS profile analysis against ancillary data measured by other reference co-located instruments. Vertical profiles of the aerosol extinction measured by a co-located

**Figure 9.** Time series of all available AOD data at 477 and 360 nm retrieved by the MAX-DOAS system, the Brewer spectrophotometer and the CIMEL sun-photometer.

lidar system are used to validate the aerosol vertical profiles retrieved by the MAX-DOAS, while the AODs in the UV and VIS  
410 range are compared with those measured by a sun-photometer and a spectrophotometer. The NO<sub>2</sub> surface concentrations are compared with in situ surface measurements, but since no other sources of HCHO data are available, the MAX-DOAS derived vertical profiles, columns or surface concentrations cannot be validated.

#### 4.1 Aerosol extinction profiles

The AOD values at 477 and 360 nm retrieved by the MAX-DOAS are compared with the AOD measured by the co-located  
415 CIMEL sun-photometer and the Brewer spectrophotometer. Quasi-simultaneous (within  $\pm 15$  minutes) measurements were found and the AODs at 477 and 360 nm were calculated using the Ångström exponent between 380 and 500 nm and the AOD at these wavelengths derived by the CIMEL. Since the Brewer's wavelength range spans up to 365 nm, climatological monthly mean Ångström exponent values, calculated from the CIMEL data, have been used to extrapolate the AOD to 477 nm. Figure 9 shows the time series of all AOD data at 477 and 360 nm (not just the quasi-simultaneous) retrieved by the three systems.  
420 The CIMEL sun-photometer was not operating for approximately 4 months during the summer of 2020 due to a delay in its scheduled annual maintenance and calibration. AOD data derived by the Brewer are available until January 2021.

Since MMF and MAPA rely on their own individual flagging schemes in order to ensure that the retrieved products are of high quality, we investigate the effect of applying different flagging schemes to the data, which are listed in Table 4.

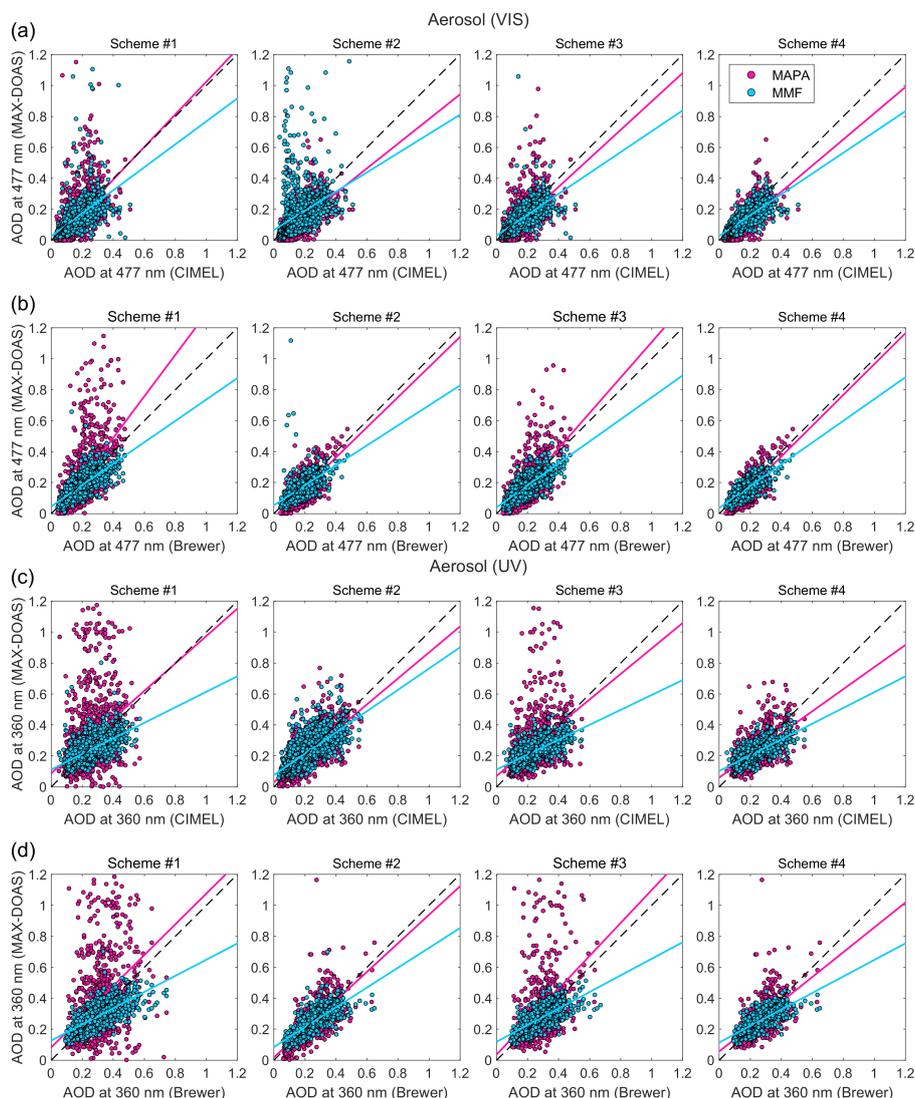

**Table 4.** The flagging schemes that are applied to the retrieved products.

Flagging scheme	Description
#1	Data are flagged as valid by the flagging algorithm of MMF
#2	Same as scheme #1, but for the flagging algorithm of MAPA
#3	Data that are not flagged erroneous neither by MMF nor by MAPA are considered valid
#4	Data are flagged as valid by both MMF and MAPA

Schemes #1 and #2 correspond to the default own flagging algorithms of MMF and MAPA, scheme #4 is expected to provide  
425 data of maximum quality since both algorithms contribute to the flagging, while scheme #3 examines whether the warnings  
raised by MMF and MAPA should be treated as valid or not. Figure 10 shows the comparison between the common AOD  
data derived by CIMEL, Brewer and the MAX-DOAS at 360 and 477 nm. Each column of the figure corresponds to a different  
flagging scheme as described in Table 4. Figure 11 presents graphically the statistics of the linear regressions (i.e., slope, offset,  
number of points and Pearson's correlation coefficient) between the reference instruments and the MAX-DOAS. The panels a  
430 – d correspond to different flagging schemes, as Figure 10.

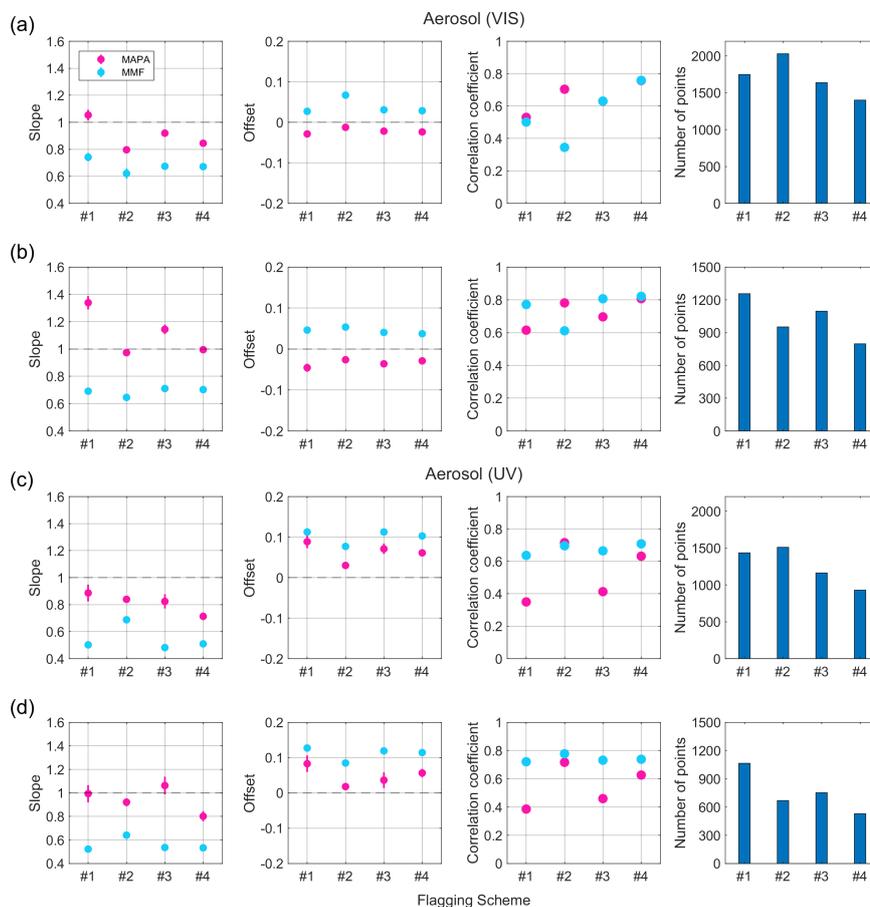

The comparison results of the MAX-DOAS against the CIMEL are slightly different than those with the Brewer. This can  
probably be explained by the fact that only few collocated measurements are available and in different periods for the two  
reference instruments (Figure 9). In the case of the AOD at 477 nm most of the outliers are filtered-out when the flagging  
scheme #4 is applied and the best agreement is observed between the reference instruments and the MAX-DOAS, both for  
435 MMF and MAPA, with similar correlation coefficients (0.79 for the CIMEL and 0.81 for the Brewer). Compared to the CIMEL,  
MAPA seems to perform slightly better than MMF when its own flagging algorithm is applied to the data, with correlation  
coefficients of 0.70 and 0.50, respectively. However, compared to the Brewer, both algorithms show very similar correlation  
coefficients (0.78 and 0.77, respectively). Swapping the flags between MMF and MAPA leads to worse agreement and more  
outliers. The results of scheme #3 indicate that some of the warning-flagged data are of lower quality and should be treated  
440 with caution.

In the case of the AOD at 360 nm, the effect of the flagging schemes is different. Here, most of the outliers are eliminated  
and the best overall agreement is achieved for scheme #2 (i.e., when MAPA's individual flagging algorithm is applied). This  
behavior is observed both for MMF and MAPA, indicating that the flagging algorithm of MAPA performs better than that  
of MMF in the UV. The correlation coefficients with the CIMEL data are 0.72 for MAPA and 0.70 for MMF, and with the  
445 Brewer data are 0.72 for MAPA and 0.78 for MMF. The flagging scheme #4 removes even more data (as expected), but does  
not improve the comparisons. The effect of the warning-flagged data (scheme #3) is more apparent in the case of the UV and  
the results suggest that they should not be considered valid. The AOD derived from the MAX-DOAS, both in the UV and the  
VIS range, is, generally, underestimated compared to the AOD measured by the CIMEL and the Brewer. However, it should  
be noted that the AODs derived by the MAX-DOAS and the reference instruments may not always refer to the same physical

**Figure 10.** Scatter plots of the AOD retrieved by the MAX-DOAS data analyzed by MMF and MAPA against the CIMEL (**a** at 477 nm, **c** at 360 nm) and the Brewer (**b** at 477 nm, **d** at 360 nm). Each column represents data that are flagged as valid according to the flagging schemes of Table 4.

450 quantity. The CIMEL and the Brewer use direct-sun observations to retrieve the total column amount of the aerosol extinction, while the MAX-DOAS sensitivity decreases rapidly with altitude (Sect. 3.4) and the derived AOD corresponds mainly to the lowermost tropospheric aerosol (partial AOD). Additionally, the vertical profiles retrieved by the OEM-based algorithms are biased towards the a priori profile at higher altitudes leading to deviations from the true profile, meaning that aerosol layers above  $\approx 2$  km cannot be reliably retrieved. Discrepancies in the AODs between the instruments are expected, usually when  
 455 aerosols are present at altitudes greater than 2 km, contributing to the total AOD, but not detected by the MAX-DOAS.

**Figure 11.** Graphical representation of the linear regression parameters (slope, offset, correlation coefficient and number of data) of the comparison between the AOD derived from MAPA and MMF against the AOD from the CIMEL (a, c) and the Brewer (b, d) at 477 nm (a, b) and 360 nm (c, d) for each flagging scheme (#1 to #4).

During the whole period of this study only a few lidar measurements of the aerosol extinction profile are available, so the true state of the aerosol profile is generally not known. Additionally, synchronous measurements between the lidar and the MAX-DOAS are even fewer, so an in-depth validation of the aerosol profiles retrieved by the MAX-DOAS needs further investigation. In this section we present the comparison of four profiles retrieved by the two systems within  $\pm 30$  min, and which are indicative for the period of study. An important issue that arises in the validation of the MAX-DOAS vertical profiles is that usually the validator (in this case the lidar system) allows the detection of aerosol layers in a much higher vertical resolution than the MAX-DOAS. When the true aerosol profile state is actually known and in order to compare meaningful results, the lidar profiles need to be smoothed (i.e., degraded to the sensitivity of the MAX-DOAS). Only the OEM-based

460

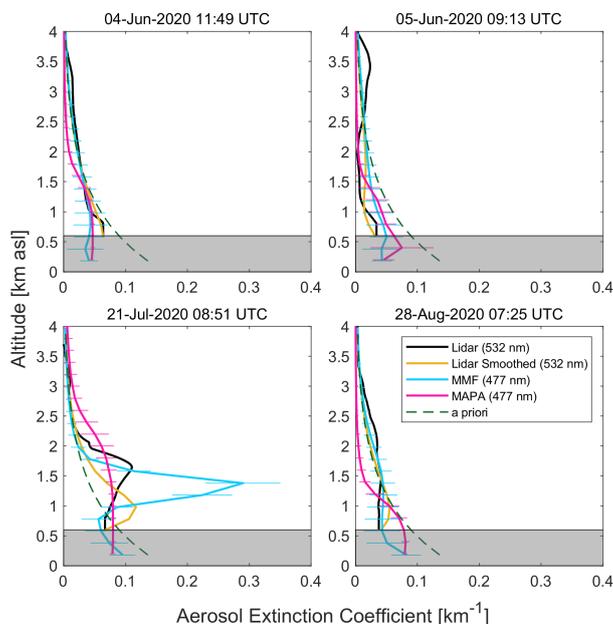

algorithm provides information that can be used to smooth the lidar profiles. The information about the sensitivity is quantified  
465 by the averaging kernel according to Rodgers and Connor (2003):

$$\mathbf{x}_s = \mathbf{x}_a + A(\mathbf{x} - \mathbf{x}_a) \quad (2)$$

where  $\mathbf{x}_s$  is the smoothed lidar profile,  $\mathbf{x}_a$  and  $A$  are the a priori profile and the averaging kernel of the OEM-based retrieval and  $\mathbf{x}$  is the initial lidar profile. Deviations of the smoothed lidar profile at each altitude depend on the a priori profile and the sensitivity of the MAX-DOAS at this altitude (Davis et al., 2020). Since the sensitivity of the MAX-DOAS decreases with  
470 altitude, the application of the averaging kernels is expected to smooth the true profiles towards lower altitudes. However, since MAPA does not quantify the sensitivity, a similar smoothing cannot be performed for MAPA retrievals and thus, the aerosol extinction profiles are directly compared with the initial lidar profiles. Another point that should be noted is the differences in the operational principles of the two instruments. The lidar retrieves the vertical profile from the air mass that is located overhead, while the MAX-DOAS scans through different air masses along the line of sight of the telescope during an elevation  
475 sequence (Gratsea et al., 2021). Its effective horizontal distance is of the order of a few kilometers and increases at elevation angles close to the horizon. Thus, differences in the retrieved extinction profiles are expected, especially at locations with large horizontal inhomogeneities of aerosols. As already mentioned (Sect. 2.7.3) a constant climatological Lidar Ratio of 50 sr was assumed for the channel of 532 nm and was applied to the backscatter profiles in order to retrieve the extinction, which may also result in uncertainties of the validator's product. So, in this study the comparisons are focused on the shape of the profiles  
480 and the retrieved aerosol layer heights rather than on the absolute values of the aerosol extinction.

Figure 12 presents the comparison of four aerosol extinction profiles in the VIS retrieved by the MAX-DOAS and the lidar. The lidar profile is trustworthy only above a certain altitude (approximately 0.6 km) owing to the geometry of the telescope and the emitted laser beam, which prevents a fraction of the backscattered radiation to reach the detector at altitudes close to the surface (overlap effect). Thus, the aerosol extinction retrieved by the lidar below 0.6 km is not presented. Since the  
485 MAX-DOAS profile retrievals in the UV are sensitive only at altitudes closer to the ground, where the lidar system is not, the profiles for 360 nm are excluded from the analysis. In Figure 12 the yellow line corresponds to the smoothed lidar profile, which is degraded to the sensitivity of the MAX-DOAS according to Eq. 2. In general, the aerosol vertical profiles retrieved by the MAX-DOAS can realistically estimate the shape of the true state, even though some differences appear between MMF and MAPA. The agreement between the shape of the MMF profiles and the smoothed lidar profiles is much better than for  
490 MAPA. This is expected since the initial lidar profile is degraded to the sensitivity of the MAX-DOAS using the averaging kernels derived by MMF and the a priori profile of the retrieval. On 4 and 5 June the aerosol load is low and both algorithms report similar profiles. In both cases the MAX-DOAS profiles fit successfully the shape of the true profile. However, on 5 June the shape of the profiles is similar only up to  $\approx 2$  km. Aerosol layers between 2 and 4 km are “invisible” to the MAX-DOAS, due to the practically zero sensitivity at these altitudes. In the other two cases MMF and MAPA provide different profiles.  
495 Discrepancies in the vertical profiles retrieved by different inversion algorithms for species measured in the VIS have also been reported in other studies (e.g., Frieß et al., 2019; Tirpitz et al., 2021). On 21 July MMF reports a more structured aerosol

**Figure 12.** Four cases of aerosol vertical profiles measured by the MAX-DOAS (cyan for MMF and magenta for MAPA) and the lidar (black for the original and yellow for the smoothed profiles). The shaded area represents altitudes, where the lidar is not capable of retrieving the aerosol extinction profile accurately due to the overlap effect.

profile with a distinct aerosol layer at about 1.3 km, while MAPA reports a smoother profile with a thick layer spanning from the surface up to  $\approx 2$  km. On 28 August, even though MMF and MAPA report profiles of different shapes below  $\approx 1$  km, the profiles agree reasonably well with the lidar profile. At higher altitudes MMF is biased towards the a priori profile due to the limited sensitivity, while the aerosol extinction retrieved by MAPA decreases rapidly. Despite the observed differences, the results of the comparisons are promising, indicating that the analysis of the MAX-DOAS data can provide a generally good estimation of the vertical aerosol extinction profiles over Thessaloniki. However, further investigation is required in order to assess the differences in the aerosol profiles provided by the two systems, but also between the two inversion algorithms, when more collocated measurements become available. Such studies will be further facilitated with a new lidar system with improved overlap height that is currently under development, which will allow the retrieval of the aerosol profiles at altitudes closer to the ground, where the MAX-DOAS shows higher sensitivity.

#### 4.2 NO<sub>2</sub> surface concentration

In Figure 13 we present a comparison of near-surface concentrations derived from the MAX-DOAS data with in situ NO<sub>2</sub> measurements. The small dots represent the hourly mean values, while the solid lines refer to the daily mean concentrations. The comparison is only performed for the hourly mean concentrations derived by the two systems, while the daily mean concentrations are shown only for a qualitative comparison. A dataset from June 2020 to March 2021 (about 10 months)

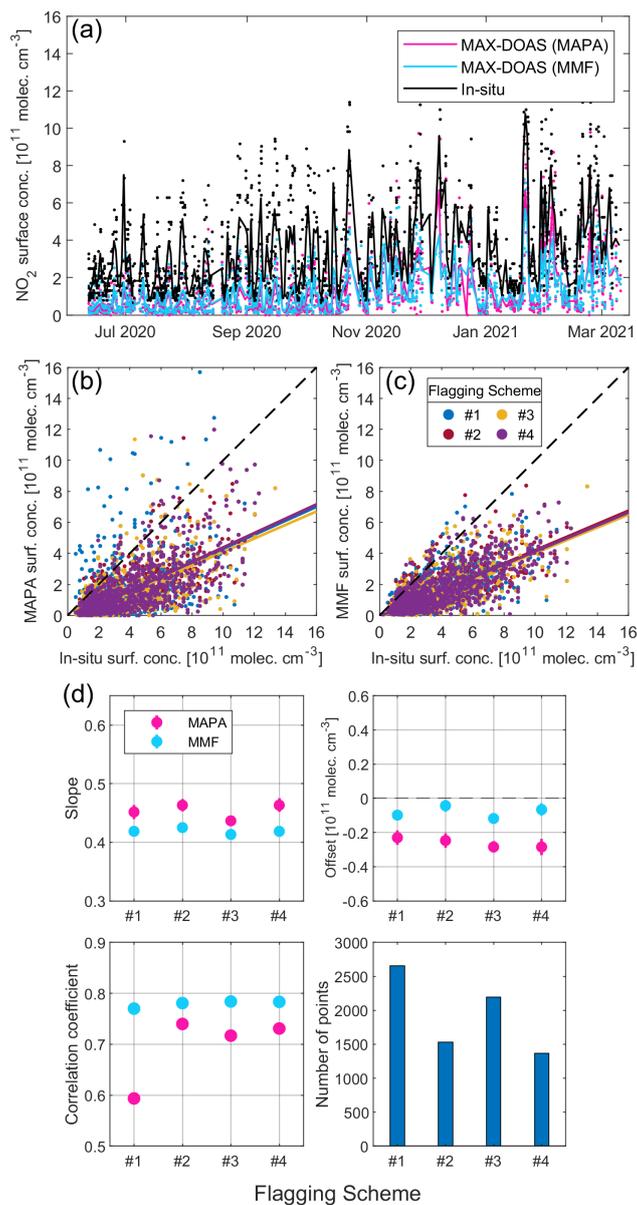

is considered in this study, in which both MAX-DOAS and in situ surface measurements were available. The MAX-DOAS reports systematically lower NO<sub>2</sub> concentrations than the in situ by ~ 55 – 60%. Since the concentrations retrieved by the MAX-DOAS are averaged along a horizontal path of a few km, which may extend over the bay, whereas the in situ data refer to a specific location (point measurements), the MAX-DOAS is generally expected to report lower values from the air-quality station, which is also occasionally affected by local emissions. Differences in the retrieved concentrations may also arise due to the slightly different altitudes of the measurement sites. Similar results have been found in other studies (e.g., Zieger et al., 2011; Friedrich et al., 2019; Chan et al., 2020; Dimitropoulou et al., 2020). Both MMF and MAPA perform well for the retrieval of the NO<sub>2</sub> surface concentrations. The effect of the different flagging schemes is not as strong as for aerosols, except for MAPA when MMF's flagging (scheme #1) is applied to the data. The performance of MMF is slightly better than MAPA's with fewer outliers and higher correlation coefficients, even though it reports as valid a much larger fraction of data (Table 3). The results of flagging scheme #3 indicate that the warning-flagged data could also be considered valid. This could be explained by the fact that a large part of the flagged data is related to the effects of clouds. As shown in previous studies (e.g., Wang et al., 2017b), under most cloud conditions (except for fog and optically thick clouds), the trace gas vertical profiles, columns and near-surface concentrations can still be retrieved, while the aerosol retrievals are stronger affected.

## 5 Conclusions

In this study we have retrieved vertical profiles of aerosols, NO<sub>2</sub> and HCHO for the first time in Thessaloniki, Greece using MAX-DOAS observations by applying an OEM-based inversion algorithm (MMF) and a parameterized algorithm (MAPA). Their performance is evaluated by intercomparing the integrated columns (i.e., VCDs for trace gases and AODs for aerosols), the dSCDs simulated by the forward models and the trace gas surface concentrations derived by the two algorithms.

The tropospheric column densities of NO<sub>2</sub> are in excellent agreement (slope very close to unity and  $R = 0.982$ ), while for HCHO, even though a generally good correlation is found ( $R = 0.927$ ), deviations from unity in the slopes are observed, which can be attributed to discrepancies between the HCHO dSCDs simulated by the forward models of MMF and MAPA. Concerning aerosols, a better agreement between MMF and MAPA is found for the AOD at 477 nm than at 360 nm due to the increased SNR in the VIS range and the stronger effect of the O<sub>4</sub> scaling factor on the retrieved AODs in the UV. No clear azimuth dependence is observed for any of the retrieved species.

The products derived by the inversion analysis of MAX-DOAS measurements by MMF and MAPA are compared with ancillary data measured by other reference instruments. The AODs retrieved by the MAX-DOAS are validated by comparison with measurements of a CIMEL sun-photometer and a Brewer spectrophotometer. Four different flagging schemes were applied to the MAX-DOAS derived data in order to evaluate the performance and effect of the flagging schemes used by the two profiling algorithms. A generally good qualitative agreement is found for both VIS and UV wavelengths (with correlation coefficients up to 0.8). The negative bias that is observed from the reference instruments is probably mostly due to the limited sensitivity of the MAX-DOAS in retrieving aerosol information at higher altitudes, especially in the UV. The results also indicate that using an intersected dataset derived by applying both flagging algorithms to the data, improves the agreement

**Figure 13.** (a) Time series of hourly mean NO<sub>2</sub> surface concentrations derived from MAX-DOAS by MMF (cyan) and MAPA (magenta) and from in situ measurements (black). The solid lines correspond to the time series of daily means. Panels b, c are the corresponding scatter plots colored by the four flagging schemes that are applied to the MAX-DOAS data and panel d shows the statistics of the comparisons.

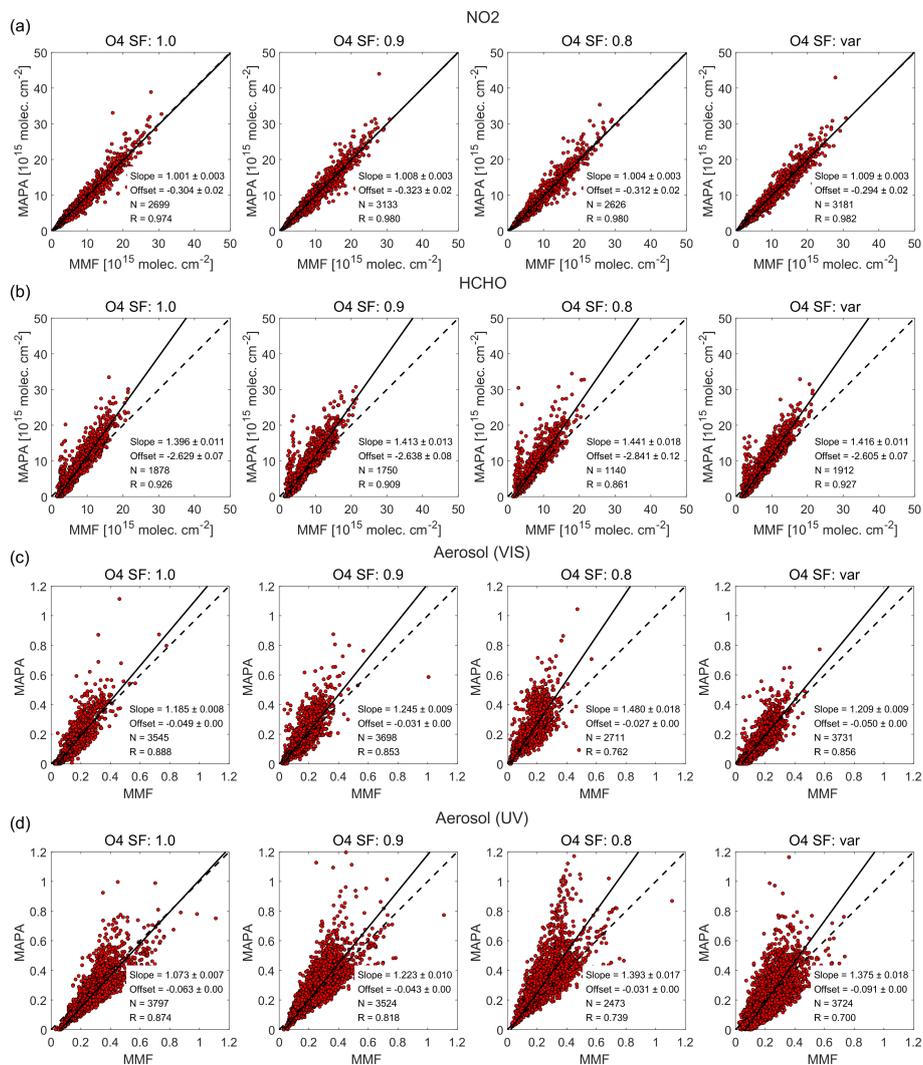

545 of AODs at 477 nm, however, a similarly good agreement is not observed in the UV, where the flagging algorithm of MAPA performs better. Four cases of aerosol extinction vertical profiles at 477 nm are compared with profiles measured by a co-located lidar system. The MAX-DOAS was found to provide a generally good estimation of the shape of the profile. The NO<sub>2</sub> surface concentrations are compared with in situ NO<sub>2</sub> observations, where the effect of the different flagging schemes is not found to have such a strong impact as for aerosols. The concentrations from both MMF and MAPA are in good agreement with  
550 the in situ measurements in terms of variability, but are highly biased by approximately 60%. MMF shows a slightly better performance ( $R = 0.78$ ) compared to MAPA ( $R = 0.73$ ).

The effect of the O<sub>4</sub> scaling factor is also investigated by comparing the integrated columns of MMF and MAPA and also by comparing the AODs derived by MAPA for different values of the scaling factor with AODs measured by the CIMEL and the Brewer. The effect of the O<sub>4</sub> scaling factor has a stronger impact on aerosols than on trace gases (where the effect is minor). The  
555 fixed value of 0.8 for the scaling factor, which is supported by many studies, does not seem to be suitable for the measurements at Thessaloniki.

#### Appendix A: Effect of the O<sub>4</sub> scaling factor

The O<sub>4</sub> scaling factor (SF) was introduced by Wagner et al. (2009) in order to remove the systematic discrepancies appearing between measured and simulated O<sub>4</sub> dSCDs. Uncertainties of the O<sub>4</sub> cross sections and/or its temperature and pressure de-  
560 pendence, aerosol optical properties and RTM errors have been suggested as possible causes for these discrepancies. Several studies have confirmed the idea of the O<sub>4</sub> scaling factor and have shown that applying a SF (commonly using a value between 0.75 and 0.9) is indeed necessary (Wagner et al., 2009; Clémer et al., 2010; Irie et al., 2011; Wang et al., 2014; Vlemmix et al., 2015b; Wang et al., 2016; Frieß et al., 2016; Wagner et al., 2019, 2021). However, other studies have not supported this requirement (Spinei et al., 2015; Ortega et al., 2016; Seyler et al., 2017; Wang et al., 2017a, b). Although the need for an  
565 O<sub>4</sub> scaling factor for retrieving aerosol information from MAX-DOAS measurements has been extensively discussed (Wagner et al., 2019), its physical mechanism is not understood and still remains an unresolved issue.

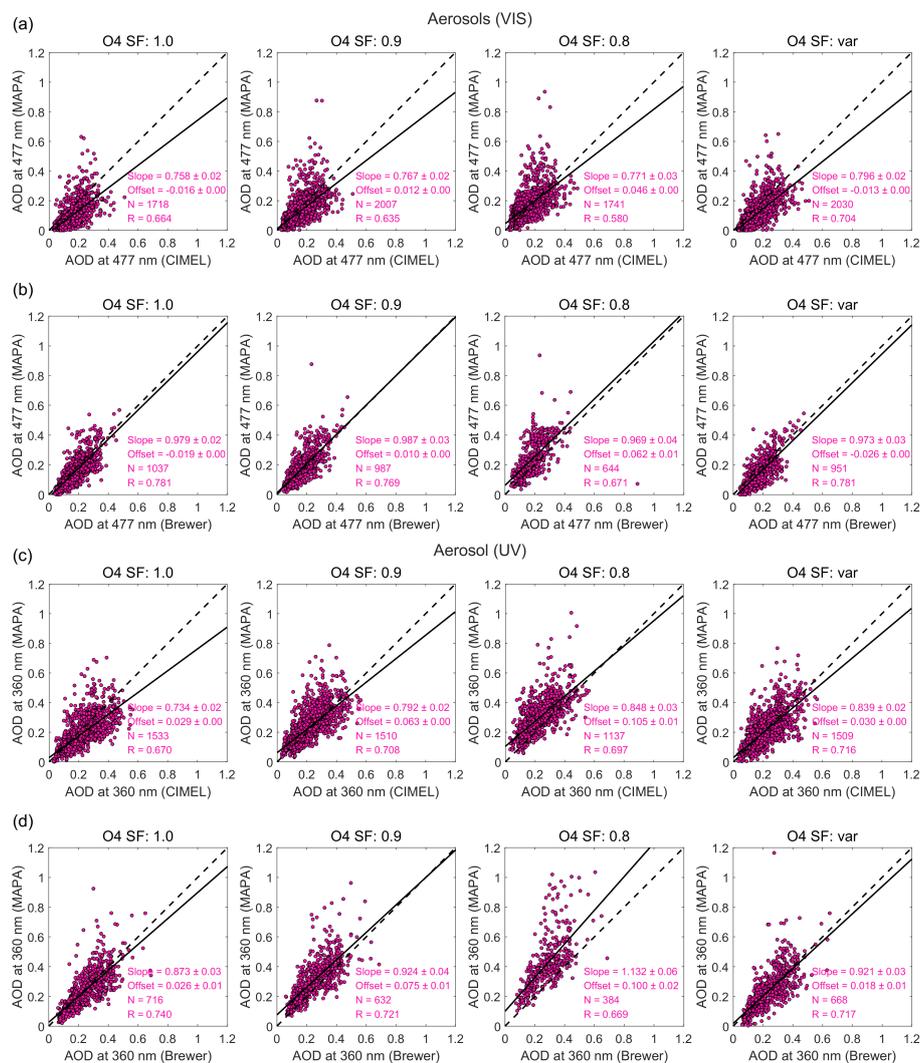

Since MAPA provides the option of scaling the modeled O<sub>4</sub> dSCDs, we have investigated the effect of the SF on the comparisons between the products of the two profiling algorithms and between AOD derived by MAPA and the reference instruments. We selected three fixed values (i.e., 1, 0.9 and 0.8, referred hereafter as SF1.0, SF0.9 and SF0.8) and a variable  
570 SF (SFvar). Figure A1 shows the effect of the O<sub>4</sub> SF on the comparison of trace gas VCDs and AOD derived by MAPA and MMF (same as Figure 5 without accounting for the different azimuth directions). Like in Figure 5, the regression results are based on an ODR and also the retrievals of aerosols in the UV are based on the flagging algorithm of MAPA. Since MMF does not take into account a scaling for O<sub>4</sub>, the use of different SFs in MAPA leads to substantial differences in the regression slopes and correlation coefficients when comparing the AODs of the two algorithms, both for 360 and 477 nm. The closest to  
575 unity slopes and the highest correlation coefficients are found, as expected, when no scaling factor is applied (SF1.0) for both wavelengths. The slopes of the fitting are 1.18 and 1.07 for the AODs at 477 and 360 nm, respectively, while the correlation coefficients are  $\sim 0.89$  and  $\sim 0.88$ . Especially for the AOD in the UV, the agreement between MMF and MAPA for the variable

**Figure A1.** Scatter plots of the integrated columns of NO<sub>2</sub>, HCHO, AOD at 477 and 360 nm (a – d, respectively) retrieved by MMF and MAPA for various O<sub>4</sub> scaling factors (columns 1 – 4).

SF substantially declines and the scatter increases. The worst results appear for SF0.8 leading also to substantial reduction in the reported valid data. The use of a scaling factor doesn't seem to affect the retrieved VCDs for NO<sub>2</sub> and HCHO, at least as  
 580 it concerns the slope and correlation coefficient of the regression, but there is some effect on the number of the data reported as valid, especially for SF0.8. Opposite to aerosols, the best correlation of the retrieved NO<sub>2</sub> and HCHO columns is achieved when using the SFvar instead of the SF1.0.

Figure A2 presents the comparison of the AODs at 360 and 477 nm retrieved by the MAX-DOAS (using MAPA) with the AODs calculated by the CIMEL and the Brewer for different O<sub>4</sub> SFs. For consistency, the individual flagging algorithm of

**Figure A2.** Comparison of the AODs at 477 nm (a, b) and 360 nm (c, d) derived by MAPA with the AODs measured by the CIMEL (a, c) and the Brewer (b, d) for different O<sub>4</sub> SFs (columns 1 – 4).

585 MAPA is used for the retrievals both in the UV and VIS. The differences in the slopes and correlation coefficients among the  
 different SFs are rather small, with the former dominated mainly by the noise in the measurements, as discussed in Sect. 4.  
 The results of SF1.0 (i.e., no scaling factor) show a similar performance with the SFvar indicating that the most suitable O<sub>4</sub>  
 SF value for Thessaloniki would be closer to unity. As for the AOD, the SF0.8 flags as invalid a larger fraction of the data  
 compared to the other SFs in all cases and the agreement between the MAX-DOAS and the reference instruments gets worse  
 590 with decreased correlation coefficients and larger offsets and slopes. Hence, the SF0.8 that is supported by many studies for

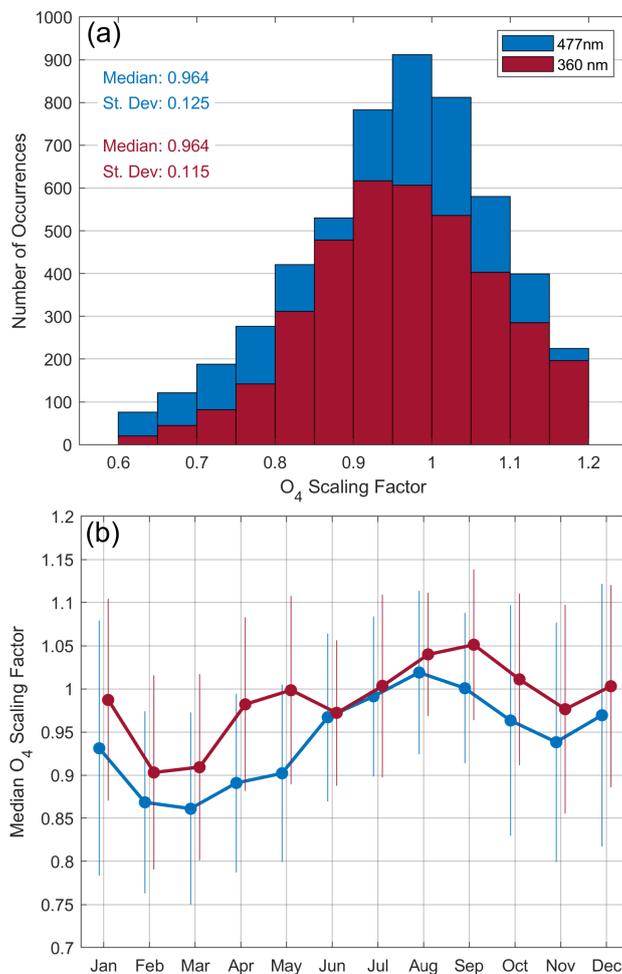

achieving better agreement between the MAX-DOAS and sun-photometers (Wagner et al., 2009) is found to be too small for the profiling of the MAX-DOAS measurements at Thessaloniki.

This is also supported by the frequency distribution of the fitted  $O_4$  SFs in the UV and VIS ranges, shown in Figure A3a. The median  $O_4$  SF fitted by MAPA is  $0.964 \pm 0.125$  and  $0.964 \pm 0.115$  at 477 and 360 nm, respectively. The histograms indicate that for most elevation sequences a scaling factor close to unity is required to bring measured and simulated  $O_4$  dSCDs into agreement. The SF<sub>0.8</sub> seems to be too low for the retrievals in Thessaloniki for both spectral ranges. However, it should be noted that an apparent seasonal pattern in the fitted  $O_4$  SF is observed both at 477 and 360 nm, shown in Figure A3b. In order to remove any possible effects of the seasonal variability of the SZA, only the  $O_4$  SFs for which  $65^\circ < SZA < 75^\circ$  are presented. The maximum  $O_4$  SFs values are reported in August ( $\sim 1.02$ ) at 477 nm and in September ( $\sim 1.05$ ) at 360 nm, while the minimum  $O_4$  SF values are found in February – March for both wavelengths (i.e.,  $\sim 0.86$  at 477 nm and  $\sim 0.91$  at 360 nm). This seasonal variability could partly be explained by the temperature dependence of the  $O_4$  absorption. Since the absorption is stronger at lower temperatures, higher  $O_4$  SFs are generally expected during summer than in winter. The seasonal pattern could also be related to the similar seasonal variability of the AOD. In general, higher AODs are observed over Thessaloniki in summer than in winter (Kazadzis et al., 2007; Giannakaki et al., 2010; Siomos et al., 2018; Fountoulakis et al., 2019). The  $O_4$  SFs for the two wavelengths show a similar, but not identical seasonality and thus, further investigation is required when more MAX-DOAS data become available.

*Author contributions.* DK developed the intercomparison and validation strategy of the two inversion algorithms, analyzed the MAX-DOAS data of Thessaloniki, performed the offline retrievals, conducted the data analysis and wrote the manuscript. MMF provided the MMF source code, supported and guided DK during the whole time for the proper use of the inversion algorithm and provided a lot of feedback for the interpretation of the OEM-based results. SB and TW provided the MAPA source code along with useful information about the retrievals and contributed to scientific discussions. KAV provided the lidar extinction profiles, IF and AK the Brewer-derived AOD and PT the in situ  $NO_2$  data. MVR, FH and DB reviewed the paper. AB supervised the whole study and provided general guidance for the manuscript preparation. All authors discussed, commented and helped reviewing the manuscript.

*Competing interests.* I declare that I or my co-authors have competing interests as follows: Steffen Beirle is associate editor of AMT. Michel Van Roozendaal is associate editor of AMT. Thomas Wagner is chief-executive editor and associate editor of AMT.
