Abstract. The need for highly accurate atmospheric wind observations is a high priority in the science community, particularly for numerical weather prediction (NWP). To address this need, this study leverages Aeolus wind LIDAR Level-2B data
15 provided by the European Space Agency (ESA) as a potential comparison standard to better characterize atmospheric motion vector (AMV) bias and uncertainty. AMV products from geostationary (GEO) and low Earth orbiting (LEO) satellites are compared with reprocessed Aeolus horizontal line-of-sight (HLOS) global winds observed in August-September 2019. Winds from two Aeolus observing modes are compared with AMVs: Rayleigh-clear (RAY) (derived from the molecular scattering signal) and Mie-cloudy (MIE) (derived from the particle scattering signal). Quality controlled (QC'd) Aeolus winds are
20 collocated with QC'd AMVs in space and time, and the AMVs are projected onto the Aeolus HLOS direction. Mean collocation differences (MCD) and the standard deviation (SD) of those differences (SDCD) are determined and analyzed.

As shown in other comparison studies, the level of agreement between AMV and Aeolus wind velocities (HLOSV) varies with the AMV type, geographic region, and height of the collocated winds, as well as with the Aeolus observing mode. In terms of global statistics, QC'd AMVs and QC'd Aeolus HLOSV are highly correlated for both observing modes. Aeolus MIE winds
25 are shown to have great potential value as a comparison standard to characterize AMVs, as MIE collocations generally exhibit smaller biases and uncertainties compared to RAY collocations. Aeolus RAY winds contribute a substantial fraction of the total SDCD in the presence of clouds where collocation/representativeness errors are also large. Stratified comparisons with Aeolus HLOSV are consistent with known AMV bias and uncertainty in the tropics, NH extratropics, the Arctic, and at mid-to upper-levels in clear and cloudy scenes. AMVs in the SH/Antarctic generally exhibit larger than expected MCD and SDCD

30 most probably due to larger AMV height assignment errors and collocation/representativeness errors in the presence of high
wind speeds and strong vertical wind shear, particularly for RAY comparisons.

1 Introduction

Improving atmospheric 3D wind observations in the troposphere has long been a high priority in the science community. In
2018, the National Academies Press published the 2017-2027 decadal survey for Earth science and applications from space
35 (National Academies, 2018) that included 3D winds in a series of observation requirement priorities and accompanying
recommendations. The survey found that radiometry-based atmospheric motion vector (AMV) tracking should be an important
approach to address the priority requirement of 3D winds.

AMVs are wind observations derived from tracking clouds and water vapor features in satellite images through time. Both
geostationary (GEO) and polar-orbiting, i.e., low Earth orbiting (LEO), satellites observe the motion of such features in several
40 spectral regions. Infrared bands that are specifically sensitive to water vapor (WV) absorption can capture different atmospheric
motions using the same channel by tracking (1) upper-level cloud-tops, and (2) water vapor motions in clear air related to
upper-tropospheric features (including the jet stream and atmospheric waves) (Velden et al., 1997). Window channel Infrared
(hereafter IR) cloud-tracked AMVs are based on longwave and shortwave channels that are useful for detecting motions in
cloudy scenes at mid- to upper-levels related to, e.g., cirrus clouds, and at lower levels related to, e.g., low stratus clouds and
45 fog, respectively (Velden et al., 2005). AMVs are regularly assimilated in numerical weather prediction (NWP), and they have
been shown to positively impact operational forecast skill (e.g., Le Marshall et al., 2008; Berger et al., 2011; Wu et al., 2014).
Since NWP data assimilation (DA) methods assume knowledge of observational error statistics, any improved characterization
of AMV observation errors has the potential to improve NWP DA and hence forecast skill.

Aeolus is a novel polar-orbiting satellite that was launched in 2018 by the European Space Agency (ESA) to observe vertical
50 wind profiles from space (Stoffelen et al., 2005; ESA, 2008; Straume-Lindner, 2018). Onboard Aeolus is a Doppler Wind
Lidar (DWL) instrument (Reitebuch et al., 2009) which observes winds along the line-of-sight (LOS) of the DWL laser
detected by precision timing of the backscattered signal. Rayleigh and Mie receivers detect molecular backscattering and
aerosol and cloud backscattering, respectively (Straume et al., 2018) and are converted into horizontal LOS (HLOS) wind
velocities (HLOS_V). Rayleigh and Mie receivers observe both clear and cloudy scenes; hence, the resultant wind retrievals
55 fall into one of four possible observing modes: Rayleigh-clear, Rayleigh-cloudy, Mie-clear, and Mie-cloudy. Rayleigh-clear
and Mie-cloudy winds are of better quality and are recommended for use in analysis based on NWP assessments by ESA and
ECMWF (Rennie and Isaksen, 2019; Rennie et al., 2020). Rayleigh-cloudy winds are not typically used as they sample the
same locations as Mie-cloudy winds and are generally contaminated by the Mie channel. Mie-clear winds are routinely
discarded as they are of poorer quality since the Mie backscattered signal is dominated by noise in clear conditions (Rennie et
60 al., 2020; Abdalla et al., 2020).

This study aims to leverage Aeolus Level-2B (L2B) HLOS wind profiles as a potential comparison standard to characterize AMV observation bias and uncertainty. The availability of the consistent, global Aeolus dataset provides the unique opportunity to assess the performance of AMVs relative to a global reference wind profile dataset observed by a single unit. Such a direct global comparison has not previously been possible due to the limited spatial coverage of other available reference datasets, e.g., rawinsonde winds, which are mostly available in the Northern Hemisphere over land (e.g., Chen et al., 2021; Liu et al., 2021; Martin et al., 2021). Further, Aeolus observations are made at a set of fixed vertical levels that represent the averages of accumulated measurements within vertical range bins. The thickness of these range bins increases with height to mitigate the decrease in signal strength with height (Rennie and Isaksen, 2020a). As such, height-related HLOS wind errors should be small relative to errors in AMV height assignment.

The structure of the paper is as follows: Section 2 describes the datasets used. Section 3 defines the quality controls, collocation methodology, and skill metrics. Section 4 compares AMVs with collocated Aeolus RAY and MIE wind observations and discusses the resulting characterization of AMVs in terms of mean collocation difference (MCD) and the standard deviation (SD) of collocation differences (SDCD) based on different sets of conditions. AMV performance metrics specific to GOES-16 and the suite of available LEO satellites are described in more detail. Section 5 summarizes the findings.

2 Data

2.1 Aeolus Level-2B winds

Aeolus Level-2B wind profiles (de Kloe, 2019; de Kloe et al., 2020) used in this study are derived from retrievals from the satellite's backup laser, known as Flight Model-B (FM-B), that was switched on in 2019. The L2B wind product consists of geo-located vector wind profiles projected along the HLOS of the FM-B laser, which points away from the sun (i.e., perpendicular to the spacecraft track) at 35° off nadir. Aeolus observations are collected as a line of profiles to the right of the satellite track. Because of the terminator orbit and sensor geometry away from the poles, winds in ascending orbits (southeast to northwest ground track) are observed around sunset (local equator crossing time (LT) is 18:00 LT), and winds in descending orbits (northeast to southwest ground track) are observed around sunrise (local equator crossing time is 06:00 LT). The satellite completes one orbit around Earth in approximately 92 minutes and has a 7 day repeat cycle.

This study uses Aeolus wind profiles (baseline B10 product) during the period of 2 August – 16 September 2019, with 12 hours of 3 September omitted to account for the corresponding Aeolus blocklisted¹ period (defined as a period of time when the Aeolus dataset is known to be degraded and should not be included in research or operations). The selected period of study was recommended by ESA for analysis as the Aeolus data are more stable and biases are relatively small (Rennie and Isaksen,

¹ The meaning of the term “blocklist” is identical to the term “blacklist”; however, “blacklist” has racist connotations (Conger, 2021). The term “blocklist” is intentionally used in an effort to support the usage of more neutral computing terminology in scientific research; in fact, the Aeolus project has already adopted this new terminology and refers to the list of dates when Aeolus data should be excluded as “blocklisted” dates.

2019; Rennie and Isaksen, 2020a). In this study, profiles of Aeolus Rayleigh-clear HLOS winds (hereafter RAY winds) and
90 Mie-cloudy HLOS winds (hereafter MIE winds) are collocated with AMVs. The AMVs projected onto the collocated Aeolus
HLOS will be referred to as AMV winds and the original AMVs will be referred to as AMV wind vectors hereafter. Data from
the other observing modes (Rayleigh-cloudy and Mie-clear) are of poorer quality and quantity and are not used.

The Aeolus winds were reprocessed by ESA using the updated L2B processor v3.3 that includes the M1 mirror temperature
bias correction that was activated on 20 April 2020 (Rennie and Isaksen, 2020a). The M1 mirror temperatures are scene-
95 dependent and vary based on the top-of-atmosphere radiation. Since the M1 mirror reflects and focuses the backscattered laser
signal onto the Rayleigh and Mie receivers, changes in the mirror shape due to thermal variations result in perceived frequency
shifts of the signal. The operational M1 bias correction uses instrument temperatures as predictors and innovation departures
from ECMWF backgrounds as a reference, and is shown to improve the quality of the Rayleigh and Mie wind retrievals,
reducing the Aeolus HLOS wind bias relative to ECMWF background winds by over 80%: the global average Rayleigh-clear
100 bias decreased to near-zero and the Mie bias decreased to -0.15 m s^{-1} (Abdalla et al., 2020). While the M1 bias correction is
capable of considerably reducing the telescope-induced wind bias, some residual bias may remain, e.g., in cases where the top-
of-atmosphere reflected radiation strongly influences the telescope temperature (Weiler et al., 2021). Additionally, residual
biases may remain in part due to potential calibration issues of the Aeolus L2B winds that could in turn lead to biases between
Aeolus and NWP background winds (Liu et al., 2022).

105 Recent studies have compared Aeolus winds with various reference wind datasets for validation (e.g., rawinsondes and NWP
forecasts). For example, Martin et al. (2021) validated Aeolus HLOS winds against rawinsonde and NWP forecast equivalents
for 2018-2019. They found that the estimates of global mean absolute biases and standard deviations of Aeolus based on
comparisons with rawinsonde, the ECMWF Integrated Forecasting System (IFS), and the German Weather Service (DWD)
forecast model reference datasets are all comparable, with bias magnitudes ranging from 1.8 to 2.3 m s^{-1} for Rayleigh and 1.3
110 to 1.9 m s^{-1} for Mie and standard deviations ranging from 4.1 to 4.4 m s^{-1} for Rayleigh and 1.9 to 3.0 m s^{-1} for Mie. In addition,
the biases vary with latitude and season in a similar way from reference dataset to reference dataset, with the largest differences
observed in the tropics and extratropics, particularly during the summer/autumn season. Similarly, Straume et al. (2020) quality
assessments showed good correspondence between Aeolus L2B winds and ECMWF model winds for September 2018. Even
though Aeolus exhibited random errors that exceeded the mission requirements (4.3 m s^{-1} for Rayleigh) or just met the
115 requirements (2.1 m s^{-1} for Mie), the Aeolus winds still had a positive impact on preliminary NWP experiments. (It should be
noted that the results from Martin et al. (2021) and Straume et al. (2020) characterize Aeolus winds before they were
reprocessed with the significant M1 wind bias correction applied. The Aeolus bias and error estimates should improve when
using the reprocessed winds.) In addition, ECMWF conducted several studies to verify the quality of Aeolus observations
(e.g., Rennie and Isaksen, 2019; de Kloe et al., 2020). They found that Aeolus provides high quality wind observations relative
120 to ECMWF backgrounds after applying the M1 bias correction and proper quality controls (QC) (see Section 3) as well as
accounting for Aeolus blocklisted dates. RAY winds minus ECMWF IFS HLOS winds have a global mean of -0.04 m s^{-1} and

a standard deviation of 5.3 m s^{-1} . MIE minus IFS winds have a global mean of -0.16 m s^{-1} and a smaller standard deviation of 3.8 m s^{-1} (Abdalla et al., 2020). Related NWP impact assessments show that Aeolus has a positive impact on operational global forecasts (Cress, 2020; Rennie and Isaksen, 2020b) at major NWP centers including ECMWF, the DWD, Météo-France, and the UK Met Office. It is noted that the ECMWF IFS is used as a reference in the calculation of the reprocessed Aeolus L2B winds (where the M1 bias correction is retroactively applied), and thus a model dependency is introduced into the dataset (Weiler et al., 2021).

Despite the high quality and positive impacts, limitations remain with the Aeolus L2B dataset (Abdalla et al., 2020; Weiler et al., 2021). Mie and Rayleigh random errors could be further improved, as the Mie error standard deviations average to approximately 3.5 m s^{-1} and Rayleigh error standard deviations increase from 4 m s^{-1} to over 5 m s^{-1} from July to December 2019 (Abdalla et al., 2020). Further, MIE winds exhibit a slow (fast) wind speed dependent bias for high HLOS speeds of negative (positive) sign. Additionally, at the time of writing, issues thought to be due to instrumentation or software malfunctions have become apparent that affect the quality of the winds. One specific issue is a more rapid decrease in the atmospheric return signal relative to the laser energy itself, and this is linked to slowly increasing random errors for Rayleigh-clear winds (Straume et al., 2021). Efforts at ESA are currently underway to resolve these issues.

2.2 Atmospheric motion vectors

AMVs examined in this study (Tables 1-2) are operationally used by the National Oceanic and Atmospheric Administration (NOAA) National Centers for Environmental Prediction (NCEP) and are archived in 6-hour satellite wind (SATWIND) BUFR files centered on the analysis times 00, 06, 12, and 18 UTC. All AMVs included in the SATWIND files are produced by NESDIS, JMA and EUMETSAT. AMVs derived from sequences of GEO satellite images are observed equatorward of $\sim 60^\circ$ latitude and are stratified by type, including IR, water vapor cloudy (WVcloud), and water vapor clear (WVclear) AMVs; visible band AMVs are not used in this study. Polar AMVs (observed at latitudes poleward of 60°) are derived from cloud-tracked IR channels in areas covered by three consecutive LEO satellite images.

Table 1: Collocation counts for each type of GEO AMV. The table lists total counts (RAY + MIE) and counts of collocated AMVs (% of total in parentheses) with forecast-independent $QI > 80\%$ that pass RAY QC and MIE QC.

Satellite	Operator	Sensor	Total Collocation Counts			Counts (%) Passing RAY QC			Counts (%) Passing MIE QC

- 150 Numerous studies have evaluated bias and uncertainty characteristics of AMVs through direct comparison with *in situ* rawinsonde observations and NWP analyses (e.g., Velden et al., 1997; Bormann et al., 2002, 2003; Le Marshall et al., 2008; Bedka et al., 2009; Velden and Bedka, 2009; Key et al., 2016; Daniels et al., 2018; Cotton et al., 2020). The derived motion wind algorithms that generate IR, WVcloud, and WVClear AMVs can vary between centers (Santek et al., 2014; Santek et al., 2019). AMV performance metrics vary significantly by season, level, type, satellite/producer, etc. (e.g., Santek et al., 2019; Daniels et al., 2018; Cotton et al., 2020; Key et al., 2016; Le Marshall et al., 2008). For example, typical values of AMV wind speed bias acquired from seven different data producers and verified against rawinsonde winds can range from -1.8 m s^{-1} to 0.3 m s^{-1} , and wind speed uncertainty represented by standard deviation can range from 4 to 6.5 m s^{-1} , with higher vector wind root mean square errors of $6\text{-}9 \text{ m s}^{-1}$. Even for a single satellite, e.g., GOES-16 or Aqua, speed bias and uncertainty can vary geographically as well as vertically.
- 160 In fact, AMVs have state-dependent errors that can vary based on wind speed and water vapor content and gradient (Posselt et al., 2019). Past reports show that AMVs tend to exhibit a slow speed bias ($1\text{-}5 \text{ m s}^{-1}$) at high levels (above 400 hPa) in the extratropics and a fast speed bias ($1\text{-}3 \text{ m s}^{-1}$) at middle levels (400-700 hPa) in the tropics (Bormann et al., 2002; Schmetz et al., 1993; von Bremen, 2008). Recent improvements to AMV derivation schemes, e.g., in GOES-16/17 and Himawari-8, have reduced the fast speed bias, with the residual bias largely attributed to height assignment errors (Cotton et al., 2020). Height assignments to the AMVs via satellite- and ground-based techniques (Jung et al., 2010; Salonon et al., 2015) have been shown to account for a large source of AMV uncertainty (Velden and Bedka, 2009). One factor of height assignment error is that AMVs are generally assigned to discrete levels when instead they better correlate with atmospheric motions in layers of varying depth that depend on the vertical moisture profile (Velden et al., 2005; Velden and Bedka, 2009). Moreover, speed biases and
- 165

uncertainties tend to be higher at higher elevations and in combination with strong wind shear (Bormann et al., 2002; Cordoba et al., 2017), and this is attributable to larger height assignment errors (hereafter the wind-shear height assignment error effect).

3 Approach and quality controls

Aeolus HLOS global wind profiles are collocated with satellite-derived AMVs. The collocation approach implemented here was also used by Hoffman et al. (2022) and follows that employed at UW-Madison/Cooperative Institute for Meteorological Satellite Studies (CIMSS) (Santek et al., 2021). AMV collocation datasets are prepared separately for RAY and MIE winds. (A single AMV might appear in both datasets.) AMV observations are compared with Aeolus observations from the same and neighboring 6-h cycles to account for all possible collocations. An Aeolus observation is retained for comparison with an AMV if the Aeolus observation satisfies *all* the following collocation criteria:

1. Aeolus time falls within 60 minutes of the AMV time.
2. Aeolus pressure is within $0.04 \log_{10}(\text{pressure})$ of the AMV height assignment. (Note that the log of pressures is used to account for the non-linear decrease of pressure with increasing altitude.)
3. Aeolus observation location is within 100 km horizontal great circle distance of the AMV location.

If multiple Aeolus observations satisfy these criteria for the same AMV observation, the Aeolus observation closest in distance is retained. Then, if multiple Aeolus observations still meet all collocation criteria, the observation closest in pressure to the AMV observation is kept for analysis. There is no need to consider closeness in time given the collocation criteria and the Aeolus orbit. After collocation, the AMV wind vector is projected onto the HLOS direction of its paired Aeolus observation.

Our choice of collocation criteria is conservative compared to those defined by the IWWG 1998 workshop (Velden and Holmlund 1998). Although the larger time and distance criteria defined by IWWG (90 vs 60 minutes and 150 vs 100 km) might retain more collocation pairs and thus a larger sample, the collocated winds would more likely have larger MCD and SDCD. Our smaller time and distance criteria restrict the number of possible Aeolus matches to any one AMV and help avoid Aeolus matches from two different orbits. The IWWG height criterion is a fixed pressure difference (25 hPa) that might be too small at lower levels where pressure layers are tightly spaced in elevation but too large in the upper atmosphere where the elevation distance between pressure layers is much larger. Our height criterion is based on a \log_{10} scale and accounts for the varying distances between pressure layers throughout the vertical and corresponds to pressure differences ranging from approximately 300 to 1 hPa for pressures from 1000 to 10 hPa, respectively.

Once collocated, Aeolus winds and AMVs are filtered by additional QC tests to retain pairs of QC'd observations. (QC was implemented after collocation in order to test and compare the use of different QC criteria without having to repeat the collocation process.) Aeolus QC criteria were chosen following ESA's recommendations for the RAY and MIE observing modes, and these are consistent with those listed in Rennie and Isaksen (2020a). Specifically, RAY winds are rejected if winds

are close to topography (pressure > 800 hPa), have horizontal accumulation lengths < 60 km, vertical accumulation lengths < 0.3 km, L2B uncertainty > 12 m s⁻¹ at upper levels (pressure < 200 hPa), or L2B uncertainty > 8.5 m s⁻¹ at lower levels (pressure > 200 hPa). L2B uncertainty refers to the Aeolus HLOS wind error estimate assigned to each wind measurement. Horizontal and vertical accumulation lengths refer to the horizontal and vertical distances over which individual measurement signals are accumulated and averaged to improve the signal-to-noise ratio. In this way, the Aeolus observations represent wind volumes and not discrete points or levels. The accumulation lengths can vary and depend on the processor settings. Similarly, MIE winds are rejected if winds are near topography (pressure > 800 hPa) or L2B uncertainty > 5 m s⁻¹ at any level. For all AMVs, a forecast-independent quality indicator (QI) of at least 80% is used to filter and retain the high-quality data; this threshold is recommended for AMV studies and in NWP by the user community and has been shown to improve statistical agreement between AMV-producing centers (Santek et al., 2019). No explicit outlier QC is applied and since there are no extreme outliers (seen below in Figs. 6 and 9), the QC that is applied is sufficient to eliminate them. Total collocation counts per satellite as well as the percentage of observations that pass QC for each AMV type and Aeolus mode are presented in Tables 1-2. (It is noted that Himawari-8 and INSAT 3D WVclear AMVs are not included in the NCEP data archive.)

The performance of QC'd AMVs relative to collocated QC'd Aeolus winds are characterized by analyzing the statistics of the difference AMV HLOS minus Aeolus HLOS. The two key statistics calculated for the collocation difference (always in the sense of AMV minus Aeolus) are the MCD and the SDCD. Because we are comparing the AMV and Aeolus HLOS, a scalar quantity, our statistics can only be analogs of the standard one. We include the formulae for all the statistics in Appendix A. It is important to emphasize that the collocation differences have several components that include errors in both AMVs and Aeolus winds. Specifically, these are due to the observation error of the AMVs and Aeolus HLOS, representativeness errors due to differences in scales observed, which are related to different shapes of the observing volumes, and to collocation errors due to the space and time mismatches between the observations. As previously mentioned, the estimated SD for Aeolus L2B winds is 3.8 m s⁻¹ for MIE and 5.3 m s⁻¹ for RAY. We note that it might be possible to estimate the statistics of the collocation and representativeness errors. The collocation difference may be considered to have three independent components: the error of the AMV winds, the error of the Aeolus winds, and the difference between the truth evaluated for the AMV and the Aeolus winds. We can isolate the first component, the AMV error, if we know the other two components, and we already have estimates of the second component, the Aeolus wind error in the L2B data. The last component is the error due to representativeness and collocation differences. The differences in time and location give rise to the collocation error. The difference in the shapes of the observing volumes gives rise to the representativeness error. If we simulate the AMV and Aeolus observations from a high-quality forecast or analysis or simulation, taken to be the truth, then we can calculate estimates of the combined representativeness and collocation errors. If the truth fields are simply interpolated to the observation locations then the calculated estimates are for the collocation errors alone. For this study we take the first step in isolating the collocation/representativeness errors by removing the influence of the Aeolus error from the SDCD, as the simulation of the AMV and Aeolus observations is out of the scope of this study. The removal of the Aeolus error estimate results in a smaller

SDCD, which still includes AMV random and representativeness errors and collocation error. The SDCD are larger for RAY comparisons than for MIE comparisons in terms of both the original (or total) and adjusted values. Although the Aeolus L2B uncertainty is highly dependent on the time period and processor used to determine the HLOS winds, it is the correct uncertainty estimate for our study.

The geometry of the Aeolus observation affects how the HLOS winds are interpreted for analysis (Straume et al., 2018). The observed HLOS wind provides both a speed and direction and represents the motion of air projected onto the line-of-sight of the laser that in 2D space is nearly orthogonal to the satellite orbit direction (see Fig. 1 in de Kloe, 2019). Thus, in the ascending orbit phase away from the poles, a positive HLOS wind indicates a westerly wind, and a negative HLOS wind indicates an easterly wind; the opposite is true for winds in the descending orbit phase. Figure 1 illustrates that in the tropics the HLOS wind is approximately equal to the zonal wind in ascending and descending orbit phases. In the left column of Fig. 1, profiles of mean HLOS wind for AMVs (solid lines) and Aeolus (long dashed lines) as well as mean AMV wind speed not projected onto the HLOS direction (short dashed lines) are shown. In the center column of Fig. 1, HLOS wind MCD (solid lines) and total SDCD (short dashed lines) are plotted as well as the adjusted SDCD with the mean Aeolus L2B uncertainty removed (long dashed lines).

Open circles indicate pressure levels at which MCD are statistically significant at the 95% level (p -value < 0.05) using the

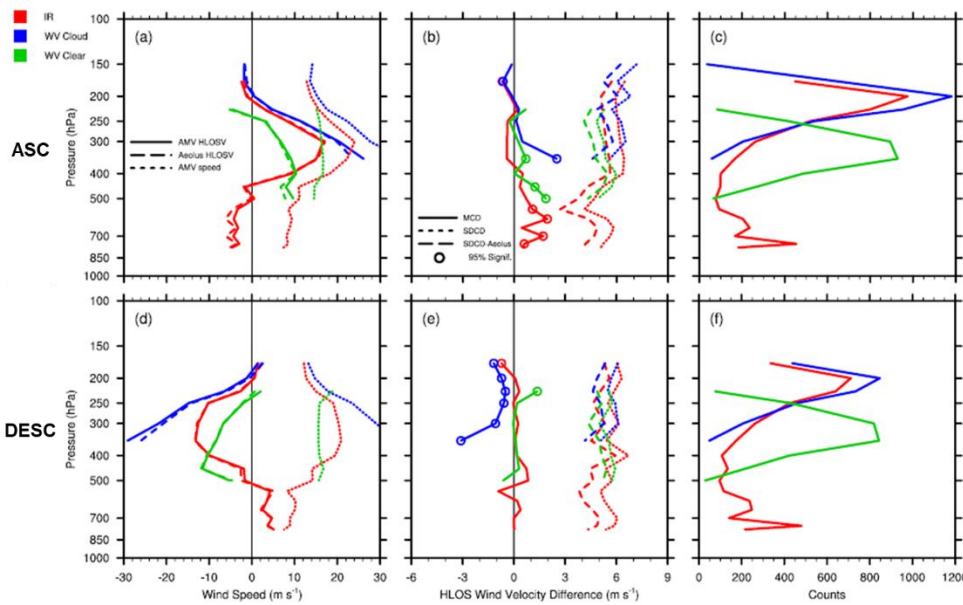

Figure 1: Vertical comparisons of collocated GOES-16 AMVs and RAY winds in the tropics (30° S to 30° N). The top row shows Aeolus ascending orbits (ASC), (a) mean AMV (solid lines) and RAY (dashed lines) winds (m s^{-1}), (b) MCD (solid), SDCD (short dashed), and AMV HLOS error as represented by SDCD-Aeolus L2B uncertainty (long dashed) (m s^{-1}); and (c) collocation counts. (d-f) as in (a-c) but for Aeolus descending orbits (DESC). Colors denote AMV type: IR (red), WV cloud (blue), and WV clear (green). Colored open circles indicate levels where MCD are statistically significant at the 95% level (p -value < 0.05) using the paired Student's t -test. Vertical zero lines are displayed in the left and center panels in black. Levels with observation counts > 25 are plotted.

paired two-sided Student's t -test. Corresponding collocation counts are shown in the right column of Fig. 1. The mean AMV and Aeolus HLOS wind and their differences exhibit similar magnitudes of opposite sign throughout the vertical between ascending (Fig. 1a-b) and descending (Fig. 1d-e) orbit phases. This indicates that mean HLOS wind differences that include winds from both ascending and descending orbit phases would be small and would represent differences of larger opposing magnitudes. Moreover, the removal of Aeolus L2B uncertainties from

265 the total SDCD results in adjusted SDCD of similar magnitude between the orbit phases, implying that the quality of Aeolus
winds is not wholly dependent on orbit phase during the study period. To simplify the interpretation of the observed HLOS
winds, we multiply HLOSV in descending orbit phases by -1. In doing so, positive HLOSV (away from the poles) now
indicates a westerly wind and negative HLOSV an easterly wind, regardless of Aeolus orbit phase. All statistics in what
follows, including Figs. 2, 3, and 5-14, are based on collocation differences that combine ascending and -1 times descending
270 orbit phase winds.

4 AMV-Aeolus comparison results

In this section we examine in detail the performance of AMVs from the GOES-16 GEO satellite and summarize the AMV
performance of all LEO satellites available in the study period. Here, the reader should keep in mind that performance is
relative to Aeolus and for the vector AMV projected onto the Aeolus HLOS. In agreement with previous studies, our results
275 confirm that the level of agreement between AMVs and Aeolus winds varies per combination of conditions including the
observing scene type (clear vs. cloudy) coupled with AMV type, geographic region, and height of the observable. Moreover,
the findings highlight the value of using Aeolus MIE winds as a comparison standard to characterize AMVs. For context, we
begin with summary statistics for samples that include all conditions.

Figure 2 summarizes the performance of all available GEO AMV HLOS winds relative to Aeolus RAY (left column) and MIE
280 winds (right column) in the period of study; likewise, Fig. 3 summarizes LEO AMV performance. The statistics include
correlation (r), MCD, and SDCD, and their formulae are listed in Appendix A. The correlation between collocated HLOS
winds describes the overall relation of AMVs to Aeolus. The other statistics have their usual meaning (Wilks, 2011) applied
to the HLOSV. Since the MCD are small compared to the SDCD, the RMSD and SDCD are very similar and in the following
we will only discuss the SDCD, but any statement concerning the SDCD also applies to the RMSD. Using the paired two-
285 tailed Student's t -test, mean differences significantly different from zero at the 90% (p-value < 0.10) and 95% (p-value < 0.05)
confidence levels are indicated in Figs. 2-3 by striped and solid bars, respectively, and dotted bars indicate the differences are
not statistically significant. Observation counts are displayed by grey-blue shading. Direct comparisons between our statistics
and those from previous studies are limited because all our statistics are HLOSV, not vector winds. Although we compare
mean AMV-Aeolus collocation differences with speed statistics, recall that in general, the HLOS wind generally approximates
290 the zonal component of the horizontal flow rather than the wind speed.

The main points from the summary collocation statistics of RAY and MIE winds with AMVs are the following: MIE
comparisons exhibit higher correlations and lower SDCD values relative to RAY, reflecting the general higher accuracy of
MIE vs. RAY winds. In Fig. 2, GOES and Himawari-8 AMVs have high correlations with Aeolus (> 0.90). MCD vary
depending on the AMV satellite, but are generally smallest in the tropics and largest in the SH extratropics where the SDCD
are larger. For RAY comparisons with GOES and Himawari-8 AMVs, the SDCD range from 5.27 m s⁻¹ in the NH extratropics
295 to 6.5 m s⁻¹ in the SH extratropics and are comparable to wind speed RMSD relative to rawinsonde winds (Santek et al., 2019).

Of the satellites listed in Fig. 2, Meteosat wind correlations are lowest and corresponding SDCD values are highest by at least 2-3 m s^{-1} . LEO AMV-Aeolus collocations in Fig. 3 exhibit statistically significant MCD that are comparable to observed wind speed biases for Aqua and Terra AMVs (Key et al., 2016; Le Marshall et al., 2008). AMVs from most LEO satellites exhibit higher SDCD values by $\sim 1\text{-}2 \text{ m s}^{-1}$ relative to GEO, particularly in the Antarctic where SDCD values are on the order of 7.5-8.5 m s^{-1} for RAY and 5.9-7.5 m s^{-1} for MIE.

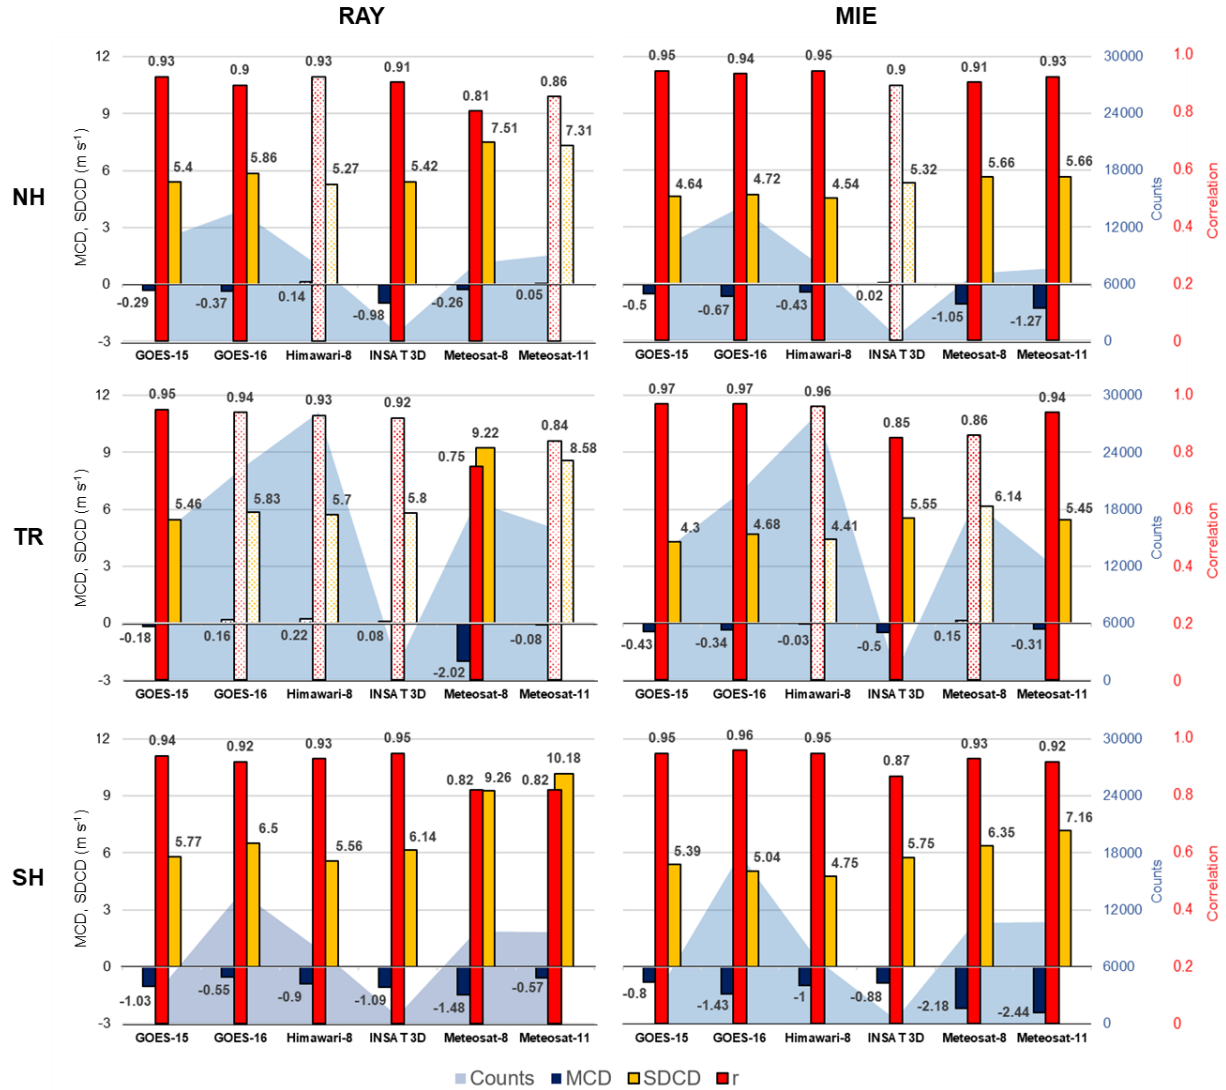

Figure 2: AMV-Aeolus global mean statistics in the (top row) NH, (middle row) tropics (TR), and (bottom row) SH for GEO satellites that include correlation (r) in red, mean collocation difference (MCD) between the HLOS winds (AMV-Aeolus) in navy blue, standard deviation of the collocation difference (SDCD) in yellow, and collocation counts as light blue shaded areas. Solid colors denote 95% statistical significance, stripes denote 90% statistical significance, and dots indicate the differences are not statistically significant.

Differences in the SH extratropics and Antarctic pole exhibit higher SDCD values compared with the rest of the globe. This is likely due to several factors. During the study period, the SH region of GEO fields-of-view covers a portion of the winter storm tracks that propagate eastward all the way around the Southern Ocean. The SH storm tracks exist year-round, and in winter (June-July-August) the upper-tropospheric subtropical jet is stronger and acts as a waveguide for eastward propagating baroclinic waves over a broader latitude range (Trenberth, 1991; Nakamura and Shimpo, 2004; Hoskins and Hodges, 2005), thus amplifying wind shear and storm track intensity. This is one factor that explains the higher SDCD values observed in GEO differences in the SH extratropics, as AMV uncertainties tend to increase with increasing wind speed (Posselt et al., 2019) and high wind shear (Bormann et al., 2002; Cordoba et al., 2017). In the Antarctic polar region, the general strengthening of the polar vortex aloft in late winter/early spring (i.e., during the study period) is related to a stronger equator-pole temperature gradient brought about by gradually increasing subtropical lower stratospheric temperatures from March to September (Zuev and Savelieva, 2019). A stronger Antarctic polar vortex is associated with stronger zonal winds aloft (and stronger shear) which could increase the corresponding SDCD values for AMVs due to the wind-shear height assignment error effect. Surface effects may also play a role, as very cold brightness temperatures at or near the polar surface may be misinterpreted as cloud tops due to the low temperature contrast between clouds and the surface snow or ice (Key et al., 2016).

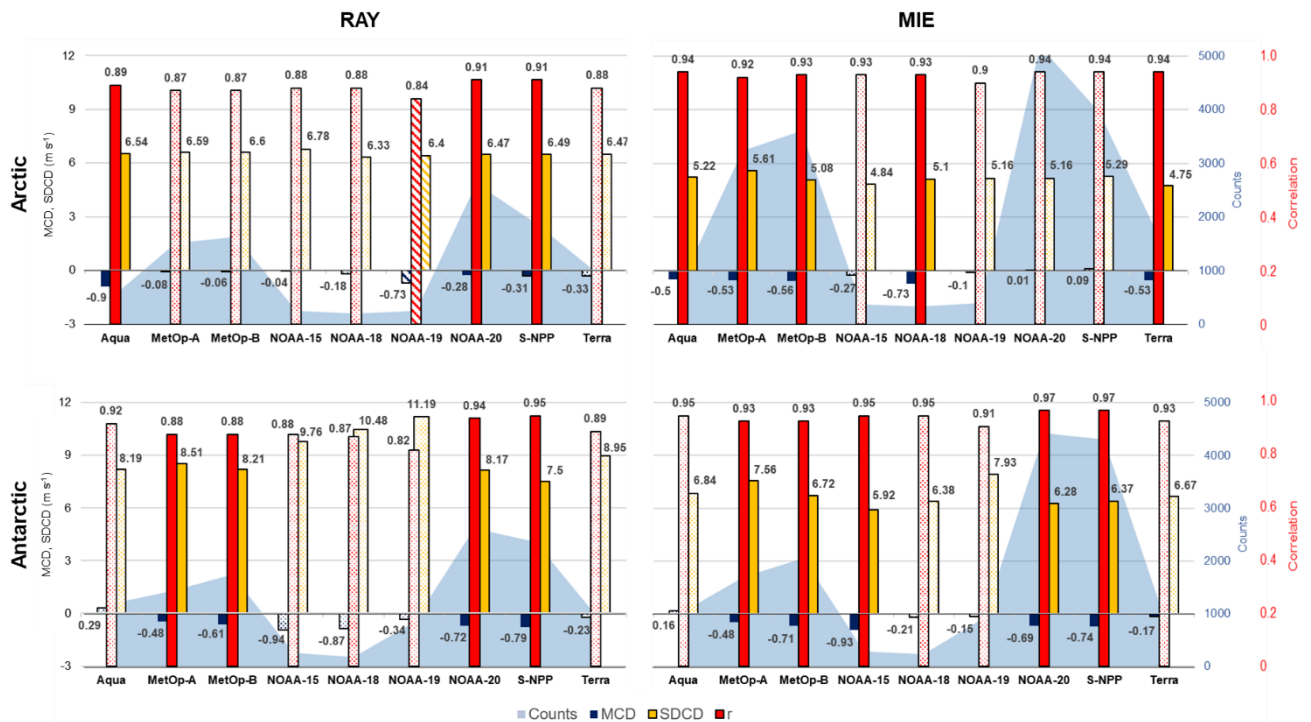

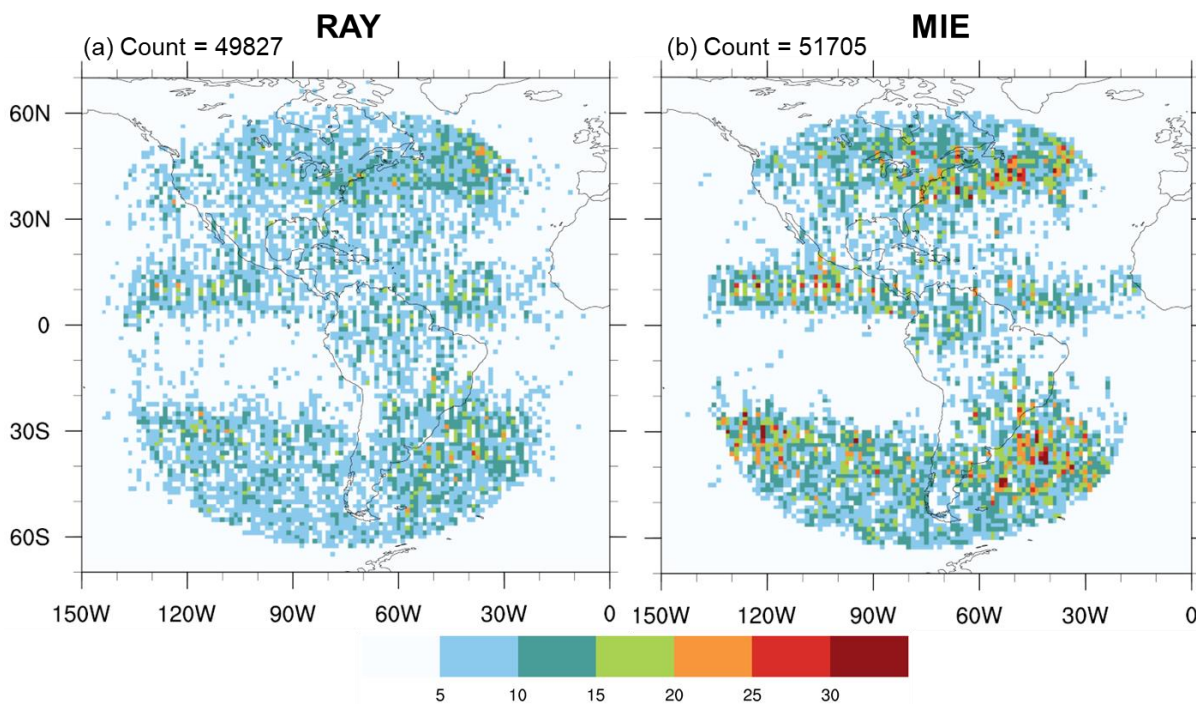

Figure 3: As in Fig. 2 but for LEO satellites.

As a case study, we examine in greater detail the performance of AMVs from GOES-16, a GEO satellite (Section 4.1). This is done because compared with other GEO satellites, GOES-16 exhibits high correlations with Aeolus RAY (> 0.90) and MIE

winds (> 0.94), relatively small SDCD ($5.8\text{-}6.5\text{ m s}^{-1}$ for RAY, $4.7\text{-}5\text{ m s}^{-1}$ for MIE), and have the largest extratropical sample size from which to compute robust statistics (see Fig. 2). The other GEO satellites are not further examined as they exhibit larger RAY SDCD (Meteosat-8 and -11), have a much smaller extratropical sample size (Himawari-8, Meteosat-8 and -11), or are not actively used in NCEP operations (GOES-15 and INSAT 3D). GOES-16 AMVs are derived from full disk images centered at 75.2° W longitude from the onboard Advanced Baseline Imager (ABI). GOES-16 cloud-top AMVs are generally of good quality and when validated against rawinsonde winds exhibit a relatively small mean difference in wind speed ranging from -1.0 m s^{-1} to $+0.5\text{ m s}^{-1}$ and mean vector differences of $3\text{-}6\text{ m s}^{-1}$ that tend to increase with height (Daniels et al., 2018). Figure 4 presents the GOES-16/Aeolus collocation number densities (i.e., the total number of collocated observation pairs within each grid cell on a 1.25° ($\sim 140\text{ km}$) resolution map) covering the period of study. QC'd GOES-16 AMVs collocated with QC'd RAY and MIE winds are shown in Fig. 4a and Fig. 4b, respectively. MIE collocations exhibit three bands of high-density winds along the intertropical convergence zone (ITCZ) and extratropical storm tracks, with few winds found between $0\text{-}30^\circ\text{ S}$. A similar but smoother version of the MIE distributions is shown for collocated RAY winds. The MIE collocation number density is greater than that for RAY, as AMV observation density tends to be higher in very cloudy or very moist scenes (Velden et al., 1997).

340

Figure 4: Number densities of quality-controlled GOES-16 AMV observations collocated with quality-controlled Aeolus (a) Rayleigh-clear (RAY), and (b) Mie-cloudy (MIE) HLOS winds. Colors indicate total number of collocated observation pairs within a grid cell at 1.25° (approximately 140 km in the N-S direction) horizontal resolution. Total observation count per panel is displayed at the top left corner. This and all subsequent plots are for all collocations with quality controlled AMV and Aeolus winds during the study period (2 August 2019 to 16 September 2019).

345

For the LEO perspective, we choose to examine the performance of all LEO IR AMVs rather than from a single satellite (Section 4.2). This is done because compared to GEO, LEO AMVs from each satellite comprise a relatively small sample of collocated winds, and this would render any associated performance metrics unreliable. Further, unlike the suite of available

Figure 5: Number densities of IR-derived AMVs from all available LEO satellites collocated with Aeolus RAY (left, a, c) and MIE (right, b, d) winds in the (a, b) Arctic (north of 60° N), and (c, d) Antarctic (south of 60° S). Colors indicate total number of collocated observation pairs within a grid cell at 1.25° (approximately 140 km in the N-S direction) horizontal resolution. Dashed latitude lines are spaced every 5 degrees. Total observation count per panel is displayed at the top left corner.

GEO satellites where each observe a different region of the globe (except for small areas where the footprints of neighboring satellites overlap), each LEO satellite observes AMVs in the same polar regions and thus samples the same atmospheric motions. Figure 5 depicts observation number densities of QC'd LEO AMVs collocated with QC'd RAY and MIE winds in the Arctic and Antarctic polar regions bounded by 60° latitude: Arctic RAY (Fig. 5a), Arctic MIE (Fig. 5b), Antarctic RAY (Fig. 5c), and Antarctic MIE (Fig. 5d). In general, more LEO/MIE collocation pairs pass QC and are retained in the analysis than for RAY winds. Collocations in the Arctic are found across the high latitudes with MIE comparisons exhibiting higher concentrations poleward of Eurasia and North America. Antarctic collocations are primarily found over the western half of the continent. In this region, water vapor features are more suitable for tracking and deriving AMVs as they exist downstream of intense upper-level storm tracks (Hoskins and Hodges, 2005) in an area of higher annual precipitation (Grieger et al., 2016).

375 4.1 GOES-16 AMVs vs. Aeolus

To increase the size of our collocation data set, we compared all types of GOES-16 AMVs to both Rayleigh-clear and Mie-cloudy winds. In addition, we do not show results from WVclear AMV collocations with Mie-cloudy winds as correlations for this category of collocations are poor and the sample size is very small (see Table 1), and this result may be unreliable. With

a larger data set it might be possible to compare Rayleigh-clear and Mie-cloudy winds to clear and cloudy AMVs only, respectively. Additionally, winds retrieved from tracking clear-sky and cloud motions represent different dynamical features and tend to behave differently. For example, the recommended time interval for tracking cloud motions is 10-15 minutes to capture short cloud lifetimes and rapid intensification/deformation, while the recommended time interval for clear-air motions of 30 minutes is suitable to capture variations in jet streams and other clear-air features (Schmetz et al., 2000).

4.1.1 Rayleigh-clear (RAY) comparisons

Figure 6 depicts density scatterplots that summarize the relationship of GOES-16 AMVs to RAY winds to highlight the regional differences in IR (Fig. 6a, 6d, 6g), WVcloud (Fig. 6b, 6e, 6h), and WVclear AMVs (Fig. 6c, 6f, 6i). Sample statistics are based on Aeolus as the reference dataset and are displayed in the lower right of each panel. AMVs are highly correlated with RAY winds (0.88-0.91 in the extratropics and 0.93-0.95 in the tropics), with most collocations for each AMV type falling close to the one-to-one line that indicates a perfect match. Note that in the NH and SH extratropics, most collocations are found in the upper-right quadrant where HLOS winds are of positive sign and indicate the dominant westerly flow of the extratropics. In the tropics, many collocations are grouped in the lower-left quadrant that indicates the easterly flow of the tropical trade winds at lower levels, and the rest are found in the upper-right quadrant that represents westerly tropical flow at upper levels. Of the three AMV types, the best match is for WVclear AMVs, with the comparisons exhibiting the smallest SDCD values in each geographic region, that in turn are comparable to known wind speed SD and RMS of all GEO AMVs relative to rawinsonde winds (Santek et al., 2019). This is expected since WVclear AMVs and Aeolus RAY winds are most probably sampling similar clear-sky scenes, and clear scenes are more homogeneous over time and space scales, which in turn implies smaller collocation differences. Ideally, one would expect samples large enough to provide statistically significant collocation differences between RAY winds and WVclear AMVs only; as it turns out, collocation differences are also statistically significant for IR and WVcloud AMVs (see Fig. 7). In these cases cloudy AMVs are collocated with Aeolus RAY winds that represent clear scenes, and since they do not observe the same type of scene, Aeolus and/or AMV representativeness errors are most probably larger (hereafter we refer to this as the cloudy/clear sampling effect).

Figure 7 presents mean vertical profiles of GOES-16 AMVs and Aeolus RAY winds, and corresponding MCD and SDCD distributions, similar to what is shown in Fig. 1. This perspective can provide additional insight into the accuracy of AMVs in representing the mean horizontal flow throughout the atmospheric column. Mean vertical profiles are plotted per AMV type in the NH extratropics (Fig. 7a-c), tropics (Fig. 7d-f), and SH extratropics (Fig. 7g-i). In Figs. 7a, 7d, and 7g, AMV HLOS (solid lines) and Aeolus HLOS (long dashed lines) generally show good agreement at all latitudes, and large gradients of HLOS correspond to layers of strong vertical wind shear inferred by the higher rate of change of AMV wind speed in the vertical (short dashed lines). Corresponding MCD are statistically significant at most levels at all latitudes (Figs. 7b, 7e, and 7h) and seem to depict known AMV biases relative to high-quality sources of wind profile observations, particularly outside of the SH. For example, in the NH extratropics, MCD range from -0.5 to -1.0 m s⁻¹ at levels where collocation counts peak and

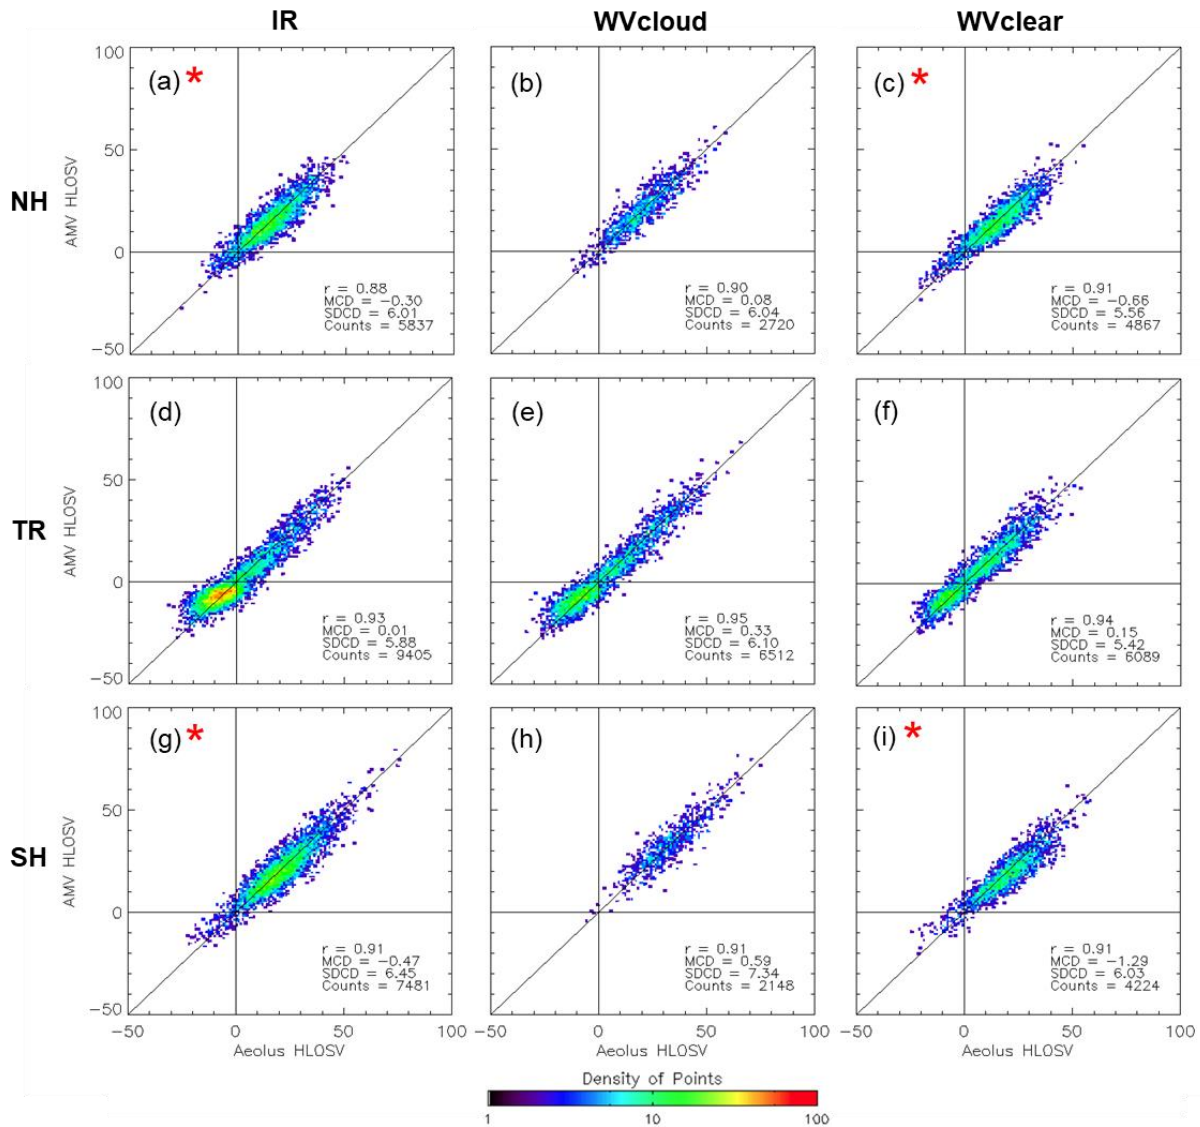

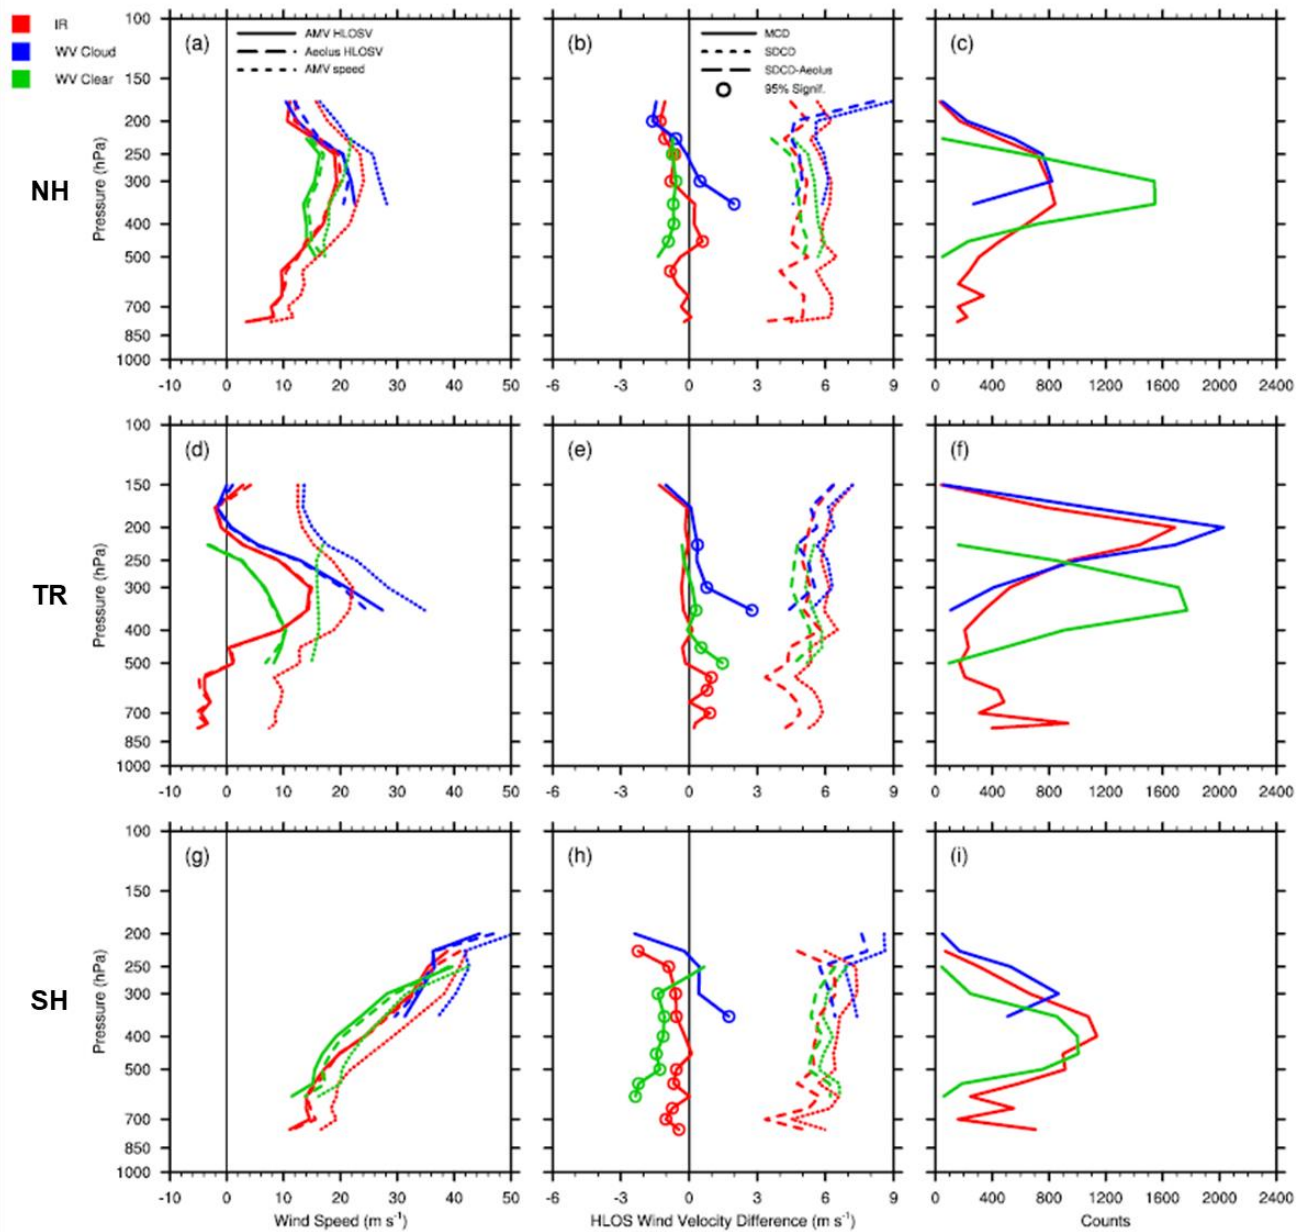

Figure 6: Density scatterplot of collocated GOES-16 AMVs and RAY winds. Rows are for the (top, a-c) NH extratropics (30-60° N), (middle, d-f) tropics (TR) (30° S to 30° N), and (bottom, g-i) SH extratropics (30-60° S). Columns are for different AMV types: (left, a, d, g) IR, (center, b, e, h) WVcloud, and (right, c, f, i) WVclear. Colors indicate total number of collocated observation pairs within the cells plotted, which are 1 ms⁻¹ on a side. Sample statistics are displayed in the bottom right corner of each panel. Horizontal and vertical zero lines are plotted in black, as is the diagonal one-to-one line. Red star denotes statistical significance at 95% using the paired two-tailed Student's t-test. HLOS V units are m s⁻¹.

could represent a small slow AMV bias as previously noted by Bormann et al. (2002). In the tropics, AMVs exhibit an apparent small fast bias, that is the positive MCD of 0.5 to 1.0 m s⁻¹, that could be associated with larger AMV errors (and larger Aeolus errors) in layers of high winds and strong vertical wind shear (Cotton et al., 2020).

415 **Figure 7: Vertical profiles of collocated GOES-16 AMVs and RAY winds. The top row shows the NH extratropics (30-60° N), (a)**
mean AMV HLOS (solid lines), RAY HLOS (long dashed lines), and mean AMV wind speed (short dashed lines) (m s^{-1}); (b)
MCD (solid), SDCD (short dashed), and AMV HLOS error as represented by SDCD-Aeolus L2B uncertainty (long dashed) (m s^{-1}); and (c)
collocation counts. (d-f) as in (a-c) but for the tropics (30° S to 30° N), and (g-i) as in (a-c) but for the SH extratropics (30-
60° S). Colors denote AMV type: IR (red), WV cloud (blue), and WV clear (green). Colored open circles indicate levels where MCD
are statistically significant at the 95% level (p -value < 0.05) using the paired Student's t -test. Vertical zero lines are displayed in the
left and center panels in black. Levels with observation counts > 25 are plotted.
 420

425 Profiles of the total RAY SDCD (short dashed lines in Figs. 7b, 7e, and 7h) that include AMV errors, Aeolus errors, and collocation/representativeness errors exhibit rather large values ($> 6 \text{ m s}^{-1}$) that tend to increase with height in layers of strong wind shear, particularly in the tropics and SH extratropics. Moreover, the Aeolus QC acts to retain HLOS V with larger uncertainties at levels above 200 hPa; this would explain the corresponding increase in total SDCD at those levels. To better isolate the AMV error, the Aeolus error estimate is removed from the total SDCD at each level, resulting in mean profiles of adjusted SDCD (long dashed lines in Figs. 7b, 7e, and 7h) that include AMV errors and collocation/representativeness errors. Overall, the adjusted SDCD for all AMV types exhibit similar magnitudes and distributions in each geographic region throughout the vertical. WVClear comparisons have slightly smaller adjusted SDCD at upper levels, suggesting that sampling

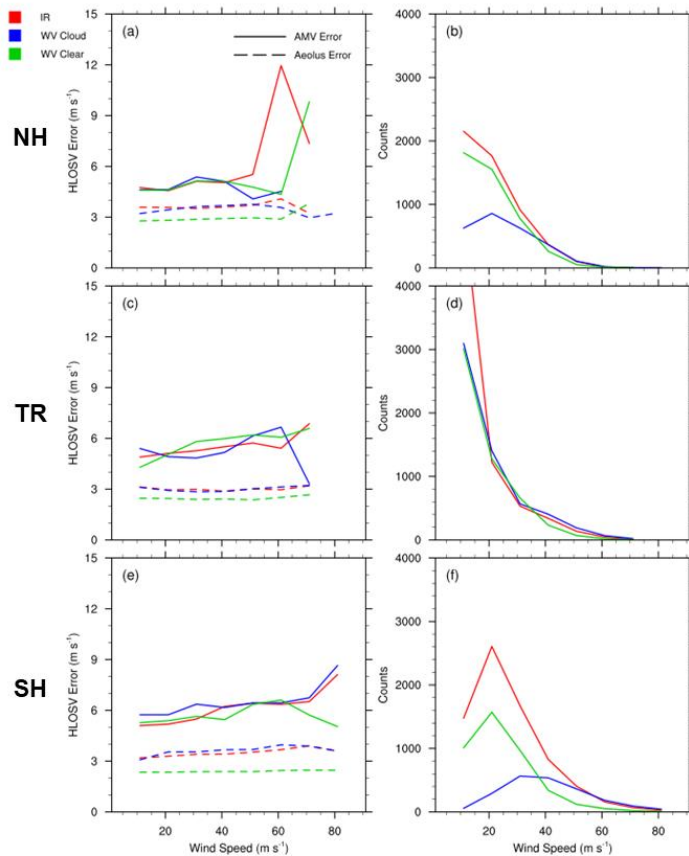

Figure 8: AMV HLOS V error (SDCD-Aeolus uncertainty) derived from GOES-16 RAY comparisons (solid lines) (m s^{-1}) and Aeolus L2B uncertainty (dashed lines) (m s^{-1}) with respect to AMV wind speed binned at 10 m s^{-1} for (a) NH, (b) tropics (TR), and (c) SH. (d-f) Counts per 10 m s^{-1} bin for each region.

differences may play a role in the higher accuracy observed for WVClear AMVs, given that WVClear representativeness errors are likely small due to Aeolus RAY and WVClear AMVs observing similar scenes. Aeolus RAY uncertainty is larger in the presence of clouds and appears to have a considerable impact on the corresponding SDCD, as the reductions in IR and WVcloud SDCD ($\sim 1 \text{ m s}^{-1}$) are larger than for WVClear SDCD (0.5 m s^{-1}). In the NH extratropics, the adjusted SDCD for each AMV type is generally constant around 5 m s^{-1} , and in the tropics it increases with decreasing pressure from 5 to 6 m s^{-1} . AMV-RAY comparisons generally exhibit larger MCD and SDCD in the SH extratropics at upper levels due to the wind-shear height assignment error effect. This is illustrated in Fig. 8 that shows that the adjusted SDCD (solid lines) for all AMV types notably increase with increasing AMV wind

455 speed in the SH extratropics relative to the other regions. This is also true for Aeolus error estimates (dashed lines) associated with IR and WVcloud comparisons in the SH (Fig. 8e).

4.1.2 Mie-cloudy (MIE) comparisons

Figure 9 presents density scatterplots like those in Fig. 6 but compares GOES-16 AMVs and MIE winds. MIE SDCD are considerably smaller than those for RAY comparisons, and this is attributed to the general higher accuracy of Aeolus MIE wind retrievals. Another possible reason is that MIE comparisons might generally have smaller collocation errors: because collocated Aeolus MIE winds and IR and WVcloud AMVs are by definition more likely sampling similar cloudy scenes at similar altitudes, we expect the Aeolus and AMV random and representativeness errors to be small (hereafter the cloudy/cloudy sampling effect). IR and WVcloud AMVs are highly correlated with MIE winds, ranging from 0.93 in the NH extratropics to 0.97 in the tropics. Most MIE collocations fall along the one-to-one line that corresponds to a perfect match. Statistics of AMV minus MIE collocation differences are generally consistent, albeit with some notable exceptions, with those for AMV comparisons with high-quality rawinsonde winds. MCD and SDCD are smallest in the tropics at -0.3 m s^{-1} and 4.4 to 4.6 m s^{-1} , respectively, particularly for WVcloud comparisons which seem to have the fewest outliers. SH extratropical comparisons exhibit the largest SDCD (around 5 m s^{-1}) but are still comparable to those associated with high-quality rawinsonde winds (Velden and Bedka, 2009; Santek et al., 2019). The smaller SDCD observed in the NH and tropics suggest that AMVs accurately represent cloud-tracked motions associated with the North Atlantic storm track in summer and the summer-shifted ITCZ; such features are well-

Figure 9: As in Fig. 6 but for comparisons of IR (left) and WVcloud (right) AMVs and MIE winds.

defined by high MIE number densities in the north and middle portions of the GOES-16 field-of-view in Fig. 4b. The larger SH SDCD suggest reduced accuracy in AMV winds that could be due to the wind-shear height assignment error effect.

Similar to Fig. 7, Fig. 10 depicts vertical distributions of AMV and MIE HLOS_V and their differences. In the tropics and NH extratropics, MIE comparisons have nearly identical profiles of HLOS_V for the IR and WVcloud samples, with the largest MCD observed at mid-levels in the tropics (at -1.5 m s^{-1}) and at upper-levels in the NH extratropics (-2.0 m s^{-1}), respectively. However, some of the larger differences occur at levels with a small sample size and may not be reliable. Despite the vertical variation of the MCD, profiles of total and adjusted SDCD are relatively constant at $4\text{-}5 \text{ m s}^{-1}$, and the contribution of Aeolus uncertainty to the total SDCD is small, as the removal of Aeolus errors only slightly reduces the SDCD. The results suggest that for MIE comparisons, the dominant factors contributing to the error consist of some combination of AMV random and representativeness/collocation error.

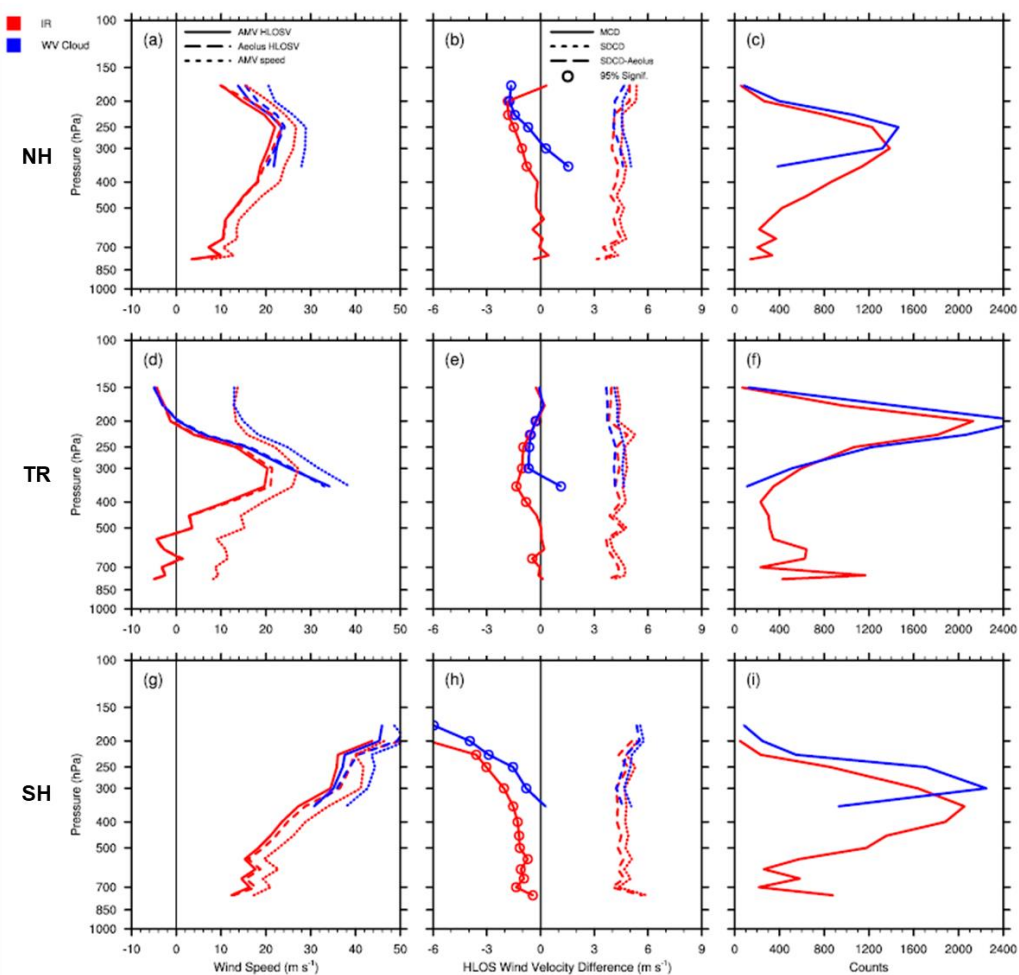

Figure 10: As in Fig. 7 but for comparisons of IR (red) and WVcloud (blue) AMVs and MIE winds.

In the NH above 250 hPa, SDCD increase slightly with decreasing pressure in a region of strong wind shear that could lead to larger AMV height assignment errors and representativeness errors. Indeed, the adjusted SDCD is shown to be larger for faster AMV wind speeds while the corresponding Aeolus MIE error estimates remain relatively constant (Fig. 11). This result in combination with likely small AMV-MIE collocation errors from the cloudy/cloudy sampling effect suggests that AMV height assignment errors dominate the larger SDCD observed in layers of high wind speed and strong shear. Additionally, in the tropics, a comparison with Aeolus MIE winds reveals a negative HLOS bias in the IR and WVcloud GOES-16 AMVs below the higher cloud-tops of the ITCZ (Fig. 10e). Larger MCD appear at levels with higher wind speeds, as do larger values of

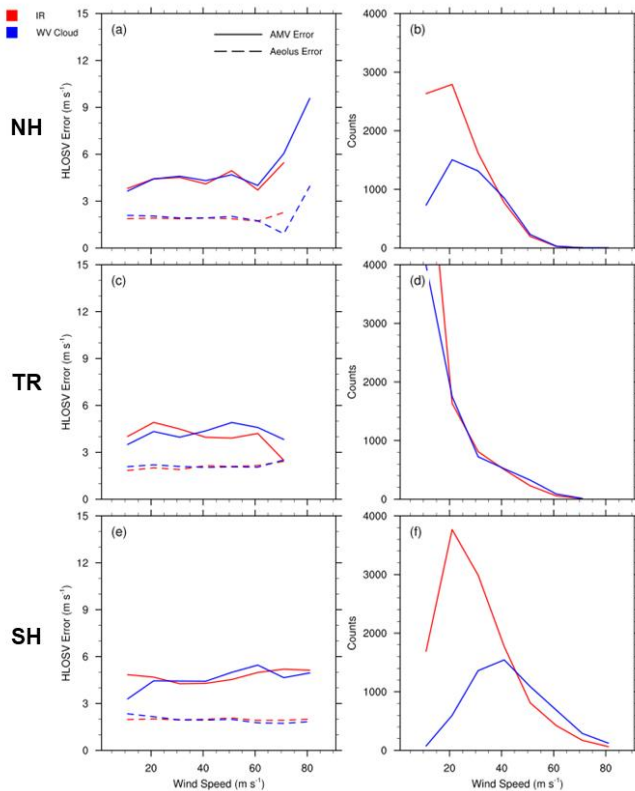

Figure 11: As in Fig. 8 but for MIE comparisons with GOES-16 IR (red) and WVcloud (blue) AMVs.

MCD are largest in the SH extratropics and are statistically significant throughout the vertical, ranging from -1.0 m s^{-1} at low levels to $< -3.0 \text{ m s}^{-1}$ above 300 hPa (Fig. 10h). Strong wind shear corresponding to an intensified jet is inferred at upper levels (Fig. 10g). The larger MCD aloft are associated with increases in adjusted SDCD with height, which are on the order of 4-6 m

adjusted SDCD, although the samples are small. Because Aeolus MIE errors remain small and constant around 2 m s^{-1} with respect to AMV wind speed (Fig. 11c), and AMV-MIE collocation errors are likely small, the results suggest that AMV height assignment errors contribute most to the negative MCD and corresponding larger SDCD, in agreement with Cotton et al. (2020, 2021) who also note a negative bias largely thought to be attributed to AMV height assignment errors. This finding is relatively new, and the fact that comparisons with Aeolus depict this feature hints at the value of using Aeolus MIE winds as a standard for comparison to characterize cloud-tracked AMVs. Additionally, our comparisons with Aeolus depict another noted feature in monitoring AMVs by Cotton et al. (2020, 2021): a pronounced negative wind speed bias in the tropics for Meteosat-8 is evidenced by large negative MCD and corresponds to large SDCD in all regions (not shown). This feature is evident in both RAY and MIE comparisons.

s^{-1} . Moreover, the large MCD represent over 8.5% of the corresponding HLOSV at upper levels and could be attributed to larger AMV height assignment errors corresponding to stronger storm tracks in winter. This is exemplified in Fig. 11e where Aeolus MIE errors are shown to be small (2 m s^{-1}) and remain relatively constant with increasing AMV wind speed, while the adjusted SDCD are larger and increase with AMV wind speeds $> 40 \text{ m s}^{-1}$. The results imply that the large systematic differences in MCD at upper levels in the SH extratropics are most probably attributed to larger AMV errors in combination with strong wind shear.

4.2 LEO AMVs vs. Aeolus

Figure 12 presents density scatterplots that compare LEO AMVs derived from IR window channels with RAY and MIE winds in the Arctic (Fig. 12a-b) and Antarctic (Fig. 12c-d) during the study period. LEO AMVs show good correspondence with both Aeolus observing modes in the polar regions. In general, comparisons in the Arctic have small yet significant MCD (around -0.2 m s^{-1}) and SDCD estimates of 5.2-6.5 m s^{-1} , while Antarctic comparisons exhibit larger MCD and SDCD. Moreover, MIE comparisons in the Arctic exhibit the smallest SDCD, and RAY comparisons in the Antarctic have the largest SDCD and more evident outliers. This suggests that during the study period, IR LEO AMVs are best able to capture cloud-tracked motions during the summer season (in the Arctic) when cloudiness increases in the vertical and more water vapor content is generally available to track features (Alekseev et al., 2018). Water vapor content in the Arctic is largest in summer due to an influx of water vapor from melting ice and snow and receding sea ice extent as well as intensified meridional moisture fluxes from low latitudes (Alexseev et al., 2018).

Figure 12: Density scatterplot of collocated IR-window AMVs from all available LEO satellites and RAY (left, a, c) and MIE (right, b, d) winds: Comparisons in (a-b) Arctic (north of 60° N), and (c-d) Antarctic (south of 60° S). Colors indicate total number of collocated observation pairs within the cells plotted, which are 1 m s^{-1} on a side. Sample statistics are displayed in the bottom right corner of each panel. Horizontal and vertical zero lines are plotted in black, as is the diagonal one-to-one line. Red star denotes statistical significance at the 95% level using the paired two-tailed Student's t-test. HLOSV units are m s^{-1} .

As was done for the GOES-16 case study, we examine the vertical differences between all LEO AMVs and Aeolus winds to ascertain how AMVs characterize the dynamical flow at the poles (Fig. 13). RAY (red colors) and MIE comparisons (blue colors) are presented together. AMV HLOSv and Aeolus HLOSv profiles are similar throughout the vertical, with notably larger MCD in the Antarctic at upper levels. In the Arctic (Fig. 13, top row), MIE winds and collocated AMVs depict faster motions relative to RAY comparisons. Statistically significant MCD are on the order of -0.5 m s^{-1} at mid-levels where collocation counts peak, representing slower AMV winds relative to Aeolus. The MCD become larger (more negative) nearer the tropopause (around 300-250 hPa) where HLOSv reach upwards of 15 m s^{-1} and AMV wind speeds reach 30 m s^{-1} , while corresponding total SDCD are generally constant but smaller for MIE ($\sim 5 \text{ m s}^{-1}$) than RAY ($\sim 7 \text{ m s}^{-1}$). Removal of the Aeolus uncertainty yields adjusted SDCD profiles that are nearly equal to the total MIE SDCD, indicating the higher accuracy of MIE winds in the Arctic at all levels including those with higher wind speeds. This independence of Aeolus MIE uncertainty to changes in wind speed is clear in Fig. 14a where Aeolus MIE errors are shown to be smaller relative to RAY and remain relatively constant with increasing AMV wind speeds. In addition, the near doubling of MIE collocation counts at mid-levels relative to RAY (Fig. 13c) could be due to increased cloudiness associated with more moisture availability in Arctic summer (Alekseev et al., 2018).

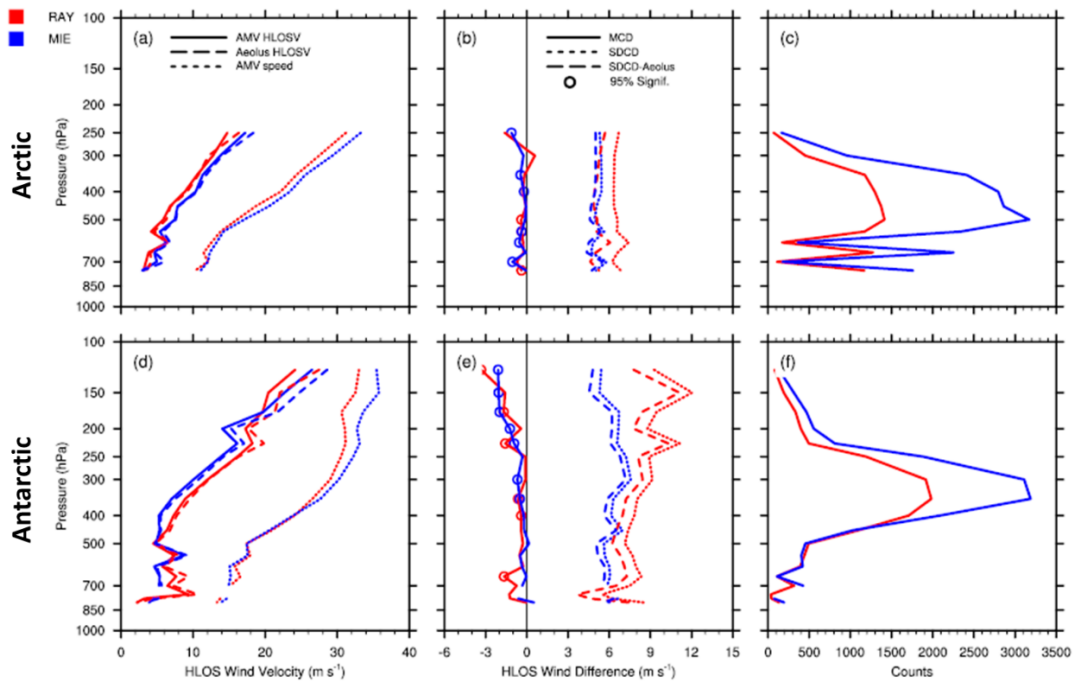

Figure 13: Vertical profiles of collocated LEO AMVs and RAY (red) and MIE (blue) winds. The top row shows the Arctic (north of 60° N), (a) mean AMV HLOSv (solid lines), Aeolus HLOSv (long dashed lines) (m s^{-1}), and mean AMV wind speed (short dashed lines) (m s^{-1}); (b) MCD (solid), SDCD (short dashed), and AMV HLOSv error as represented by SDCD-Aeolus L2B uncertainty (long dashed) (m s^{-1}); and (c) collocation counts. (d-f) as in (a-c) but for the Antarctic (south of 60° S). Colored open circles indicate levels where MCD are statistically significant at the 95% level ($p\text{-value} < 0.05$) using the paired Student's t -test. Vertical zero lines are displayed in the center panels in black. Levels with observation counts > 25 are plotted.

In the Antarctic (Fig. 13, bottom row), HLOS_V increase from 5 m s⁻¹ at mid-levels to nearly 30 m s⁻¹ at very high levels (~150 hPa), and RAY comparisons are shown to capture generally faster motions throughout much of the vertical column. MCD are small (around -0.5 m s⁻¹) at mid-levels where collocation counts peak but are larger aloft and represent over 10% of the

Figure 14: As in Fig. 8 but for LEO IR RAY and MIE comparisons at the poles.

corresponding HLOS_V. Larger MCD aloft could be attributed to the wind-shear height assignment error effect related to the strengthening of the Antarctic polar vortex in late winter/early spring. As shown in the Arctic, MIE comparisons in the Antarctic have smaller total SDCD (5-7 m s⁻¹) than RAY (6-12 m s⁻¹, respectively) throughout the vertical; however, Antarctic MIE and RAY SDCD are larger than in the Arctic and appear to increase with height. Higher SDCD values at upper levels may be attributed to larger AMV and Aeolus errors in layers of faster winds. Adjusted SDCD as well as Aeolus error estimates for RAY comparisons increase with increasing AMV wind speed (Fig. 14c), suggesting that both AMV errors and Aeolus errors in layers of high winds and strong shear contribute to the larger SDCD observed in the Antarctic.

5 Summary and conclusions

This study summarizes statistical comparisons of AMVs with the novel Aeolus L2B HLOS winds for samples stratified by specific sets of conditions and discusses their relationship to known AMV characteristics. Because Aeolus observes the HLOS_V—the horizontal wind projected onto the HLOS of the DWL—derived from the detection of molecular and aerosol backscattering signals, the assessments of mean collocation differences (AMV minus Aeolus) and SD of the differences are all in terms of AMV winds projected onto the collocated Aeolus HLOS. In the tropics, due to the Aeolus observing geometry, HLOS_V represents the zonal wind. Aeolus HLOS_V profiles utilized in this study are classified as RAY or Rayleigh-clear

winds (representing mostly clear-sky scenes) and MIE or Mie-cloudy winds (representing cloudy scenes only). Winds quality controlled (QC'd) following recommendations by ESA for Aeolus and by the user community for the satellite winds are retained for analysis. The performance of QC'd AMVs relative to collocated QC'd Aeolus winds are characterized by analyzing sample statistics of the collocated differences, AMV HLOS_V minus Aeolus HLOS_V. These statistics should not be strictly interpreted as overall AMV performance, as differences arise from errors in both AMVs and Aeolus winds and from representativeness and collocation errors.

Comparisons of GOES-16 AMVs and IR cloud-tracked AMVs from LEO satellites are assessed to estimate the dependence of AMVs on different combinations of conditions including Aeolus observing mode/scene type (clear or cloudy), AMV type (IR, WVcloud, and WVclear), and geographic region (tropics and extratropics for GOES-16, Arctic and Antarctic polar regions for LEO). GOES-16 was chosen as a representative of GEO performance, as the AMVs exhibit high correlations with Aeolus, relatively low MCD and SDCD, and have a large sample size from which to compute robust statistics. The summary assessment of all LEO AMVs provides a unique, comprehensive perspective on the characteristics of polar AMVs using a larger sample of collocated Aeolus wind profiles relative to other available datasets, e.g., rawinsonde profile data. Vertical distributions of differences in HLOS_V are examined, as this perspective has the potential to provide additional insight into how accurately each AMV type represents the horizontal flow in the vertical. AMVs exhibit different characteristics in clear and cloudy scenes that vary with geographic region and in the vertical, in agreement with the findings in Velden et al. (1997), Posselt et al. (2019), and others. Overall, GEO and LEO AMVs are found to compare as well with Aeolus RAY and MIE winds as they do to conventional data sources and NWP products, particularly in the tropics, NH extratropics, in the Arctic, and at mid- to upper-levels in both clear and cloudy scenes. SH comparisons generally exhibit larger than expected SDCD that could be attributed to larger height assignment errors and larger representativeness and collocation errors in regions of high winds and strong vertical wind shear.

The main findings from comparing GOES-16 AMVs with RAY and MIE winds are the following. Aeolus MIE winds show great potential value as a comparison standard to characterize AMVs. MIE comparisons generally exhibit smaller biases and uncertainties compared to RAY, reflecting the higher accuracy of MIE winds and AMVs in cloudy scenes as well as larger collocation errors for RAY winds in cloudy scenes. This is attributed to a combination of smaller Aeolus MIE uncertainties and smaller collocation/representativeness errors due to the cloudy/cloudy sampling effect, that is, the fact that both Aeolus and AMV winds are, by definition, sampling similar cloudy scenes at similar altitudes. The contribution of Aeolus MIE uncertainty to the overall SDCD is small; in fact, removal of Aeolus uncertainties further reduces the small MIE SDCD without much change to its vertical distribution, suggesting that for MIE comparisons, the dominant factors contributing to the total error consist of AMV random errors and representativeness/collocation errors. Additionally, the AMV-Aeolus MIE comparisons depict a relatively new finding that is also noted in Cotton et al. (2020, 2021) and is largely thought to be attributed to AMV height assignment errors: a negative speed bias in the IR and WVcloud AMVs in the tropics. The fact that comparisons with Aeolus exhibit this feature hints at the usefulness of Aeolus MIE winds as a standard for comparison to

characterize AMVs. (It should be noted that because the period of study is relatively short, the datasets are not large enough
650 to examine in detail many of the “features” identified and studied in the NWP SAF AMV monitoring. However, it could be
possible to verify the identification of such features in AMV comparisons with Aeolus observations by using a larger
collocation dataset, which the authors are preparing and making publicly available.)

Regarding GOES-16 RAY comparisons, sampling differences may play a role in the higher correlation between Aeolus RAY
winds and WVclear AMVs, since they both represent similar clear-sky scenes. This is especially true in the tropics and NH
655 extratropics where MCD are small and SDCD are comparable to AMV error values compared with high-quality rawinsonde
winds. It is likely that collocation errors play a larger role in the RAY SDCD for IR and WVcloud AMVs due to the
cloudy/clear sampling effect, where clear-sky Aeolus winds are collocated with cloudy AMVs and thereby observe different
scenes, yielding larger errors. In addition, the removal of Aeolus uncertainties from the total SDCD considerably reduces the
RAY SDCD, particularly for IR and WVcloud comparisons, indicating that Aeolus contributes a substantial fraction of the
660 total SDCD in the presence of clouds.

Polar AMVs have smaller MCD for MIE compared to RAY, although Antarctic AMVs have larger SDCD than the Arctic. In
fact, GEO and LEO comparisons in the SH/Antarctic exhibit the largest SDCD of all regions examined. Large wind shear is
evident in the SH/Antarctic throughout much of the atmospheric column, and this can dramatically affect AMV height
assignment errors. Indeed, AMV errors are shown to generally increase with increasing AMV wind speed, as do corresponding
665 Aeolus errors for RAY winds, suggesting that both contribute to the larger SDCD observed in layers of high wind speed.
Additionally, larger RAY MCD aloft could be attributed to larger collocation/representativeness errors due to IR AMVs and
RAY winds viewing different scenes. The possible mischaracterization of very cold surface temperatures as clouds may also
be a factor. For GOES-16 MIE comparisons in the SH, AMV errors are larger and increase with AMV speeds $> 40 \text{ m s}^{-1}$ while
Aeolus MIE errors are small and remain relatively constant. This implies that the large systematic differences in MCD at upper
670 levels in the SH extratropics are most probably attributed to larger AMV errors in combination with the wind-shear height
assignment error effect.

The use of Aeolus winds as a benchmark dataset for the comparative assessment of AMVs has valuable implications for future
research, including the validation of 3D winds and the use of such data in NWP. For example, the findings presented here
contribute to the ongoing development of a feature track correction (FTC) observation operator to account for AMV height
675 assignment and other biases in data assimilation (Hoffman et al., 2022). Future studies should use larger datasets like those the
authors are preparing to compare clear-scene AMVs with Aeolus Rayleigh-clear winds only, and cloudy-scene AMVs with
Aeolus Mie-cloudy winds only. Such studies are anticipated to yield additional insights into the seasonal performance of AMV
characteristics representing different dynamical features in clear and cloudy scenes and how this might be accounted for or
improved upon in AMV algorithms. Moreover, the robustness of dynamical features identified in AMV monitoring could be
680 further validated following this approach. In addition, Aeolus Mie-cloudy comparisons using larger datasets are expected to

have a significant impact towards improving our understanding and characterization of AMV quality in cloudy scenes, given the cloudy/cloudy sampling effect and the small contribution of Aeolus Mie-cloudy error to the total SDCD throughout the vertical in all geographic regions, implying that the corresponding adjusted SDCD better depicts true AMV uncertainty. This is especially critical where AMV height assignment errors are likely large but Aeolus Mie-cloudy errors are small and remain relatively constant with respect to height and AMV wind speed, e.g., in layers of strong vertical wind shear and in the SH. One lesson learned from this study is that QC of both AMV and Aeolus observations is critical and largely improves the results. The Aeolus project has done much to eliminate errors of all types, but some improvements are expected, e.g., via the removal of DWL instrument calibration-dependent error. Further, some of the bias corrections currently applied depend on ECMWF forecasts, and the analysis of Liu et al. (2022) demonstrates that additional bias corrections for Aeolus are possible, and that such corrections can improve NWP analysis and forecast results (Garrett et al., 2022).

Appendix A

Formulae for the statistics used in this study are presented here. Since HLOS_V is a scalar, these formulae correspond directly with the standard textbook formulae. The collocation database is composed of pairs (x_i, y_i) for $i=1, n$, where n is the number of collocations, i is the collocation index, x is the Aeolus HLOS_V, and y is the AMV HLOS_V. The correlation (r) between collocated HLOS_V describes the overall relation of AMVs to Aeolus and is defined as

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{s_x s_y} \quad (\text{A1})$$

Overbars denote sample means. The corresponding standard deviations s_x and s_y are defined as

$$s_m \equiv \sqrt{\frac{1}{n-1} \sum_{i=1}^n (w_i - \bar{w})^2} \quad (\text{A2})$$

where w can equal x or y . The collocation difference (CD) is the difference in m s^{-1} between each pair of collocated AMV HLOS_V and Aeolus HLOS_V,

$$CD = y_i - x_i \quad (\text{A3})$$

and the mean (MCD) represents the sample mean of the CD for select conditions, such as a specific geographic region, pressure level, AMV type, or Aeolus observing mode.

$$MCD = \frac{1}{n} \sum_{i=1}^n (CD) \quad (\text{A4})$$

Using (A2), we can define the corresponding SDCD in terms of CD:

$$SDCD = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (CD_i - MCD)^2} \quad (\text{A5})$$

Finally, the “adjusted SDCD” s_{adj} is defined as the SDCD with the corresponding Aeolus error estimate s_x removed:

$$s_{adj} = \sqrt{SDCD^2 - s_x^2} \quad (\text{A6})$$

Data availability

710 The Aeolus L2B Earth Explorer data used in this study are publicly available and can be accessed via the ESA Aeolus Online Dissemination System (<https://aeolus-ds.eo.esa.int/oads/access/>). The NCEP SATWIND BUFR AMV dataset can be provided by the corresponding author (katherine.lukens@noaa.gov) upon request. Additionally, the authors are preparing an Aeolus-AMV collocation dataset that will be provided upon request.

Author contributions

715 Kevin Garrett and Kayo Ide proposed the project as co-investigators and provided expertise that guided this work. Brett Hoover and David Santek developed the collocation algorithm used. Katherine E. Lukens performed most of the work that included the implementation of the collocation algorithm and comparison analysis. David Santek and Ross N. Hoffman provided additional intellectual support that considerably improved the article. Katherine E. Lukens prepared the manuscript with contributions from all co-authors.

720 Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

The authors thank the two anonymous referees for their careful and helpful comments that considerably improved the article. The authors also thank their colleagues at NOAA/NESDIS/STAR for overseeing this work as well as Mike Hardesty, Iliana
725 Genkova, and the rest of the US Aeolus Cal/Val team for guidance and support. The University of Wisconsin-Madison S4 supercomputing system (Boukabara et al., 2016) was used in this work.
