**Abstract.** Lightning is one of the major sources of nitrogen oxides ( $\text{NO}_x$ ) in the atmosphere, contributing to the tropospheric concentration of ozone and to the oxidising capacity of the atmosphere. Lightning produces between 2-8 Tg N per year globally and on average about  $250 \pm 150$  mol  $\text{NO}_x$  per flash. In this work, we estimate the moles of  $\text{NO}_x$  produced per flash (L $\text{NO}_x$  production efficiency) in the Pyrenees (Spain, France and Andorra) and in the Ebro Valley (Spain) by using nitrogen dioxide ( $\text{NO}_2$ ) and cloud properties from the TROPOspheric Monitoring Instrument (TROPOMI) as well as lightning data from the Earth Networks Global Lightning Network (ENGLN) and from the European Co-operation for Lightning Detection (EUCLID). The Pyrenees are one of the areas in Europe with the highest lightning frequency and, due to their remoteness as well as experiencing very low  $\text{NO}_x$  background, enables us to better distinguish the L $\text{NO}_x$  signal produced by recent lightning in TROPOMI  $\text{NO}_2$  measurements. We compare the L $\text{NO}_x$  production efficiency estimates for eight convective systems in 2018 using two different sets of TROPOMI research products, provided by the Royal Netherlands Meteorological Institute (KNMI) and the Deutsches Zentrum für Luft- und Raumfahrt (DLR). According to our results, the mean L $\text{NO}_x$  production efficiency in the Pyrenees and in the Ebro Valley, using a three-hour chemical lifetime, ranges between 14 and 103 mol  $\text{NO}_x$  per flash from the eight systems. The mean L $\text{NO}_x$  production efficiency estimates obtained using both TROPOMI products and ENGLN lightning data differ by  $\sim 23\%$ , while they differ by  $\sim 35\%$  when using EUCLID lightning data. The main sources of uncertainty when using ENGLN lightning data are the estimation of background  $\text{NO}_x$  that is not produced by lightning and the time window before the TROPOMI overpass that is used to count the total number of lightning flashes contributing to fresh-produced L $\text{NO}_x$ . The main source of uncertainty when using EUCLID lightning data is the uncertainty in the detection efficiency of EUCLID.

## 20 1 Introduction

Lightning is one of the major sources of nitrogen oxides ( $\text{NO}_x = \text{NO} + \text{NO}_2$ ) in the upper troposphere (e. g., Schumann and Huntrieser, 2007) and references therein]. Lightning channels are formed by plasma reaching several thousands of Kelvin (Wallace, 1964). Such a high temperature produces dissociation of nitrogen and oxygen air molecules (Ripoll et al., 2014b, a; Kieu et al., 2021), contributing to the formation of  $\text{NO}_x$  by the Zeldovich mechanism (Zeldovich et al., 1947). Lightning-induced nitrogen oxides ( $\text{LNO}_x$ ) contribute about 10% to global  $\text{NO}_x$  emissions and play an important role in determining the concentration of ozone and other chemical species in the upper troposphere as well as the oxidising capacity of the atmosphere (e. g., Labrador et al., 2005; Schumann and Huntrieser, 2007; Murray et al., 2012; Gordillo-Vázquez et al., 2019). Lightning produces between 2-8 Tg N per year globally (100-400 mol  $\text{NO}_x$  per flash) and on average about 250 mol  $\text{NO}_x$  per flash Schumann and Huntrieser (2007).

30 Reducing the uncertainty of the  $\text{NO}_x$  production by lightning and understanding the factors that influence this production is still a challenge. Aircraft measurements have significantly contributed to determining the production of  $\text{NO}_x$  per flash, or  $\text{LNO}_x$  Production Efficiency (PE) (e. g., Huntrieser et al., 2002, 2016; Allen et al., 2021b). However, aircraft campaigns cannot provide a continuous monitoring of  $\text{LNO}_x$  and are difficult to carry out in some regions. Nadir-viewing satellite instruments such as the Ozone Monitoring Instrument (OMI), the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographyY (35 SCIAMACHY) and the TROPOspheric Monitoring Instrument (TROPOMI) measure spectra that are employed to estimate column densities of  $\text{NO}_2$  over thunderstorms. Several authors have used OMI  $\text{NO}_2$  measurements to estimate the  $\text{LNO}_x$  PE in a case-based approach or systematically over different regions (Beirle et al., 2010; Marais et al., 2018), including midlatitude regions (Bucsela et al., 2019), tropical regions (Allen et al., 2019) and the U.S. (e. g., Pickering et al., 2016; Lapierre et al., 2020; Zhang et al., 2020; Allen et al., 2021a). Satellite-based measurements can help to estimate  $\text{LNO}_x$  amounts over regions where 40 aircraft campaigns are rare or to systematically investigate possible relationships between the characteristics of thunderstorms and  $\text{LNO}_x$  over different geographical regions (Bucsela et al., 2019). However, the opacity of thunderclouds can strongly affect the retrieval of  $\text{NO}_2$  (Beirle et al., 2009), while convection can transport  $\text{NO}_x$  released at the surface to the upper troposphere, where it is mixed with freshly produced  $\text{LNO}_x$ . Therefore, the use of atmospheric and radiative models in combination with  $\text{NO}_2$  measurements is needed to estimate the  $\text{NO}_x$  Production Efficiency ( $\text{LNO}_x$  PE).

45 The TROPOMI instrument on board the European Space Agency Sentinel-5 Precursor (S5P) satellite was launched on 13 October 2017. TROPOMI operates from a low Earth polar orbit that provides daily global measurements of several trace gases (including  $\text{NO}_2$ ) and cloud properties (Veefkind et al., 2012). The horizontal resolution at nadir is  $3.6 \text{ km} \times 7.2 \text{ km}$  before 6 August 2019, while it is  $3.6 \text{ km} \times 5.6 \text{ km}$  thereafter. This unprecedented spatial resolution represents a unique opportunity to investigate the  $\text{LNO}_x$  PE from satellite measurements. Recently, Allen et al. (2021a) used, for the first time, 50 TROPOMI measurements to estimate the  $\text{LNO}_x$  PE for 29 cases in the USA lightning data from the Earth Network Global Lightning Network (ENGLN) and from the Geostationary Lightning Mapper (GLM) aboard the Geostationary Operational

Environmental Satellite-16 (GOES-16). They reported  $175 \pm 100$  and  $120 \pm 65$  mol  $\text{NO}_x$  per flash using ENGLN and GLM lightning data, respectively. These values are at the lower end of the globally averaged  $\text{LNO}_x$  PE of  $250 \pm 150$  mol  $\text{NO}_x$  per flash as given by Schumann and Huntrieser (2007).

55 In this work, we, for the first time, quantify the amount of  $\text{LNO}_x$  over the Pyrenees and the Ebro Valley in Spain by using different TROPOMI- $\text{NO}_2$  and cloud research products provided by two different European research institutes, such as KNMI and DLR. The Pyrenees are one of the areas in Europe with the highest lightning frequency (Molinie et al., 1999; Pineda et al., 2010; Anderson and Klugmann, 2014) and are a suitable place to distinguish the  $\text{LNO}_x$  signal due to their remoteness and very low  $\text{NO}_x$  background (Vinken et al., 2014). Airflows over the studied areas are influenced by the proximity of the  
60 Mediterranean Sea and the Atlantic Ocean, the high mountains of the Pyrenees, cold fronts crossing Europe, and a thermal low centered over the Iberian Peninsula (Pineda et al., 2010). In this study, we analyze eight thunderstorms taking place in April and May 2018, the months with the highest occurrence of lightning in Spain (Pineda et al., 2010). During late spring, lightning activity in the area reaches its maximum over the mountains and is driven by solar heating (Esteban et al., 2006; Pineda et al., 2010). Therefore, we expect that during this time of the year a number of thunderstorms are active during the  
65 TROPOMI overpass ( $\sim 13:30$  LT). We combine two TROPOMI research products with lightning data from the ENGLN (Zhu et al., 2017; Lapierre et al., 2020) and the European Co-operation for Lightning Detection (EUCLID) systems (Schulz et al., 2016). Apart from providing new valuable estimates of  $\text{LNO}_x$  for Europe, this analysis will enable us to quantify the influence of using different lightning data sets and different TROPOMI  $\text{NO}_2$  and cloud research products for the estimates of  $\text{LNO}_x$  PE. It is important to emphasize that the analyzed thunderstorms are not confined to the Pyrenees, but include lightning in adjacent  
70 regions where significant boundary layer pollution can be present. Therefore, a careful analysis of the background  $\text{NO}_x$  is still needed to estimate the  $\text{LNO}_x$  for the analyzed cases.

## 2 Data sets and methods

### 2.1 TROPOMI $\text{NO}_2$ and cloud research products

We use TROPOMI  $\text{NO}_2$  and cloud research products for eight deep convective systems in the Pyrenees and adjacent regions  
75 between April and May 2018. TROPOMI is a passive imaging spectrometer with eight spectral bands covering the ultraviolet (UV), visible (VIS), near infrared (NIR), and short-wavelength IR (SWIR) spectral regions (Veefkind et al., 2012). TROPOMI provides spectral data that is combined with different methods/algorithms to retrieve  $\text{NO}_2$  column densities and cloud properties (e.g., Wang et al., 2008; Loyola et al., 2018; Marais et al., 2021; Liu et al., 2021a). In this work, we use two different sets of TROPOMI research products. The variables extracted from the TROPOMI products are the Slant Column Density (SCD)  $\text{NO}_2$   
80 , the error of the SCD  $\text{NO}_2$  , the quality assurance (QA) value, the stratospheric Vertical Column Density (VCD) of  $\text{NO}_2$  , the stratospheric Air Mass Factor (AMF), the Cloud Fraction (CF) and the Optical Centroid Pressure (OCP).

The first set of TROPOMI research products are here referred to as the Royal Netherlands Meteorological Institute (KNMI) version 2.1 research product (Allen et al., 2021a; van Geffen et al., 2022; Zhang et al., 2021) (TROP-KNMI) based on the official TROPOMI  $\text{NO}_2$  Algorithm Theoretical Basis Document (ATBD) (van Geffen et al., 2021). This product is not au-

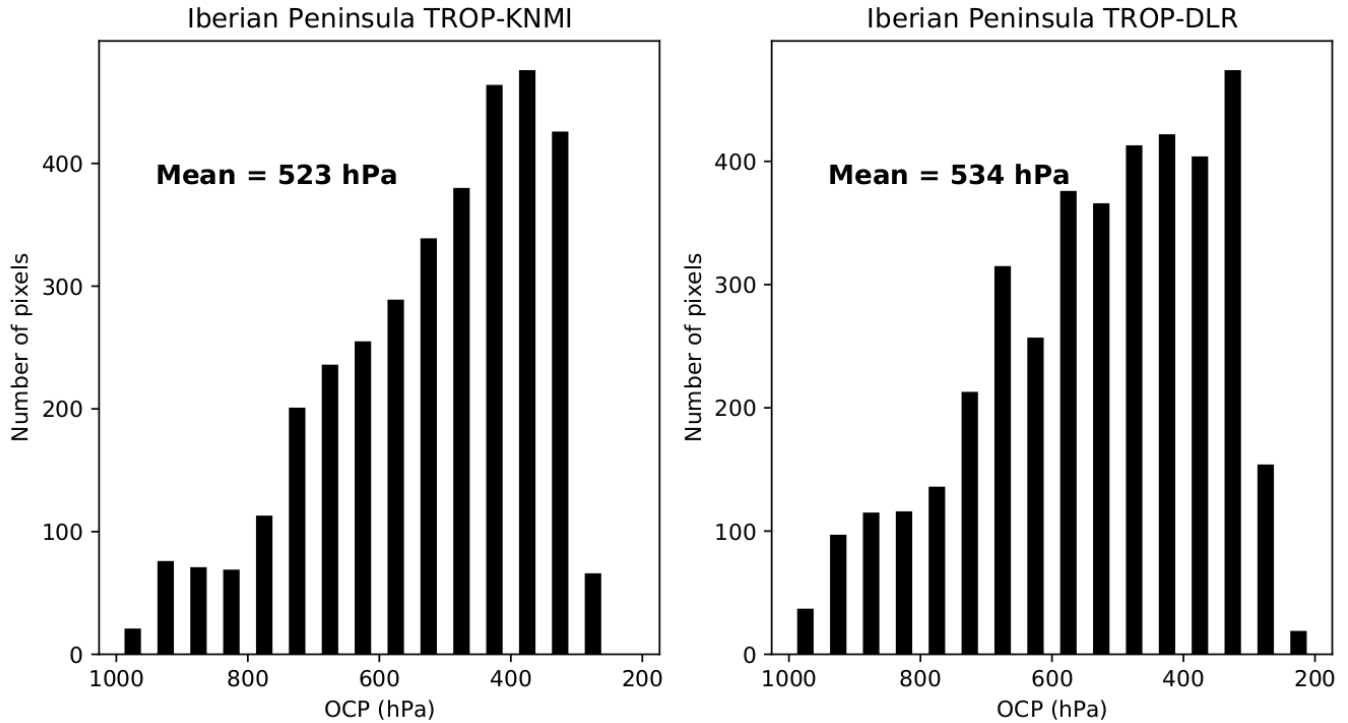

85 tomatically produced for all the TROPOMI orbits. We produce it on a case-by-case basis as needed to analyze particular  
thunderstorms. The TROP-KNMI cloud research product is based on the Fast Retrieval Scheme for Clouds from the Oxygen  
A-band-S (FRESCO-S) algorithm with a Cloud as Reflecting Boundaries (CRB) model of clouds (Koelemeijer et al., 2001).  
In the CRB model, clouds are described as a Lambertian reflecting boundary. The separation of the contribution of the tropo-  
90 sphere and stratosphere to the NO<sub>2</sub> column density for the TROP-KNMI NO<sub>2</sub> research product is based on a priori chemical  
profiles from the chemistry transport model TM5-MP (Williams et al., 2017; Myriokefalitakis et al., 2020). We use the ver-  
sion 2.1\_test of this product, a modified NO<sub>2</sub> product that increases the data coverage over bright pixels over deep convective  
clouds and includes a spike removal to better deal with saturation and blooming effects in the radiance spectra (Williams et al.,  
2017; Ludewig et al., 2020; Allen et al., 2021a). The reflectance value at 440 nm is reconstructed from the Differential Optical  
Absorption Spectroscopy (DOAS) method polynomial and the Ring correction as input to the routine that calculates the cloud  
95 (radiance) fraction in the NO<sub>2</sub> window. We refer to van Geffen et al. (2021b) and Allen et al. (2021a) for a detailed description  
of the TROP-KNMI NO<sub>2</sub> and cloud research products. Following Allen et al. (2021a), we use pixels with a quality assurance  
value above 0.28 (fair or better quality). This selection ensures that the SCD NO<sub>2</sub> error is less than  $2 \times 10^{19}$  molec m<sup>-2</sup>.

We refer to the second set of TROPOMI research products as the Deutsches Zentrum für Luft- und Raumfahrt (DLR)  
research product (TROP-DLR). The TROP-DLR cloud research product uses the OCRA/ROCINN algorithms for retrieving  
100 cloud properties (Loyola et al., 2018). The cloud properties provided by ROCINN uses the Clouds-As-Layers (CAL) model  
(Loyola et al., 2018). In the CAL model, clouds are treated as optically uniform layers using a more realistic cloud scattering  
model than the CRB model (Lindfors et al., 2018). This product is produced on a case-by-case basis as needed to analyze  
particular thunderstorms. We refer to Loyola et al. (2018) for a more extended description of the TROP-DLR cloud research  
product. The TROP-DLR NO<sub>2</sub> research product uses a Directionally dependent STRatospheric Estimation Algorithm from  
105 Mainz (DSTREAM) to separate the contribution of the troposphere and stratosphere to the NO<sub>2</sub> column density (Liu et al.,  
2021b). This method does not require any input from atmospheric models. The DSTREAM method does not distinguish free  
tropospheric diffuse NO<sub>2</sub> from stratospheric NO<sub>2</sub>. This is different in the TROP-KNMI approach, where a free tropospheric  
column is derived from the TM5-MP profiles. In the case of TROP-KNMI, the stratospheric NO<sub>2</sub> retrieval does not include  
free tropospheric NO<sub>2</sub>, while it does include free tropospheric NO<sub>2</sub> in the case of the TROP-DLR product. So, we expect the  
110 tropospheric background to be substantially higher in the TROP-KNMI product than in the TROP-DLR product. The detailed  
description of the TROP-DLR NO<sub>2</sub> research product can be found in (Liu et al., 2021b). In this work, we use pixels with a SCD  
NO<sub>2</sub> error lower than  $2 \times 10^{19}$  molec m<sup>-2</sup> to be consistent with the QA threshold defined for the TROP-KNMI product.

115 Pixels with deep convection are defined as pixels in which the effective cloud fraction is greater than 0.95 (Allen et al., 2021a)  
and the OCP value is lower than a threshold. The threshold is defined as the averaged OCP for all lightning flashes included  
in this study. We calculate it using OCP values for all pixels containing lightning flashes during the 5 h period before the  
TROPOMI overpass according to the TROPOMI cloud products, providing that the OCP value is not undefined. The averaged  
OCP for the TROP-KNMI and the TROP-DLR products are 523 hPa and 534 hPa, respectively. These pressures are slightly  
higher than the 500 hPa threshold employed by Pickering et al. (2016) and Allen et al. (2021a) for deep convective systems  
over the USA. Figure 1 shows the distributions of OCP values for TROP-KNMI and TROP-DLR using ENGLN lightning

120 data over all the studied cases. Both distributions peak around 400 hPa, while there are more lightning flashes taking place in pixels with OCP values between 650 hPa and 500 hPa in the case of the TROP-DLR product than the TROP-KNMI product (3923 versus 3489 pixels). We have calculated the T-test for the means of the OCP distributions plotted in Figure 1, obtaining a p-value lower than 0.05. This p-value indicates that differences in the mean OCP derived from the TROP-KNMI and the TROP-DLR products are statistically significant.

**Figure 1.** Distributions of OCP for pixels containing ENGLN flashes 5 hours prior to the TROPOMI overpass for the TROP-KNMI (left panel) and the TROP-DLR (right panel) products for all the studied cases.

## 125 2.2 Lightning measurements

We apply lightning data provided by two lightning location systems, ENGLN and EUCLID, to calculate the amount of  $LNO_x$  produced per flash (or  $LNO_x$  PE).

The ENGLN is a global network composed of both broadband sensors from the Earth Networks Total Lightning Network (Liu et al., 2014) and Very Low Frequency (VLF) sensors from the World Wide Lightning Location Network (Hutchins et al.,  
 130 2012) that provide the position, time of occurrence, polarity and peak current of lightning strokes. ENGLN has a Detection Efficiency (DE) of about 90% for Cloud-to-Ground (CG) strokes over the USA (Marchand et al., 2019). In this work, we use the flash product provided by ENGLN. This product is based on the flash criteria proposed by Liu and Heckman (2011), to

cluster these strokes into flashes, in which two strokes are part of the same flash if they occur in a 0.7 s temporal window and in a 10 km spatial window.

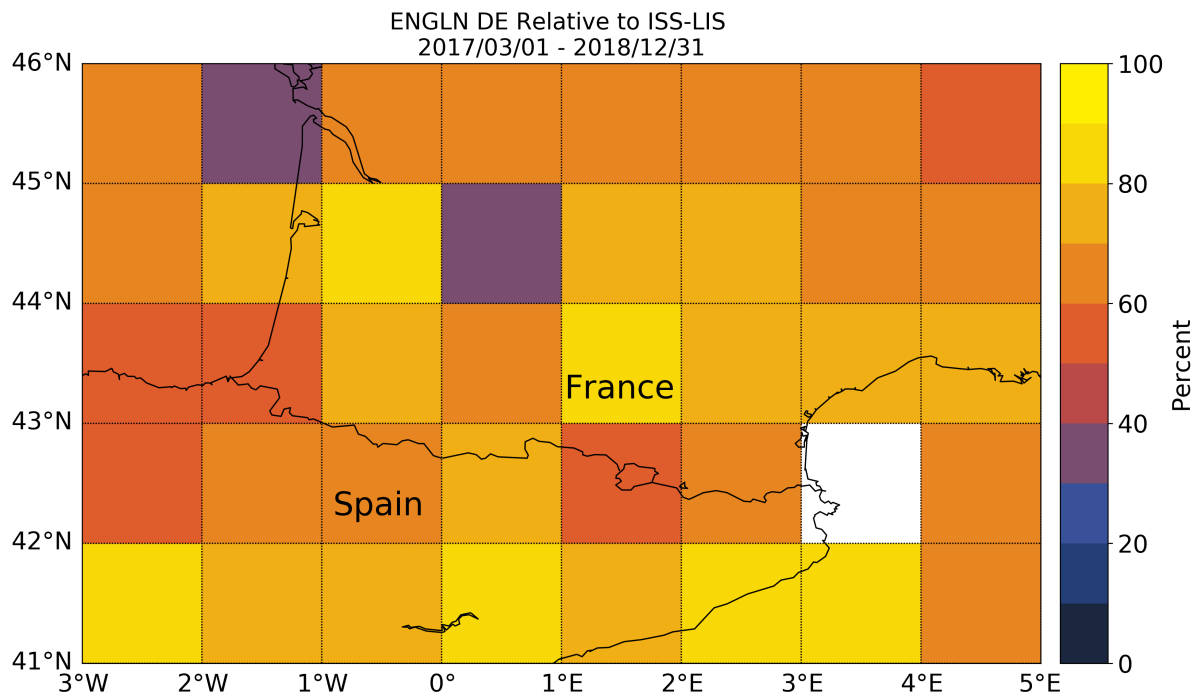

135 We use lightning data from the Lightning Imaging Sensor (LIS) onboard the International Space Station (ISS) (Blakeslee et al., 2020) to estimate the DE of ENGLN over the Pyrenees. ISS-LIS detects optical emissions from lightning with a frame integration time of 1.79 ms with a spatial resolution of 4 km (Bitzer and Christian, 2015; Blakeslee et al., 2020). LIS sorts contiguous events into groups, and clusters groups into flashes with a temporal criteria of 330 ms and a spatial criteria of 5.5 km (Mach et al., 2007). ISS-LIS has a spatially uniform DE of about 60%. We compare ENGLN and ISS-LIS lightning data  
140 over the Pyrenees using the Bayesian approach proposed by Bitzer et al. (2016) with 330 ms and 25 km as the matching criteria. The Bayesian approach is more accurate than direct comparison between lightning data, as neither of the detection systems can be characterized as the truth. We show in Figure 2 the spatial distribution of the obtained ENGLN DE over the Pyrenees. The average DE in this region is  $68 \pm 12\%$  based on 30<sup>th</sup> understorms simultaneously detected over the area by ENGLN and ISS-LIS.

145 EUCLID is a European network composed of 149 lightning sensors manufactured by Vaisala Inc. and distributed over Europe (Schulz et al., 2016). Despite the high DE of EUCLID over Europe, the mean DE of EUCLID over the Pyrenees and the Ebro Valley is only about 30-60% (Poelman and Schulz, 2020) because of the low number of stations over that area and in Africa. We have selected two thunderstorms taking place between April and May 2018 over the Pyrenees and the Ebro Valley that were simultaneously detected by EUCLID and ISS-LIS. We have compared the total number of flashes reported by  
150 EUCLID and ISS-LIS in both thunderstorms, calculating a DE of 0.40 in the Pyrenees and a DE of 0.15 in the Ebro Valley. We use  $27\% \pm 12\%$  as the DE correction for EUCLID. The significant difference between the DE of EUCLID and ENGLN over the Pyrenees represents a good opportunity to investigate the influence of Lightning Location Systems (LSS) DE on the LNO<sub>x</sub> PE.

### 2.3 Meteorological and chemistry data

155 As we will describe in section 2.4, estimating the tropospheric background concentration of NO<sub>x</sub> (NO<sub>x</sub> that is not produced by lightning) is essential for the calculation of LNO<sub>x</sub>. Although the Pyrenees are an area with relatively low background-NO<sub>x</sub> concentration (Vinken et al., 2014), tropospheric background-NO<sub>x</sub> can be transported from the boundary layer to the upper troposphere by convection or advected from the Ebro Valley or the city of Barcelona. Therefore, we cannot neglect the background-NO<sub>x</sub> and have to subtract it from the VCD satellite measurements. To account for this, we use a combination of  
160 meteorological and chemical data as described below.

We use meteorological data provided by the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5-reanalysis data set. In this work, we use the 1-hourly ERA5 horizontal wind averaged between 200 hPa and 500 hPa pressure levels with a horizontal resolution of 0.25°. For each TROPOMI pixel containing lightning flashes prior to the TROPOMI overpass, we use the wind velocity and direction to estimate the advection of LNO<sub>x</sub>. All the pixels that satisfy the deep  
165 convection constraint and that are not influenced by the spreading of LNO<sub>x</sub>, are then considered as non-flashing pixels and employed to estimate the background-NO<sub>x</sub>.

**Figure 2.** Spatial distribution of the ENGLN DE (in %) relative to ISS-LIS between March 2017 and December 2018 over Northern Spain, Southern France and Andorra.

Alternatively, we use airborne measurements to estimate the background-NO. Measurements of  $\text{NO}_x$  over convective systems are rare and there are not previous airborne campaigns over convective systems in the Pyrenees and the Ebro Valley. However, we have found NO measurements over a convective system in the studied area from the In-service Aircraft for a Global Observing System (IAGOS) and from the Civil Aircraft for the Regular Investigation of the Atmosphere Based on an Instrument Container (CARIBIC) NO measurements (Brenninkmeijer et al., 2007). On 22 June, 2005, a CARIBIC flight passed over a convective system in the Pyrenees. Unfortunately, we do not have access to lightning data for that day, only cloud satellite products. However, the measured ratio  $\text{NO}/\text{NO}_y$  can be used to estimate the age of the freshly produced  $\text{NO}_x$  (Huntrieser et al., 2002). The measured ratio of NO to  $\text{NO}_y$  (about 0.1) during the passage over the convective system suggests no impact of fresh  $\text{LNO}_x$ . The measured mixing ratio of CO can be used as a proxy for upward transport of NO from the boundary layer (Huntrieser et al., 2002). Measured simultaneous increases of CO and NO on 22 June, 2005 flight suggest upward transport of polluted boundary layer air, confirming that the airplane passed across a convective system. The measured mixing ratio of NO at 12 km altitude during the passage over the convective system was  $0.3 \pm 0.1$  ppb, in agreement with previous airborne NO measurements over convective systems without lightning in Europe during the EULINOX campaign (Huntrieser et al., 2002).

180 We assume a NO/NO<sub>2</sub> ratio in the upper troposphere of 2 mol mol<sup>-1</sup> (Silvern et al., 2018). Therefore, we use 0.45 ppb as an alternative to the estimation of the background-NO<sub>x</sub> from non-flashing pixels.

We can estimate the VCD of NO<sub>x</sub> using CARIBIC measurement at 12 km. We assume that the shape of the vertical profile of NO<sub>x</sub> of the 22 June, 2005 convective system case is similar to the mean vertical profile of NO<sub>x</sub> reported by Huntrieser et al. (2002) in Europe (Fig. 7a in (Huntrieser et al., 2002)). Using the shape of the EULINOX profile and the CARIBIC  
185 measurement at 12 km, we can estimate the mixing ratio of NO<sub>x</sub> between the surface and 12 km level. Finally, we can integrate the vertical profile to obtain the VCD of NO<sub>x</sub>, resulting in  $0.75 \times 10^{19}$  molec m<sup>-2</sup>.

## 2.4 Calculation of the LNO<sub>x</sub> Air Mass Factor

TROPOMI provides total SCD NO<sub>2</sub>. In the case of cloudy pixels, TROPOMI provides the SCD NO<sub>2</sub> over the cloud top and in the upper parts of the clouds. As we will see in section 2.5, our LNO<sub>x</sub> PE algorithm requires the VCD LNO<sub>x</sub> to be determined  
190 from the SCD NO<sub>2</sub>. The ratio to convert SCD NO<sub>2</sub> to VCD LNO<sub>x</sub> is called the AMF<sub>LNO<sub>x</sub></sub> and its calculation requires a priori estimations of the mean LNO<sub>2</sub> and LNO<sub>x</sub> profiles over the studied region (Pickering et al., 2016) and of the absorption of the atmosphere (Beirle et al., 2009; Bucseala et al., 2013). The AMF<sub>LNO<sub>x</sub></sub> is obtained by calculating the scattering weights for each of the eight studied cases using the viewing geometry and the cloud properties for each pixel. It is important to note that a conversion of NO<sub>2</sub> SCD into NO<sub>2</sub> VCDs using an overall AMF followed by a conversion of VCD NO<sub>2</sub> into VCD NO<sub>x</sub>  
195 using a mean NO<sub>2</sub> to NO<sub>x</sub> ratio is not appropriate, as explained by Beirle et al. (2009).

We employ the ECMWF – Hamburg (ECHAM)/Modular Earth Submodel System (MESSy version 2.54.0) Atmospheric Chemistry (EMAC) model (Jöckel et al., 2016) to extract the mean LNO<sub>2</sub> and LNO<sub>x</sub> profiles over the studied area by performing two simulations (with and without lightning). We perform the simulations following the Quasi Chemistry-Transport Model (QCTM) mode proposed by Deckert et al. (2011). Firstly, we perform a one year global simulation (January 1, 2018 to  
200 January 1, 2019) without lightning nudged towards ERA-Interim reanalysis meteorological fields. Secondly, we perform a second simulation with lightning for the same period using numerically identical meteorological fields as the simulation without lightning. The QCTM mode decouples the dynamics from the chemistry in order to operate the model as a chemistry-transport model, implying that small chemical perturbations do not alter the simulated meteorology by introducing noise (Deckert et al., 2011). The simulations are conducted in T42L90MA resolution, i.e. with a quadratic Gaussian grid of 2.8° × 2.8° in latitude  
205 and longitude with 90 vertical levels reaching up to the 0.01 hPa pressure level and with 720 s time steps (Jöckel et al., 2016). LNO<sub>x</sub> is calculated by using the MESSy submodel LNOX (Tost et al., 2007). Lightning is parameterized according to the updraft velocity (Grewe et al., 2001) and using a scaling factor that ensures a global lightning occurrence rate of ~45 flashes per second (Christian et al., 2003; Cecil et al., 2014). We set the production of NO<sub>x</sub> per flash following Price et al. (1997) and employ the C-shaped vertical profiles of LNO<sub>x</sub> reported by Pickering et al. (1998). We use the same chemical setup and  
210 chemical mechanism as described by Jöckel et al. (2016) for RC1 simulations.

We extract the vertical profiles of NO and NO<sub>2</sub> with and without lightning for May 2018 coincident with the TROPOMI overpass time to calculate the LNO<sub>2</sub> and LNO<sub>x</sub> vertical profiles. We obtain that the day in May 2018 with the highest LNO<sub>x</sub> column density is May 13, 2018. Figure 3 shows the vertical profiles obtained from the EMAC simulations. Both LNO<sub>x</sub> and

LNO<sub>2</sub> vertical profiles peak between 300 hPa and 250 hPa pressure levels (between ~9 and 11 km altitude), while the vertical profiles of LNO<sub>x</sub> and LNO<sub>2</sub> calculated by Pickering et al. (2016) over the Gulf of Mexico peak at about 150 hPa. The reason for this difference is that thunderstorms are taller at sub-tropical latitudes than at mid-latitudes. Non-negligible values of LNO<sub>x</sub> and LNO<sub>2</sub> values between 100 and 200 hPa (Figure 3) may have been transported to the Pyrenees from tropical latitudes.

We use the LNO<sub>2</sub> and LNO<sub>x</sub> vertical profiles from the simulations to calculate the  $AMF_{LNO_x}$  following Bucsele et al. (2013). We use the TOMRAD forward vector radiative transfer model (Dave, 1965) to calculate the scattering weights for each of the 8 studied cases using the viewing geometry and the cloud properties for each pixel, which depend on the TROPOMI cloud product. We obtained  $AMF_{LNO_x}$  values ranging between 0.28 and 0.71.

## 2.5 Calculation of the LNO<sub>x</sub> PE

We use the TROPOMI LNO<sub>x</sub> PE method proposed by Allen et al. (2021a). Figure4 shows an overview graphic indicating the variables that are included in the calculation of LNO<sub>x</sub> PE, while Appendix 5 indicates the list of acronyms. The source of these variables are TROPOMI products, lightning data, simulations and parameters that are introduced based on literature. The LNO<sub>x</sub> PE is calculated as

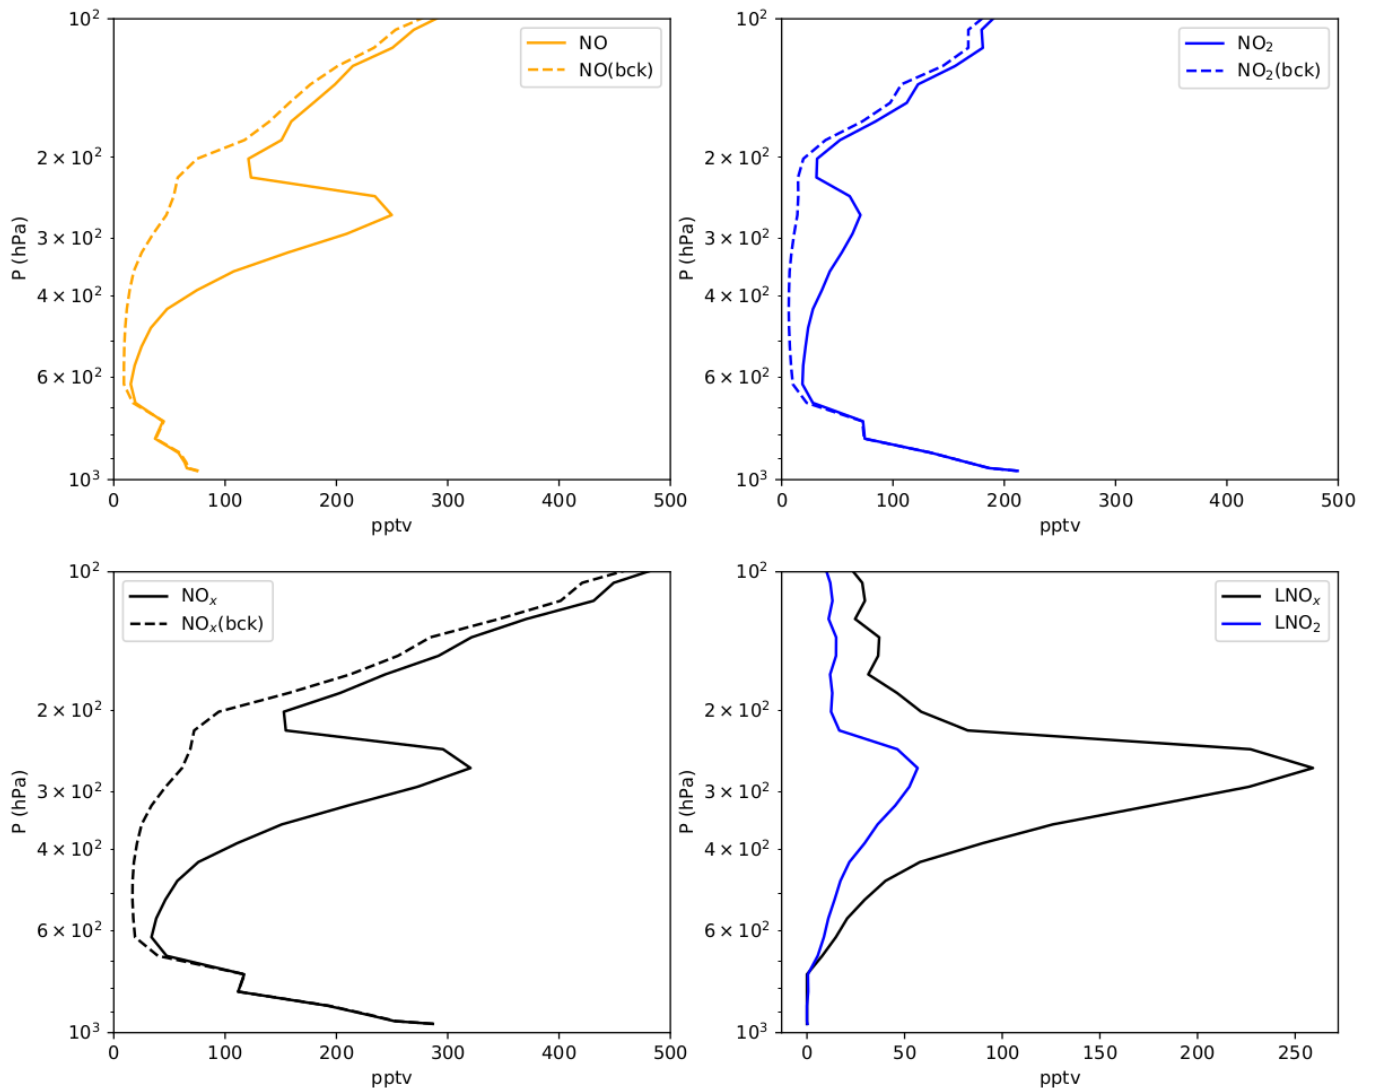

$$PE = [V_{tropLNO_x} \times A] / \left[ N_A \times DE^{-1} \sum_i (\exp(-t_i/\tau)) \right], \quad (1)$$

where  $PE$  are the moles of NO<sub>x</sub> produced per flash,  $V_{tropLNO_x}$  is the tropospheric column of NO<sub>x</sub> produced by recent lightning (molec cm<sup>-2</sup>) and that is calculated from the TROP-NO<sub>2</sub>,  $A$  is the area (cm<sup>-2</sup>) of the thunderstorm with deep convection or with undefined OCP,  $N_A$  is the Avogadro's number (molec mol<sup>-1</sup>),  $DE$  is the detection efficiency of ENGLN or EUCLID and  $\tau$  is the lifetime of NO<sub>x</sub> in the near field of convection, assumed as 3 hours (Nault et al., 2017; Allen et al., 2021a). The lifetime is uncertain and can vary between 2 hours and 2 days (e.g., Pickering et al., 1998; Beirle et al., 2010; Nault et al., 2017, and references therein), as it depends on the height where LNO<sub>x</sub> is emitted, the proximity to deep convection and how it is transported by convection in each particular thunderstorm.  $t_i$  is the age of individual flashes at the time of the overpass (the time since the flash occurred) and  $F$  is the total number of flashes 5 hours prior to the TROPOMI overpass of each pixel. We use a 5 h flash window because it is larger than the assumed 3 hours lifetime of NO<sub>x</sub> in the near field of convection. Sensitivity studies using other flash windows are performed in Section 3.3.  $V_{tropLNO_x}$  is calculated as

$$V_{tropLNO_x} = Median(\mathbf{V}_{tropNO_x}) - V_{tropbck}, \quad (2)$$

where  $\mathbf{V}_{tropNO_x}$  is the vector containing the VCD NO<sub>x</sub> over pixels with deep convection or with undefined cloud fraction and  $V_{tropbck}$  is the background-NO<sub>x</sub>. We use the median instead of the mean of  $\mathbf{V}_{tropNO_x}$  in order to remove the influence of possible outlier pixels.  $\mathbf{V}_{tropNO_x}$  is defined as

$$\mathbf{V}_{tropNO_x} = [\mathbf{S}_{NO_2} - avg(\mathbf{V}_{stratNO_2} \times AMF_{strat})] / AMF_{LNO_x}, \quad (3)$$

**Figure 3.** Vertical mixing ratio profiles of NO (upper left panel), NO<sub>2</sub> (upper right panel), NO<sub>x</sub> (lower left panel), LNO<sub>x</sub> and LNO<sub>2</sub> (lower right panel) extracted from EMAC simulations with (solid lines) and without (dashed lines) lightning (background: bck) on 13 May, 2018 at 12 h LT (close to the TROPOMI overpass).

where  $\mathbf{S}_{\text{NO}_2}$  is the vector containing the SCD of NO<sub>2</sub>,  $\mathbf{V}_{\text{stratNO}_2}$  is the vector containing the stratospheric VCD of NO<sub>2</sub> and  $\mathbf{AMF}_{\text{strat}}$  is the vector of stratospheric AMF. As previously explained by Allen et al. (2021a), values of  $\mathbf{V}_{\text{stratNO}_2}$  and  $\mathbf{AMF}_{\text{strat}}$  are sometimes missing over pixels affected by deep convection. Therefore, using the average  $\mathbf{V}_{\text{stratNO}_2} \times \mathbf{AMF}_{\text{strat}}$  product increases the number of pixels available to estimate  $V_{\text{tropNO}_x}$ .

Following Allen et al. (2021a), we calculate  $V_{\text{tropbck}}$  as the 30<sup>th</sup> and the 10<sup>th</sup> percentile of  $\mathbf{V}_{\text{tropNO}_x}$  over non-flashing pixels with deep convection. These percentiles are in agreement with airborne measurements during the EULINOX campaign

**Figure 4.** Overview graphic showing the variables that are included in the calculation of LNO<sub>x</sub> PE.

(Huntrieser et al., 2002). Alternatively, we calculate the background as the mean  $V_{tropNO_x}$  concentration averaged over three  
 250 days with low lightning activity over the Pyrenees from TROPOMI data and using CARIBIC measurements in a convective  
 system with low lightning activity over the Pyrenees (as described in section 2.3). Several events are outside the Pyrenees,  
 with considerably higher background NO<sub>x</sub>. Thus, the local tropospheric background estimate over the clean Pyrenees can be  
 considered as a lower limit.

## 2.6 Calculation of the background-NO<sub>x</sub> based on days with low lightning activity

255 Apart from calculating the background-NO<sub>x</sub> from non-flashing pixels in a case-based approach, we have selected three cases  
 with low lightning activity before the TROPOMI overpass to estimate the mean background-NO<sub>x</sub> over convective systems.  
 In particular, we have used TROPOMI measurements on 8 April, 12 April and 13 April 2018 in the region between 41°N -  
 45°N degrees latitude and 3°W - 5°E degrees longitude. The total number of lightning flashes 3 hour prior to the TROPOMI  
 overpass for the three studied cases were 149, 65 and 50, respectively. The mean  $V_{tropNO_x}$  during these days using the TROP-  
 260 KNMI research product were  $1.07 \times 10^{19}$  molec m<sup>-2</sup>,  $1.98 \times 10^{19}$  molec m<sup>-2</sup> and  $0.39 \times 10^{19}$  molec m<sup>-2</sup>, while the  
 $V_{tropNO_x}$  using the TROP-DLR research product were  $0.37 \times 10^{19}$  molec m<sup>-2</sup>,  $1.00 \times 10^{19}$  molec m<sup>-2</sup> and  $-0.5 \times 10^{19}$   
 molec m<sup>-2</sup>. Negative values suggest that the average stratospheric column is exceeding the local vertical column (eq. (3)) or  
 the tropospheric background is exceeding the signal (eq. (2)). The average background  $V_{tropNO_x}$  for the TROP-KNMI and the

TROP-DLR research products were, respectively,  $1.06 \times 10^{19}$  molec  $m^{-2}$ , and  $0.37 \times 10^{19}$  molec  $m^{-2}$ . These estimates are, respectively, slightly above and below the background VCD of  $NO_x$  estimated using CARIBIC measurements ( $0.75 \times 10^{19}$  molec  $m^{-2}$ ).

### 3 Results

In this section we present  $LNO_x$  estimates for eight selected cases. We describe the TROPOMI product for the selected cases in Section 3.1. The  $LNO_x$  PE estimates are presented in Sections 3.2, while a sensitivity analysis of the results is discussed in Section 3.3.

#### 3.1 Selected case studies

The eight selected cases correspond to eight thunderstorms that were active no more than 5 hours before the TROPOMI overpass on the following days: 29 April, 7 May, 12 May, 21 May, 22 May, 26 May, 28 May and 30 May 2018. Unfortunately, the TROP-DLR research product was not available for the case on 30 May 2018 because the raw data files are missing. In addition, the thunderstorm taking place on 26 May 2018 had a significant lightning activity between  $45^\circ N$  and  $46^\circ N$ , but we do not have access to EUCLID data north of  $45^\circ N$ .

Figure 5 shows the ENGLN lightning data and some of the variables from the TROP-DLR product for the case 29 April 2018. Figure 6 is similar to Figure 5 but instead showing EUCLID lightning data and some of the variables from the TROP-KNMI product. Lightning activity is distributed between the Ebro Valley, the Pyrenees and the French coast.

The upper left panels of Figures 5 and 6 show the position of lightning flashes and the calculated VCD  $NO_x$  in pixels with deep convection. A comparison of the upper left maps of Figures 5 and 6 shows that there are more lightning flashes reported by ENGLN than by EUCLID. The upper right panels show the SCD- $NO_2$  for each of the used TROPOMI products, indicating that there are not significant differences between them. Areas with high lightning activity coincide with areas with high SCD- $NO_2$ , suggesting that the  $LNO_x$  signal is detectable by TROPOMI. There are also high SCD- $NO_2$  values near the city of Barcelona, a highly populated area producing high emissions of  $NO_x$ . However, pixels near Barcelona do not satisfy the deep convective constraint.

The center left and right panels show the stratospheric VCD of  $NO_2$  and the calculated  $AMF_{LNOX}$ , respectively. The  $VCD_{stratNO_2}$  from the TROP-DLR product is slightly larger than from the TROP-KNMI product, while both, the stratospheric VCD of  $NO_2$  and the stratospheric AMF of  $NO_2$ , are more homogeneous for the TROP-DLR product than for the TROP-KNMI product. The method to separate the contribution of the troposphere and stratosphere to the  $NO_2$  column density are different for each product, which can affect the spatial distribution of the  $VCD_{stratNO_2}$  and the  $AMF_{stratNO_2}$ . The TROP-KNMI  $NO_2$  product uses a priori chemical profiles from the chemistry transport model TM5-MP (Myriokefalitakis et al., 2020), while the TROP-DLR  $NO_2$  product uses the DSTREAM method to separate the contribution of the troposphere and stratosphere to the  $NO_2$  column density (Liu et al., 2021b), (see section 2). Inhomogeneities in the TROP-KNMI product are due to jumps in the tropopause level associated with thunderstorms (Pan et al., 2014). The TROP-KNMI product uses

the temperature of the tropopause, which may jump up and down by a few levels linked to horizontal changes in temperature gradients. The STREAM model used in the TROP-DLR product will absorb free tropospheric NO<sub>2</sub> into the stratosphere, while the free tropospheric background may be larger in the TM5-MP model which is used to estimate the stratospheric column in the TROP-KNMI product (Boersma et al., 2018). As the obtained values of AMF are different for each product because they  
300 depend on the cloud information.

Finally, the lower panels show that there are not significant differences between the cloud products, except for some pixels in which the TROP-DLR product estimates larger cloud fractions. The existence of more pixels with high cloud fractions in the TROP-DLR product than in the TROP-KNMI product can influence the total number of pixels labeled as cloud convective pixels. The values of AMF<sub>LNO<sub>x</sub></sub> for each product differ because they depend on details of the cloud product.

305 We present in Figures 7 and 8 similar plots for the case 7 May. As in the case 29 April, lightning activity is distributed between the Ebro Valley, the Pyrenees and the French coast. Areas with high lightning activity coincide with areas with high SCD-NO<sub>2</sub>, while there are also high SCD-NO<sub>2</sub> values near the city of Barcelona. We can see the same differences between the TROP-KNMI and the TROP-DLR products as in the case 29 April. Figures 9 and 10 show plots for the case 28 May 2018. In this case, lightning activity is limited to the Ebro valley and the Pyrenees. There is a profuse LNO<sub>x</sub> signal in the  
310 SCD-NO<sub>2</sub> map. The stratospheric VCD of NO<sub>2</sub> and the stratospheric AMF of NO<sub>2</sub> provided by the TROP-KNMI product are more homogeneous than in the previous two cases. The rest of the cases analyzed in this study are plotted in the Supplement.

Figure 11 shows the velocity and direction of the horizontal wind averaged between the 200 hPa and 500 hPa pressure levels for the cases on 29 April, 7 May and 28 May, 2018. The average of the wind velocity is calculated with the values provided by ERA5 on the pressure levels 200 hPa, 250 hPa, 300 hPa, 350 hPa, 400 hPa, 450 hPa and 500 hPa. On 29 April,  
315 2018 strong southerly winds could have transported LNO<sub>x</sub> to the north, which is in agreement with the relative position of flashes and pixels with high concentration of NO<sub>2</sub> as shown in Figures 6 and 5. On 7 May, 2018 northeasterly winds could have transported LNO<sub>x</sub> to the southwest according to the location of the flashes, in agreement with Figures 7, 8. Finally, the wind velocity was weak on 28 May, 2018 and transport of lightning NO<sub>x</sub> from the the flash positions is unlikely, in agreement with Figures 9 and 10. We have calculated the Pearson correlation coefficient ( $r$ ) between the SCD of NO<sub>2</sub> in convective cells  
320 with flashes and the total number of flashes reported by ENGLN in each cell averaged over all the studied cases. We have obtained  $r = 0.18$  for TROP-DLR and  $r = 0.11$  for TROP-KNMI. These values indicate a positive correlation between the SCD of NO<sub>2</sub> and flashes that is larger for the case of TROP-DLR than for TROP-KNMI. This correlation is larger when we use the tropospheric winds to identify the cells that have been influenced by LNO<sub>x</sub>. We have copied each flash to the cells that are influenced by the LNO<sub>x</sub> produced by the flash with the purpose of calculating the upwind correlation coefficient by taking  
325 into account the transport of LNO<sub>x</sub>. With that we obtain  $r = 0.20$  for TROP-DLR and  $r = 0.15$  for TROP-KNMI. The received larger correlation coefficients indicate that accounting for the transport of LNO<sub>x</sub> can improve the estimation of LNO<sub>x</sub> PE.

### 3.2 LNO<sub>x</sub> PE estimates

In this section, we present the LNO<sub>x</sub> PE estimates for the selected cases using two different methods to estimate the background-NO<sub>x</sub>. The first method (subsection 3.2.1) is exclusively based on case by case TROPOMI measurements, as it uses non-flashing

330 pixels with deep convection to estimate the background- $NO_x$ . The second method (subsection 3.2.2) uses fixed values for the background- $NO_x$  from measurements over days with low lightning activity.

### 3.2.1 $LNO_x$ PE estimates using non-flashing pixels to estimate the background- $NO_x$

In this section, we present the  $LNO_x$  PE estimates for the selected cases by using the 30<sup>th</sup> and the 10<sup>th</sup> percentile of  $V_{tropNO_x}$  over non-flashing pixels with deep convection as background- $NO_x$  estimations. Table 1 shows the results for eight cases in the Pyrenees using the described method and the TROP-KNMI research product, while Table 2 shows the results using the TROP-DLR research product. Here we have used a 5 h time window before the TROPOMI overpass and a chemical lifetime of  $NO_x$  ( $\tau$ ) of 3 h for all the cases shown in these tables. We have chosen these values for the flash window and  $\tau$  as reference values to show the  $LNO_x$  estimates in Table 1. However, later in Section 3.3, we perform a sensitivity analysis using different values for flash window and  $\tau$ . The case-based averaged age of individual flashes ranges between 0.9 hours for 7 May and 2.3 hours for 26 May.

In this section, we present the  $LNO_x$  PE estimates for the selected cases using two different methods to estimate the background- $NO_x$ . The first method (subsection 3.2.1) is exclusively based on case by case TROPOMI measurements, as it uses non-flashing pixels with deep convection to estimate the background- $NO_x$ . The second method (subsection 3.2.2) uses fixed values for the background- $NO_x$  from measurements over days with low lightning activity.

345 Columns 1 and 2 show the date and thunderstorm region of each studied case and some mean values, respectively. Column 3 shows the total number of lightning flashes reported by ENGLN/EUCLID 5 h before the TROPOMI overpass without application of a DE. The total number of flashes reported by ENGLN is always larger than reported by EUCLID. Minor differences in the total number of flashes between both TROPOMI products (compare Tables 1 and 2) are due to minor differences in the product grids.

350 Column 4 shows the OCP averaged for all lightning flashes reported by ENGLN. Significant differences are obtained between the cases. As lower limit, we obtain 339 hPa from the TROP-DLR research product for 7 May case, while we obtain an upper limit of 629 hPa from the TROP-KNMI research product for the 12 May case. The mean OCP values for the TROP-KNMI and the TROP-DLR products are 527 hPa and 491 hPa, respectively. These values do not coincide with mean OCP values showed in Fig. 1 because they correspond to the mean OCP per lightning flash instead of to the mean OCP value per  
355 pixel. As a consequence, the mean OCP values showed in Column 4 are dominated by pixels with high lightning activity. The OCP values depend on the intensity of convection in each thunderstorm as well as on the phase of the thunderstorm during the TROPOMI overpass (Emersic et al., 2011).

Columns 5 and 6 of Tables 1 and 2 show the median tropospheric VCD of  $NO_x$  ( $V_{tropNO_x}$ ) and the mean product of the stratospheric VCD of  $NO_2$  ( $V_{stratNO_2}$ ) times the AMF strat over pixels with deep convection, respectively. Higher values of  
360  $V_{stratNO_2}$  and the product of  $V_{stratNO_2}$  times AMF strat for the TROP-DLR research product compared to the TROP-KNMI product can be seen for all cases, except for the case on 30 May. As described in section 2.5,  $V_{tropNO_x}$  is calculated by using a subtraction between the SCD of  $NO_2$  and  $V_{stratNO_2}$ . As  $V_{stratNO_2}$  is larger for the TROP-DLR research product, we receive lower values of  $V_{tropNO_x}$  than for the TROP-KNMI research product.

Column 7 shows the mean  $AMF_{LNO_x}$  over pixels with deep convection for each case. The value of  $AMF_{LNO_x}$  ranges between 0.34 and 0.80, while the averaged values for the TROP-KNMI and TROP-DLR products are 0.50 and 0.54, respectively.  
365 These values are in agreement with typical values reported by Allen et al. (2021a) for thunderstorms observed by TROPOMI over the U.S. ( $0.41 \pm 0.10$ ) and are similar as the averaged  $AMF_{LNO_x}$  value in thunderstorms (0.46) reported by Beirle et al. (2009) over the Pacific.

Background- $NO_x$  values as the 30<sup>th</sup> and the 10<sup>th</sup> percentile of  $V_{tropNO_x}$  over non-flashing pixels with deep convection  
370 ( $V_{tropbck}$ ) are shown in column 8. As in the case of  $V_{tropNO_x}$ , we receive lower values of  $V_{tropbck}$  for TROP-DLR than for the TROP-KNMI research product. Despite similarities in the SCD  $NO_2$  from both products, higher  $V_{stratNO_2}$  values in the TROP-DLR product produce lower values in  $V_{tropbck}$  after the subtraction of the stratospheric contribution. There are even some negative values, suggesting that the average stratospheric column exceeds the local vertical column (eq. (3)) or the tropospheric background exceeds the signal (eq. (2)).  $V_{tropbck}$  values show a large variability, although the mean values are of  
375 the same order as the background estimated from CARIBIC measurements ( $0.75 \times 10^{19}$  molec  $m^{-2}$ ) and from TROPOMI

measurements over convective systems with low lightning activity ( $1.06 \times 10^{19}$  molec  $m^{-2}$  for the TROP-KNMI product and  $0.37$  molec  $cm^{-2}$  for the TROP-DLR research product), as detailed in Section 2.6.

The  $LNO_x$  PE for each case using ENGLN and EUCLID lightning data are shown in column 9 and 10 of Tables 1 and 2, respectively. We have used the standard deviation over all cases in order to estimate the error of the mean PE. We can see a  
380 factor of  $\sim 2$  difference between the  $LNO_x$  PE using different backgrounds for most of the cases, indicating that the method to estimate the background introduces a significant uncertainty of the results. Using the TROP-KNMI research product, we obtain lower  $LNO_x$  PE for ENGLN than for EUCLID ( $47 \pm 33$  mol  $NO_x$  per flash vs  $69 \pm 34$  mol  $NO_x$  per flash). On the contrary, we obtain slightly higher  $LNO_x$  PE for ENGLN than for EUCLID when using the TROP-DLR product ( $58 \pm 33$  mol  $NO_x$  per flash vs  $51 \pm 25$  mol  $NO_x$  per flash). The mean  $LNO_x$  PE values averaged over ENGLN and EUCLID for the TROP-KNMI  
385 and the TROP-DLR products are 58 and 54.5 mol  $NO_x$  per flash, respectively. The  $LNO_x$  PE value using the TROP-KNMI product is then higher than the value using the TROP-DLR product. We suggest that this slight difference is caused by the higher stratospheric VCD  $NO_2$  value in the TROP-DLR product.

The standard deviations of the  $LNO_x$  PE derived from the TROP-DLR and the TROP-KNMI products are rather similar, suggesting that the variability in the column densities of  $NO_2$  provided by the TROP-DLR  $NO_2$  product is similar to the  
390 variability provided by the TROP-KNMI product.

The average number of pixels with deep convection and satisfying the quality criterion using the TROP-KNMI product is 370, while it is 758 for the TROP-DLR product. This difference is a consequence of the cut-off employed for both the retrieved cloud fraction and OCP. The cloud fraction over the studied cases is about 30% larger for the TROP-DLR product than for the TROP-KNMI product, while the OCP is about 10% lower for the TROP-DLR product than for the TROP-KNMI product,  
395 leading to more pixels with deep convection in the case of TROP-DLR product than in the case of TROP-KNMI product. We have found that using 650 hPa as OCP threshold for the TROP-KNMI product instead of 523 hPa produces a similar total number of pixels with deep convection and satisfying the quality criterium using the TROP-KNMI and the TROP-DLR products. This change in the OCP threshold for the TROP-KNMI product produces a change of only +14% in the  $LNO_x$  PE estimates, as more pixels with low convection would be included in the estimation of the background- $NO_x$ .

### 400 3.2.2 $LNO_x$ PE estimates using fixed background- $NO_x$ values

Let us now estimate the average  $LNO_x$  PE over all cases using the background- $NO_x$  based on days with low lightning activity as calculated in Section 2.6. Instead of using the  $V_{tropbck}$  values of Tables 1 and 2, we use  $1.06 \times 10^{19}$  molec  $m^{-2}$ , and  $0.37 \times 10^{19}$  molec  $m^{-2}$  for estimations of the  $LNO_x$  PE based on the TROP-KNMI and the TROP-DLR research products, respectively. We obtain  $86 \pm 63$  mol  $NO_x$  per flash by using the TROP-KNMI product with ENGLN lightning data,  $160 \pm$   
405  $102$  mol  $NO_x$  per flash by using the TROP-KNMI product with EUCLID lightning data. These values are larger than the mean  $LNO_x$  PE using non-flashing pixels ( $47 \pm 33$  and  $69 \pm 34$  mol  $NO_x$  per flash). By using the background- $NO_x$  based on days with low lightning activity, we calculate  $44 \pm 61$  mol  $NO_x$  per flash by using the TROP-DLR product with ENGLN lightning data and  $53 \pm 59$  mol  $NO_x$  per flash using the TROP-DLR product with EUCLID lightning data. The  $LNO_x$  PE estimates based on the TROP-DLR product for the two cases of 7 May and 12 May are negative when using the background- $NO_x$ .

410 based on days with low lightning activity, causing lower values of LNO<sub>x</sub> PE and larger standard deviations than using the TROP-KNMI product. These values are in agreement with the mean LNO<sub>x</sub> PE using non-flashing pixels ( $58 \pm 33$  and  $51 \pm 25$  mol NO<sub>x</sub> per flash). We calculate the average LNO<sub>x</sub> PE over all cases by using the background-NO<sub>x</sub> estimated from CARIBIC measurements ( $0.75 \times 10^{19}$  molec m<sup>-2</sup>), as described in Section 2.6. We obtain  $96 \pm 67$  mol NO<sub>x</sub> per flash using the TROP-KNMI product with ENGLN lightning data,  $176 \pm 108$  mol NO<sub>x</sub> per flash using the TROP-KNMI product with  
415 EUCLID lightning data. These values are larger than the mean LNO<sub>x</sub> PE using non-flashing pixels ( $47 \pm 33$  and  $69 \pm 34$  mol NO<sub>x</sub> per flash). Finally,

We calculate the average LNO<sub>x</sub> PE over all cases by using the background-NO<sub>x</sub> estimated from CARIBIC measurements ( $0.75 \times 10^{19}$  molec m<sup>-2</sup>), as described in Section 2.6. We obtain  $96 \pm 67$  mol NO<sub>x</sub> per flash using the TROP-KNMI product with ENGLN lightning data,  $176 \pm 108$  mol NO<sub>x</sub> per flash using the TROP-KNMI product with EUCLID lightning data.  
420 These values are larger than the mean LNO<sub>x</sub> PE using non-flashing pixels ( $47 \pm 33$  and  $69 \pm 34$  mol NO<sub>x</sub> per flash). Finally, we calculate  $17 \pm 48$  mol NO<sub>x</sub> per flash by using the TROP-DLR product with ENGLN lightning data and  $34 \pm 74$  mol NO<sub>x</sub> per flash using the TROP-DLR product with EUCLID lightning data. Again, the standard deviation of the TROP-DLR LNO<sub>x</sub> PE using a fixed value as background-NO<sub>x</sub> mixing ratio is lower than in the previous cases, as a consequence of low VCD NO<sub>x</sub> of the cases 12 May and 7 May. The LNO<sub>x</sub> PE estimates using the TROP-DLR product are negative because the  
425 tropospheric VCD of NO<sub>x</sub> is lower than the CARIBIC-based estimated background-NO<sub>x</sub> (fourth column in Table 2). The obtained TROP-DLR values are lower than the mean LNO<sub>x</sub> PE using non-flashing pixels ( $58 \pm 33$  and  $51 \pm 25$  mol NO<sub>x</sub> per flash).

Given that the standard deviation of the received LNO<sub>x</sub> PE estimates by using fixed values of the background-NO<sub>x</sub> are larger than the means for the TROP-DLR product, we conclude that using fixed values for the background is not adequate in  
430 this case-based study. This is a consequence of the observed large variability of the tropospheric VCD of NO<sub>x</sub> for each studied thunderstorms. Fixed background values could be useful to estimate the mean LNO<sub>x</sub> PE over a number of case studies but less useful to individual case studies.

### 3.3 Sensitivity analysis and uncertainties

In this section we discuss the most important uncertainties in the estimation of LNO<sub>x</sub> PE presented in section 3.2.1. We  
435 calculate the uncertainty associated with each parameter by comparing the maximum and the minimum received LNO<sub>x</sub> PE values to the mean of the value for the possible choices of that parameter.

Let us begin by discussing the contribution of the employed lightning data to the uncertainty of the LNO<sub>x</sub> PE estimates. The mean LNO<sub>x</sub> PE of both TROPOMI products (KNMI and DLR) by using ENGLN lightning data is 52.5 mol NO<sub>x</sub> per flash, while it is 60 mol NO<sub>x</sub> per flash using EUCLID lightning data. Therefore, the uncertainty introduced by different lightning  
440 data sets is 7%. We have calculated the T-test for the means of the LNO<sub>x</sub> PE estimates when using ENGLN and EUCLID lightning data, obtaining a p-value of 0.43. Therefore, we conclude that differences in LNO<sub>x</sub> PE using ENGLN and EUCLID are not statistically significant based on the T-test for the means. It is important to mention that the statistical significance is influenced by the population of the sample.

The LNO<sub>x</sub> PE estimates by using different TROPOMI products (KNMI versus DLR) are not similar, as obtained in section 3.2.1. There is a 23% difference between the LNO<sub>x</sub> PE estimates using both TROPOMI products and ENGLN lightning data, and a 35% difference when using EUCLID lightning data. The difference is reduced when using only ENGLN lightning data, whose DE is higher than for EUCLID. The total uncertainty introduced by the choice of the TROPOMI product based on the means LNO<sub>x</sub> PE per flash between ENGLN and EUCLID lightning data is only 3%. We obtain a p-value of 0.44 by calculating the T-test for the means of the LNO<sub>x</sub> PE estimates when using TROP-KNMI and TROP-DLR, indicating that differences in LNO<sub>x</sub> PE using different TROPOMI products are not statistically significant.

As shown in Tables 1 and 2, the estimation of the background-NO<sub>x</sub> as the 30<sup>th</sup> or as the 10<sup>th</sup> percentile of  $V_{tropNO_x}$  over non-flashing pixels with deep convection can significantly influence the LNO<sub>x</sub> PE estimates. The average LNO<sub>x</sub> PE between both TROPOMI products using the 30<sup>th</sup> percentile of  $V_{tropNO_x}$  is 42 mol NO<sub>x</sub> per flash, while it is 70 mol NO<sub>x</sub> per flash using the 10<sup>th</sup> percentile of  $V_{tropNO_x}$ . Therefore, the choice of the background-NO<sub>x</sub> method contributes to the uncertainty of 29%. The p-value obtained by calculating the T-test for the means of the LNO<sub>x</sub> PE estimates by using the 30<sup>th</sup> or the 10<sup>th</sup> percentile of  $V_{tropNO_x}$  over non-flashing pixels with deep convection as background-NO<sub>x</sub> is lower than 0.05, which indicates that differences in LNO<sub>x</sub> PE using different methods to estimate the background-NO<sub>x</sub> products are statistically significant.

The DE of the used LLS can also contribute to the uncertainty of the LNO<sub>x</sub> PE estimates. As explained in section 2.2, we obtain a DE for ENGLN over the Pyrenees of  $0.676 \pm 0.12$  (ranging between 0.556 and 0.769). The obtained mean LNO<sub>x</sub> PE using both TROPOMI products and a DE of 0.769 is 59 mol NO<sub>x</sub> per flash, while it is 43 mol NO<sub>x</sub> per flash when using a DE of 0.556. Therefore, the uncertainty of the DE of ENGLN contributes to a LNO<sub>x</sub> PE uncertainty of 17%. For EUCLID, we obtain a DE of  $0.27 \pm 0.12$ . The obtained mean LNO<sub>x</sub> PE using EUCLID data corrected by a DE of 0.40 is 86 mol NO<sub>x</sub> per flash, while it is 33 mol NO<sub>x</sub> per flash when using a DE of 0.15. Therefore, the uncertainty of the DE of EUCLID contributes to a LNO<sub>x</sub> PE uncertainty of 62%. The contribution of the DE of EUCLID to the uncertainty is higher than the contribution of the DE of ENGLN because the DE of EUCLID is significantly lower than the DE of ENGLN.

The lifetime of NO<sub>x</sub> in the near field of convection ( $\tau$ ) is another parameter that can introduce uncertainty to the LNO<sub>x</sub> PE estimates. We have used 3 h, but it can vary between 2 and several days (Penner et al., 1998; Nault et al., 2017; Allen et al., 2021a). Nault et al. (2017) reinterpreted previous analyses of the lifetime of NO<sub>x</sub> in the near field of convection from the Deep Convective Clouds and Chemistry (DC3) by including rapid CH<sub>3</sub>O<sub>2</sub>NO<sub>2</sub> and alkyl and multifunctional nitrates (ANs) and reported that it can vary between 2 h and 12 h. Based on the recent estimations from Nault et al. (2017), we have performed the LNO<sub>x</sub> PE calculations using the TROPOMI products and ENGLN lightning data and setting  $\tau = 12$  h as an upper limit keeping the time windows used at 5 h, obtaining a mean LNO<sub>x</sub> PE of 38 mol NO<sub>x</sub> per flash. Given that the LNO<sub>x</sub> PE with  $\tau = 3$  h is 52.5 mol NO<sub>x</sub> per flash, we estimate that  $\tau$  contributes to the uncertainty of the LNO<sub>x</sub> PE by about 18%.

The *time window before the TROPOMI overpass*, that is used to count the total number of lightning flashes contributing to freshly produced LNO<sub>x</sub>, can also be a source of uncertainty. We have calculated the LNO<sub>x</sub> PE estimates using a time window of 1 h instead of 5 h in order to get an estimation of the uncertainty introduced by the time window. We receive 88 mol NO<sub>x</sub> per flash as the mean value by using the TROP-KNMI and the TROP-DLR products and ENGLN lightning data. The LNO<sub>x</sub> PE estimations uses the same TROPOMI products and lightning data with a time window of 5 h was 52.5 mol NO<sub>x</sub> per flash.

**Table 3.** Sources of differences in the mean LNO<sub>x</sub> PE estimates.

Source of difference	Influence on the LNO <sub>x</sub> PE estimate
Lightning data set (ENGLN or EUCLID)	7%
TROPOMI product (DLR or KNMI v2.1)	3%
Background-NO <sub>x</sub> estimation (10% or 30% of non-flashing pixels)	29%
Lightning detection system DE using ENGLN	17%
Lightning detection system DE using EUCLID	62%
Lifetime of NO <sub>x</sub> in the near field of convection ( $\tau$ )	18%
Time window before the TROPOMI overpass	29%
Other (lightning parameterization, scattering weights, deep convection definition)	30%
Overall uncertainty using ENGLN	57%
Overall uncertainty using EUCLID	83%

According to our estimations, the time window contribution to the uncertainty of the LNO<sub>x</sub> PE is about 29%. We do not  
 480 perform calculations using a larger time window, because studying the transport of LNO<sub>x</sub> at longer time scales is out of the  
 scope of this work.

The sources of differences in the LNO<sub>x</sub> PE estimation evaluated in this study are summarized in Table 3. As discussed  
 in previous studies (e.g., Pickering et al., 2016; Allen et al., 2019; Lapierre et al., 2020; Zhang et al., 2020; Allen et al.,  
 2021a), there are other possible sources of uncertainty, such as the calculation of the *AMF* (LNO<sub>x</sub> profile type and lightning  
 485 parameterization and NO<sub>x</sub>/NO<sub>2</sub> ratios in the simulations, scattering weights calculations) contributing to the uncertainty of  
 about 30% or the method to select the OCP to be used for the definition of deep convection, contributing to the uncertainty of  
 about 10%, or other systematic errors in the retrieval algorithms of TROPOMI. However, estimates of the influence of these  
 parameters for the uncertainty of LNO<sub>x</sub> PE on the particular area of the Pyrenees is out of the scope of this paper, as we do not  
 expect them to be dependent on the studied area.

490 We can estimate the overall LNO<sub>x</sub> PE uncertainty by summing the uncertainties in PE collected in Table 3. We obtain an  
 overall LNO<sub>x</sub> PE uncertainty of 57% using ENGLN lightning data and 83% using EUCLID lightning data.

## 4 Discussion

Previous studies have used OMI NO<sub>2</sub> measurements to estimate the LNO<sub>x</sub> PE over different regions, as shown in Table 4.  
 Pickering et al. (2016) reported a LNO<sub>x</sub> PE of  $80 \pm 45$  mol per flash over the Gulf of Mexico. Bucsela et al. (2019) system-  
 495 atically estimated the LNO<sub>x</sub> PE over mid-latitudes, obtaining an average LNO<sub>x</sub> PE of  $180 \pm 100$  mol per flash. Interestingly,  
 Bucsela et al. (2019) (see Table 1) found a lower LNO<sub>x</sub> PE in Europe ( $150 \pm 90$  mol per flash). Allen et al. (2019) reported a  
 mean LNO<sub>x</sub> PE over the tropics of  $170 \pm 100$  mol per flash. Lapierre et al. (2020) reported a LNO<sub>x</sub> PE over the USA of  $\sim 24$   
 mol per flash (estimated from mol per stroke calculations), while Zhang et al. (2021) reported  $90 \pm 50$  mol per flash over the  
 USA. Recently, Allen et al. (2021a) have estimated the LNO<sub>x</sub> PE in 29 thunderstorms over the USA by using new TROPOMI  
 500 NO<sub>2</sub> data, finding a LNO<sub>x</sub> PE of  $120 \pm 50$  mol per flash based on the use of ENGLN lightning data. We have calculated the  
 T-test for the means of the LNO<sub>x</sub> PE estimates when using ENGLN lightning data together with the TROP-KNMI product and

**Table 4.** Some recent LNO<sub>x</sub> PE estimates. CNLND stands for the China National Lightning Detection Network.

Area	Instrument	Lightning system	LNO <sub>x</sub> PE estimate (mol per flash)	Reference
Gulf of Mexico	WWLLN	OMI	80 ± 45	Pickering et al. (2016)
Mid-latitudes	WWLLN	OMI	180 ± 100	Bucsela et al. (2019)
Tropics	WWLLN	OMI	170 ± 100	Allen et al. (2019)
USA	ENGLN	OMI	~24	Lapierre et al. (2020)
USA	CNLND and ENGLN	OMI	90 ± 50	Zhang et al. (2020)
USA	ENGLN and GLM	TROPOMI	120 ± 50	Allen et al. (2021a)
Pyrenees and Ebro Valley	ENGLN and EUCLID	TROPOMI	58 ± 44	This work

the LNO<sub>x</sub> PE estimates provided by Allen et al. (2021a) when using ENGLN lightning data, obtaining a p-value lower than 0.05. Therefore, we conclude that differences in LNO<sub>x</sub> PE between the Pyrenees and the U.S. are statistically significant.

We have used the LNO<sub>x</sub> PE algorithm employed by Pickering et al. (2016); Bucsela et al. (2019); Allen et al. (2019) and Allen et al. (2021a) to provide new LNO<sub>x</sub> PE estimates based on TROPOMI NO<sub>2</sub> measurements over the Pyrenees. We obtain 47 ± 33 (69 ± 34) mol NO<sub>x</sub> per flash using the TROP-KNMI research product and ENGLN (EUCLID) lightning data and 58 ± 33 (51 ± 25 mol NO<sub>x</sub>) mol NO<sub>x</sub> per flash using TROP-DLR product and ENGLN (EUCLID) lightning data. Our mean LNO<sub>x</sub> PE estimates are slightly lower than the LNO<sub>x</sub> PE reported by Pickering et al. (e.g., 2016); Allen et al. (e.g., 2019); Zhang et al. (e.g., 2020); Allen et al. (e.g., 2021a) and a factor of ~2 higher as determined by Lapierre et al. (2020). The employed method uses only TROPOMI measurements over cloudy pixels to estimate fresh-produced LNO<sub>x</sub>. As a consequence, part of the LNO<sub>x</sub> produced before the TROPOMI overpass can be overlooked. Consequently, the obtained LNO<sub>x</sub> PE can be biased low.

When comparing our results with TROPOMI-based estimates by Allen et al. (2021a) over the USA using ENGLN lightning data (120 ± 50 mol), we obtain lower LNO<sub>x</sub> PE estimates, which is in agreement with Bucsela et al. (2019), who reported a lower LNO<sub>x</sub> PE over Europe than over the USA. We estimate a mean tropospheric VCD of NO<sub>x</sub> of 3.5 × 10<sup>19</sup> molec m<sup>-2</sup> from the TROP-KNMI product. Allen et al. (2021a) reported a slightly higher mean VCD of NO<sub>x</sub> of 4.4 × 10<sup>19</sup> molec m<sup>-2</sup> from the TROP-KNMI product. The Pyrenees are a low contaminated area, which explains that the tropospheric VCD of NO<sub>x</sub> is lower than for the 29 cases studied by Allen et al. (2021a) over the USA. We have also found comparable influence of the background-NO<sub>x</sub> on the uncertainty of our results than Allen et al. (2021a), (29% vs 22.5%). The explanation of this difference could be that Allen et al. (2021a) analyzed 29 cases, while in this study we have analyzed only eight cases.

The obtained LNO<sub>x</sub> PE are significantly influenced by the TROPOMI (KNMI and DLR) and the lightning (ENGLN and EUCLID) data sets. The difference between the LNO<sub>x</sub> PE calculated by using the TROP-KNMI and the TROP-DLR products together with the ENGLN lightning data is 3%. There is a factor of 3.5 difference in the estimated median tropospheric VCD of NO<sub>x</sub> using the TROP-KNMI product (3.5 × 10<sup>19</sup> molec m<sup>-2</sup>) and the TROP-DLR product (0.96 × 10<sup>19</sup> molec m<sup>-2</sup>), while the differences in the provided mean stratospheric VCD of NO<sub>2</sub> over pixels with deep convection is 14% (7.3 and 8.3 × 10<sup>19</sup> molec m<sup>-2</sup> for the TROP-KNMI and the TROP-DLR products, respectively). The background-NO<sub>x</sub> is estimated from non-flashing pixels, leading to a similar V tropLN Ox and LNO<sub>x</sub> PE values. However, using a fixed value for the background-NO<sub>x</sub>

produces significantly lower LNO<sub>x</sub> PE for the TROP-DLR product than for the TROP-KNMI product, as a consequence of the lower tropospheric VCD of NO<sub>x</sub> obtained from the TROP-DLR product.

530 Despite significant differences in the DE of ENGLN and EUCLID in the studied area, we have not found significant differences in the mean estimation of the LNO<sub>x</sub> PE using lightning data from both networks after correction with the DE. The LNO<sub>x</sub> PE estimates using the TROP-DLR product together with ENGLN and EUCLID lightning data are nearly similar ( $58 \pm 33$  mol NO<sub>x</sub> per flash and  $51 \pm 25$  mol NO<sub>x</sub>, respectively). However, we have found that the LNO<sub>x</sub> PE obtained using the TROP-KNMI product are different for ENGLN ( $47 \pm 33$  mol per flash) and EUCLID data ( $69 \pm 34$  mol per flash). We have  
535 found that the received LNO<sub>x</sub> PE using ENGLN ranges between 39 and 59 mol NO<sub>x</sub> per flash after correction by the DE  $0.676 \pm 0.12$ , while the calculated LNO<sub>x</sub> PE using EUCLID ranges between 33 and 86 mol NO<sub>x</sub> per flash after correction by the DE  $0.27 \pm 0.12$ . Therefore, we conclude that the higher DE of ENGLN provides more precise LNO<sub>x</sub> PE than EUCLID in the studied area.

## 5 Conclusions

540 We have estimated the LNO<sub>x</sub> PE over the Pyrenees, a European region with high lightning activity and relatively low concentration of background-NO<sub>x</sub>. We have used two lightning data sets (ENGLN and EUCLID) and two TROPOMI NO<sub>2</sub> and cloud products (DLR and KNMI v2.1) in this study. The main conclusions of this work are as follows:

1. We obtain  $47 \pm 33$  mol NO<sub>x</sub> per flash using the TROP-KNMI research product and ENGLN lightning data,  $69 \pm 34$  mol NO<sub>x</sub> per flash using TROP-KNMI research product and EUCLID lightning data,  $58 \pm 33$  mol NO<sub>x</sub> per flash using  
545 the TROP-DLR product and ENGLN lightning data and  $51 \pm 25$  mol NO<sub>x</sub> per flash by using TROP-DLR product and EUCLID lightning data. Overall, the obtained LNO<sub>x</sub> PE ranges between 14 and 103 mol NO<sub>x</sub> per flash. These estimates are lower than the globally averaged LNO<sub>x</sub> PE ( $250 \pm 150$  mol per flash) estimated by Schumann and Huntrieser (2007) and the LNO<sub>x</sub> PE estimates from the TROPOMI measurements and ENGLN lightning data in the USA by Allen et al. (2021a) ( $120 \pm 50$  mol per flash).
- 550 2. We have used different methods to estimate the background-NO<sub>x</sub>, i.e., the background-NO<sub>x</sub> from non-flashing pixels and from measurements over days with low lightning activity. We have found that the most important sources of uncertainty for LNO<sub>x</sub> PE are the estimation of the background-NO<sub>x</sub> and the time window prior to the TROPOMI overpass time used to collect the lightning data (both about 29%). The overall uncertainty when using ENGLN lightning data is 57%. When using EUCLID lightning data, the most important source of uncertainty is the DE of EUCLID (about 62%),  
555 while the overall uncertainty when using EUCLID lightning data is 83%.
3. The estimated median tropospheric VCD of NO<sub>x</sub> in convective systems after subtraction of the stratospheric NO<sub>2</sub> contribution is a factor of 3.5 lower for the TROP-DLR product than for the TROP-KNMI product as a consequence of larger stratospheric VCD of NO<sub>2</sub> in the TROP-DLR product over pixels with deep convection.

4. The uncertainty introduced by the estimate of the background-NO<sub>x</sub> is considerably larger than the uncertainty introduced  
560 by the choice of the lightning data set (ENGLN or EUCLID).

This paper reports on partly new and partly established methods to estimate LNO<sub>x</sub> PE. It confirms that the uncertainty in  
the calculation of LNO<sub>x</sub> PE is still high, even when using high resolution measurements from TROPOMI. It also suggests  
that the LNO<sub>x</sub> PE varies substantially between different regions, as suggested by a comparison between our results and recent  
OMI- and TROPOMI-based LNO<sub>x</sub> PE over the USA (Lapierre et al., 2020; Allen et al., 2021a). This study also shows that  
565 differences in LNO<sub>x</sub> PE estimates can be caused by the different lightning monitoring systems. The launch of the Meteosat  
Third Generation (MTG) geostationary satellites of the European organization for the exploitation of METEOROLOGICAL SATEL-  
lites (EUMETSAT) in 2022 will for the first time provide a continuous monitoring of the occurrence of lightning flashes from  
space in Europe and Africa through the instrument Lightning Imager (LI) from 2023 onwards (Stuhlmann et al., 2005). Light-  
ning data from the MTG-LI can contribute to improve LNO<sub>x</sub> estimates over the studied region, Europe and Africa. In fact,  
570 lightning data from the geostationary GLM has already contributed to new LNO<sub>x</sub> PE estimations over America (Allen et al.,  
2021b, a). High temporal and spatial resolution observations from the Geostationary Environment Monitoring Spectrometer  
(GEMS) and the future NO<sub>2</sub> retrieving instruments on-board geostationary satellites, such as the SENTINEL-4 GEO in 2023  
(Courrèges-Lacoste et al., 2017) and the Tropospheric Emissions: Monitoring of Pollution (TEMPO) (Zoogman et al., 2017)  
in 2022 will also contribute to provide more data to estimate the LNO<sub>x</sub> PE over Asia, North America, Europe and Africa.

575 *Data availability.* All data used in this paper are directly available after a request is made to authors F. J. P. I (FranciscoJavier.Perez-  
Invernon@dlr.de) or H. H. (Heidi.Huntrieser@dlr.de). The official TROPOMI data are available via ESA's public data hub (<https://s5phub.copernicus.eu/>). The ERA5 meteorological data are freely accessible through Copernicus Climate Change Service (C3S) (2017): ERA5:  
Fifth generation of ECMWF atmospheric reanalyses of the global climate Copernicus Climate Change Service Climate Data Store (CDS)  
(<https://cds.climate.copernicus.eu/cdsapp>). ENGLN and EUCLID data were obtained freely by request from Earth Networks (<https://www.earthnetworks.com>) and AEMET ([http://www.aemet.es/es/datos\\_abiertos](http://www.aemet.es/es/datos_abiertos)), respectively. The lower left and right panels show the cloud fraction and the OCP, respectively.

**Figure 10.** TROP-KNMI product and EUCLID lightning data for the case 28 May 2018. The upper left panel shows the positions of lightning flashes (red dots) reported by EUCLID during the 5 h period before the TROPOMI overpass and the calculated VCD NO<sub>x</sub>. The upper right panel shows the SCD of NO<sub>2</sub>, center left and right panels show the stratospheric VCD of NO<sub>2</sub> and the AMF<sub>LNO<sub>x</sub></sub>, respectively. The lower left and right panels show the cloud fraction and the OCP, respectively.

**Figure 11.** Horizontal wind velocity and direction averaged between 200 hPa and 500 hPa pressure levels for the studied cases on 29 April, 7 May and 28 May, 2018. The horizontal winds are extracted from ERA5-reanalysis data. We show in the title the spatial median of the wind velocity.
