Abstract Due to rapid urbanization and intense human activities, the urban heat island (UHI) effect has become a more concerning climatic and environmental issue. A high spatial resolution canopy UHI monitoring method would help better understand the urban thermal environment. Taking the city of Nanjing in China as an example, we propose a method for evaluating canopy UHI intensity (CUHII) at high resolution by using remote sensing data and machine learning with a Random Forest (RF) model. Firstly, the observed environmental parameters [e.g., surface albedo, land use/land cover, impervious surface, and anthropogenic heat flux (AHF)] around densely distributed meteorological stations were extracted from satellite images. These parameters were used as independent variables to construct an RF model for predicting air temperature. The correlation coefficient between the predicted and observed air temperature in the test set was 0.73, and the average root-mean-square error was 0.72°C. Then, the spatial distribution of CUHII was evaluated at 30-m resolution based on the output of the RF model. We found that wind speed was negatively correlated with CUHII, and wind direction was strongly correlated with the CUHII offset direction. The CUHII reduced with the distance to the city [centercentre](#), due to the de-creasing proportion of built-up areas and reduced AHF in the same direction. ~~In some cases, LST is not suitable as a predictive factor for AT.~~ The RF model framework developed for real-time monitoring and assessment of high [spatial and temporal](#) -resolution (30m and 1h) CUHII provides scientific support for studying the changes and causes of CUHII, as well as the spatial pattern of urban thermal environments.

1 Introduction

Throughout the world, cities have formed rapidly owing to population growth and people gathering in certain areas to settle and build their lives. Such urbanization brings not only economic development but also the Urban Heat Island (UHI) phenomenon (Oke, 1982; Grimmond and S.U.E., 2007; Mirzaei, 2015; Cao et al., 2016; Zhao et al., 2020). Two major types

of UHIs can be distinguished: (a) the canopy urban heat island (CUHI), and (b) the surface urban heat island (SUHI). The particular type of UHI is defined based on the height above the ground at which the phenomenon is observed and measured (Oke, 1982). The UHI effect has become an indisputable fact and brings adverse impacts on urban ecology and energy consumption (Roth, 2007; Yang et al., 2019; Yang et al., 2020c; Zheng et al., 2020). UHIs amplify thermal stress, so people residing in urban areas are **relatively** more impacted during heatwave episodes (Koken et al., 2003; Estrada et al., 2017). A recent study on the global UHI predicted that about 30% of the world's population is exposed to lethal high temperatures for at least 20 days per year, and by 2100, this proportion was projected to reach 48% (Mora et al., 2017). UHIs also have the potential to impact vegetation phenology (Kabano et al., 2021), diurnal temperature range (Argüeso et al., 2014), water consumption and general thermal comfort (Salata et al., 2017). Due to its negative impacts, the UHI effect has become a key challenge in achieving urban sustainability and assessing this phenomenon has attracted increasing interest over the last decade or so (Corburn, 2009; Pandey et al., 2014; Malings et al., 2017). In general, both background weather conditions (e.g., the wind vector and heatwaves) and city-specific characteristics (including the presence of urban green space, properties of built-up materials, and the intensity of human activity) influence the UHI's mean intensity and variation (Zhao et al., 2014; Manoli et al., 2019). Concerning these factors, the UHI also shows significant intracity variability since urban areas are highly heterogeneous. Therefore, exploring the formation and causes of UHIs is crucial for decision-makers involved in the planning of urban developments and allocating public resources.

There are two main approaches to studying UHIs: numerical simulation and observation. Numerical simulation can reduce the need for a large number of observations and reveal mechanistic insights by investigating the impacts of cities on meteorological variables (Chun and Guldmann, 2014; Zou et al., 2014; Zhang et al., 2015; Taleghani, 2016; Li et al., 2020). For instance, (Zhang et al., 2015) investigated the influence of land use/land cover (LULC) and anthropogenic heat flux (AHF) on the structure of the urban boundary layer in the Pearl River Delta region, China, through a series of numerical experiments. However, it is important to acknowledge that numerical simulation is a simplification of the real world and cannot replace actual observations. Observational studies of UHIs are arguably more robust in their findings (Hu et al., 2016; Chakraborty and Lee, 2019; Dewan et al., 2021), and can mainly be categorized into the following three methods: (1) in-situ (field) measurement, (2) mobile measurements, and (3) remote sensing technology.

In-situ (field) measurements include conventional measurements from national meteorological stations which are usually located in rural areas, and high-density microclimate observations from experiments or high-density automatic sites over various underlying surfaces.~~In-situ (field) measurements include meteorological measurements, which are observed by meteorological stations, and high density observations, which are usually measured by high spatial resolution observation stations.~~ It is easy to compare long-term series of air temperature (AT) between urban and rural stations based on meteorological observation data (Liu et al., 2006; Liu et al., 2008; Xinfu et al., 2008; Yang et al., 2012; Scott et al., 2018; Nganyiyimana et al., 2020). With the analysis of meteorological data in a long time series, the contribution and trend changes of UHI intensity (UHII) can be clearly discovered. Meanwhile, however, owing to the limitations of meteorological sites in terms of their spatial representation, it is difficult to build a comprehensive understanding on the spatial distribution

of urban thermal environment parameters [such as urban canopy temperature, land surface temperature (LST) and vegetation] (Liu et al., 2008; Nganyiyimana et al., 2020). To overcome these limitations, high-density observation stations are used to explore the spatial distribution of the urban thermal environment and its relationship with the surrounding environment (Hu et al., 2016; Bassett et al., 2016; Ching et al., 2018; An et al., 2020). Deploying denser observation stations or urban microclimate surveys can to some extent compensate for the limitation of a coarse spatial resolution. However, such approaches are usually unsuitable for large-scale studies due to restrictions imposed by certain natural conditions, social activities, as well as the high cost of construction and maintenance (An et al., 2020). For example, mobile transect surveys have been used in many studies (Merbitz et al., 2012; Akdemir and Tagarakis, 2014; Hankey and Marshall, 2015; László and Szegedi, 2015; Al-Ameri et al., 2016; Liu et al., 2017; Popovici et al., 2018), as they can easily obtain the distribution of parameters along a designed route using only a set of equipment attached to a mobile vehicle. However, it is rather costly to obtain observations at a fine resolution, broad coverage and high synchronicity with such an approach.

To overcome these possible issues, LST data from aerial sensors and earth observing satellites are commonly employed in UHI studies, and so remote sensing data such as those from AVHRR (Roth et al., 1989; Caselles et al., 1991; Gallo et al., 1993a), Landsat (Y et al., 2007; Zhou et al., 2015; Zhao et al., 2016), MODIS (Peng et al., 2012; Zhou et al., 2015; Li et al., 2017; Yang et al., 2018; Chakraborty and Lee, 2019), aerial images (Buyadi et al., 2013; Heusinkveld et al., 2014; Yu et al., 2020) and so on (Zhao et al., 2020; Gallo et al., 1993b; Qin et al., 2001; Chakraborty et al., 2020) are widely used to explain the spatial distribution of the surface UHI and its relationship with the local environment (e.g., LULC). Remote sensing data have good application prospects as they can provide fine resolution and wide data coverage at times when other ground-based observations cannot. However, due to the influence of precipitation and clouds, the retrieval of LST sometimes can be challenging. In addition, each satellite remote sensing dataset has its own characteristics (Zhao et al., 2016; Chakraborty and Lee, 2019). For example, Landsat images have a high spatial resolution (30 m) that can show urban block sizes, but the temporal resolution is rather low (16 days). The MODIS LST dataset has the advantage of high temporal resolution (four times per day), but the spatial resolution is only 1 km (Yang et al., 2018; Yang et al., 2019).

LST derived by satellites has become an important indicator for exploring variation characteristics of the SUHI, because LST is closely related to the land cover type/structure, population density, anthropogenic heat release, etc., and it also can significantly influence surface air temperature, wind field, humidity and surface fluxes in the urban region (Ho et al., 2016; Yang et al., 2019; Li et al., 2020, 2021). However, ~~Meanwhile~~, the LST can only quantify the SUHI effect, which is seriously affected by meteorological factors, e.g., cloud and evaporation. In contrast, as an important indicator reflecting the energy exchange between the atmosphere and land in the urban canopy, AT is more representative than LST. In particular, AT is more related with human health and ecological changes in cities (Ho et al., 2016). While

UHI studies based on AT observed by meteorological sites suffer from limited spatial coverage, which impedes a comprehensive understanding on the influencing factors and causes of canopy UHI (CUHI). Thus, there is an urgent need to develop rapid, high spatiotemporal resolution AT and refined CUHI intensity (CUHII) estimation methods to explore the mechanisms under which anthropogenic factors (e.g., urban land-use changes, anthropogenic heat emissions, urban

100 morphology and size) and natural factors (e.g., meteorological conditions and geographical differences) influence the CUHIs of complex and diverse cities.

Therefore, in this study we: (1) based on remote sensing data, AT and wind speed data as well as other environmental information from meteorological observations, retrieved the AT data at a 30-m-~~spatial and one-hour-temporal~~ resolution in the study area by using machine learning; (2) calculated the CUHII distribution based on the retrieved AT data, and further
105 explored the shape, intensity and influencing factors of the CUHI by combining local LULC, wind vector and urban morphology data.

2 Materials and Methods

2.1 Study areas

Nanjing, the capital city of Jiangsu Province in China, is located along the lower reaches of the Yangtze River and, as part of
110 the Yangtze River Delta Urban Agglomeration, has a high level of urbanization. In fact, Nanjing has been experiencing rapid urbanization since China's economic reform in 1978. According to the National Bureau of Statistics, the population in Nanjing increased from 6.13 million in 2000 to 8.34 million in 2018. In 2016, the built-up area of Nanjing expanded to 773.79 km², pushing the city to rank as the ninth-largest among all Chinese cities (Wang et al., 2020b). The total GDP in 2020 was about 1.48 trillion CNY, ranking ninth among all Chinese cities.~~Along with economic development, Nanjing's~~
115 ~~UHHI was observed to be 0.5°C in 2005 and is increasing at 0.109°C·(10 yr)⁻¹ (Xinfa et al., 2008).~~

2.2 Data

All of the satellite remote sensing data employed in this study are from the geospatial data cloud (<https://www.gscloud.cn/>), including those gathered by the Landsat 8 Operational Land Imager (OLI). OLI has nine bands, including a coastal band, blue band, green band, red band, near-infrared band, two shortwave infrared bands, a panchromatic band, and a cirrus band.
120 Due to the low temporal resolution (16 days) of the Landsat 8 OLI dataset and the vulnerability to cloud cover, data from three instances of cloudless conditions over Nanjing were selected for use in this paper—namely, 10:43 local time (LT) on 11 August 2013, 2 September 2015 and 21 July 2017. The specific band ranges and uses of Landsat 8 OLI are shown in Table S1 of the supplementary information.

~~High-density automatic M~~eteorological observation data, including AT (~~with resolution of the minimum observed scales~~
125 ~~are~~0.5°C ~~intervals~~ on 11 August 2013 and 0.1°C ~~intervals~~ on 2 September 2015 and 21 July 2017), wind speed and wind direction, at 11:00 LT on the day closest to the satellite transit time, were selected. All weather stations in operation on those three days were included, numbering 218 totally and 63, 79 and 76 respectively (Figure 1). Figure 1 shows the 2-m AT and LULC on these three days. Compared with the LULC, the spatial patterns of AT on these three days are quite different (Figure 1).

130 In addition to global climate change, the influence of human activities on the CUHI cannot be ignored. Previous studies have pointed out that AHF is closely related to the change in built-up areas and population density around the stations, which reflects the fact that the effects from both anthropogenic emissions and land-use change are related to latent heat flux and sensible heat flux (Zhou et al., 2012; Yang et al., 2020b; Wang et al., 2020a; Zhang et al., 2021). Therefore, AHF was retrieved via a physical method (Bing Chen and Shi, 2012; Chen et al., 2012; Chen et al., 2014) based on 1000-m spatial resolution NOAA nighttime lighting data and with local economic development and energy consumption data, and the AHF data at the same time in Nanjing were provided by Chen et al (Bing Chen and Shi, 2012; Chen et al., 2012; Chen et al., 2014).
135 Note that the AHF here varied annually. We expect that AHF distribution can shape the main morphology of urban thermal environment. We can not get AHF data at diurnal and seasonal scales. In future, if we got high-temporal-resolution AHF data, we will update them in the model. And lastly, the digital elevation model (DEM) data (30-m spatial resolution) used in
140 this study are based on the second version of ASTER-GDEM, which is provided by the Geospatial Data Cloud site, Computer Network Information Center, Chinese Academy of Sciences. (<http://www.gscloud.cn>)

3. Random Forest model framework for air temperature retrieval

3.1. Construction of Random Forest model

The Random Forest (RF) model is a highly flexible machine learning algorithm that can analyze data with missing values or noise and has good anti-interference ability. To date, the RF model has been widely used as a feature selection tool for high-dimensional data to, for example, identify the importance of variables and predict or classify related variables. In this study, an RF model was constructed for each time's dataset to evaluate the AT using the RF package in R language.
145

3.1.1 Data Preparation

The process of urbanization will have a significant impact on CUHIs (Zhou et al., 2015). To comprehensively take into account the local urban environment, 18 factors were selected as independent variables (~~Table 1~~), including anthropogenic parameters (i.e., AHF), geometric parameters (distance from the city center, proportion of LULC area, altitude, longitude, latitude, slope, aspect), and physical parameters [proportion of impervious surface (IS) area, albedo, normalized difference vegetation index (NDVI), normalized difference built-up index (NDBI), green normalized difference vegetation index (gNDVI), soil-adjusted vegetation index (SAVI), normalized difference moisture index (NDMI)]. Their sources and spatial resolution are summarized in table 1. The inversion methods for these environmental variables were as follows: Based on Landsat 8 OLI satellite data, the LULC in Nanjing was divided into four broad categories (built-up, cropland, vegetation, and water body) by combining a support vector machine method and visual interpretation. The remote sensing indices were calculated using corresponding bands (Yang et al., 2012; Shi et al., 2015). The IS and surface albedo data were extracted via multi-band information (Son et al., 2017; Liang, 2001). Then, the geometric center of the built-up area was calculated as the city center, and the distances between the meteorological stations and the city center were calculated. Slope and aspect were
155
160

calculated based on the DEM data using ArcMap 10.2. The methods used for extracting the IS data and calculating the remote sensing indices and surface albedo are given in Text S1, together with the accuracy of IS and albedo. All the above data (except for DEM, aspect and slope) were extracted for each of the three years corresponding to the three selected Landsat images. Taking the data on 21 July 2017 as an example, Figure 2 shows the spatial distribution of some of the environmental parameters, i.e., IS, distance from city center, AHF, and NDVI, where high spatial consistency between these parameters and the urban structure can be seen. For example, high-density built-up areas correspond closely to high AHF and low vegetation cover.

Due to advection and turbulent transport, neighborhood surroundings can affect the local temperature (Yang et al., 2012; Shi et al., 2015). Therefore, a fixed buffer zone was built surrounding the meteorological stations. Within the buffer zone of each station the proportion of IS area and that of each LULC type, and the average values of surface albedo, AHF, NDVI, NDBI, SAVI, gNDVI and NDMI were calculated. Together with longitude, latitude, altitude and distance to the city center, these parameters were fed into the RF model as independent variables, with AT as the target variable. In addition, to find out the optimal size of the buffer zones for the model, we compared the model performances for different buffer zone sizes, i.e., buffer zones with a radius of 500 m, 1000 m, 2000 m and 5000 m, respectively. Figure 3 summarizes the research framework of this paper.

3.1.2 Five-Fold Cross-Validation

This paper uses the coefficient of determination (R^2) and root-mean-square error (RMSE) as verification indicators. R^2 indicates the degree of fit between the predicted AT and the observed AT, and the RMSE can reflect the credibility of the prediction result.

The cross-validation (CV) method can be used to evaluate the performance of the RF model (Zheng et al., 2020). In this paper, we employ the five-fold CV method, in which the entire dataset is randomly divided into five subsets—each time four subsets are used to train the RF model, and the remaining one is used for validating. After constructing the model, the validation data are used to calculate the current R^2 and RMSE, and the process is repeated until each of the five folds has been used as validation data. The randomness in the process of selecting samples for modeling gives the model the advantage of being robust and highly accurate. With enough decision trees, it can ensure that each sample is used as a training sample and a test sample, effectively avoiding overfitting.

3.1.3 Variable selection and model parameter setting

Since not every variable in the model makes a prominent contribution to the performance, deleting those variables that can reduce the prediction accuracy can improve the performance and simplify the model. Therefore, the number of variables should be minimized on the premise of improving or not affecting the performance of the model. The contribution of each variable is judged by two indicators: the percentage increase in mean-square error (%IncMSE), and the percentage increase in node purity (IncNodePurity). Using the backward selection method, the variable with the smallest contribution is

identified and removed, and the model is re-run. These steps are then repeated until only one variable remains. The R^2 and RMSE under different combinations of variables were evaluated (Figure S1). For each model, the combination of variables with the largest R^2 and smallest RMSE was selected. Using this approach, eight, seven and six variables were selected for the model on 11 August 2013, 2 September 2015 and 21 July 2017, respectively (Table 32).

To build an RF model, two important parameters need to be set: the number of decision trees (Ntree) and the number of variables sampled at each node (Mtry). The RF models were established with Ntree from 50 to 1200, with 50 as the step length, and Mtry from 1 to 16 respectively, with 1 as the step length to traverse all the parameters. Figure 4 presents the R^2 and RMSE values in each five-fold CV test.

The principle of parameter selection is to choose a simpler model (smaller Ntree and Mtry) under the premise of good performance. In the end, the optimal Mtry and Ntree based on the datasets on 11 August 2013, 2 September 2015 and 21 July 2017 were 7 and 200, 10 and 150, and 7 and 50, respectively.

3.2. Model testing

Table 24 compares the performance of the RF model with different buffer sizes (500 m, 1000 m, 2000 m, and 5000 m) in the five-fold CV. The RF model based on the dataset on 11 August 2013 and 2 September 2015 within 1-km buffer zones performed best, with an R^2 and RMSE of 0.57 and 0.65°C, and 0.59 and 0.69°C, respectively. On 21 July 2017, [geospatial data cloud](#) meanwhile, the R^2 and RMSE with a 2-km buffer zone were 0.47 and 0.80°C respectively, outperforming other buffer sizes. In this study, we chose the 2-km buffer radius. As can be seen from Table 24, on 11 August 2013 and 2 September 2015, the R^2 and RMSE with the 1-km buffer zone was very close to that from the optimal buffer size, i.e., the 2-km buffer zone, whereas on 21 July 2017 the R^2 and RMSE with the 1-km buffer zone deteriorated considerably compared to that with the 2-km buffer zone. In addition, according to recent studies, the effective range that can influence local temperature is within 2 km (Yuyu Ren, 2011; Yang et al., 2012; Shi et al., 2015). Therefore, a 2000-m buffer was finally chosen in this study.

In addition, three methods of AT modelling were also compared—two linear regressions (stepwise linear regression (Alonso and Renard, 2019; Mira et al., 2017) and geographically weighted regression (GWR) (Wang et al., 2020a; Li et al., 2021)) and one nonlinear regression (the RF model (Alonso and Renard, 2020)). A detailed description of the linear regression methods is provided in Text S2. For each model, the combination of variables with the largest R^2 and smallest RMSE was selected. Using this approach, eight, seven and six variables were selected for the model on 11 August 2013, 2 September 2015 and 21 July 2017, respectively (Table 3). Table 32 also shows the performance of each model based on the dataset within a 2000-m buffer zone. Compared to the other methods, the RF model achieves better R^2 and RMSE, indicating its higher capability in fitting nonlinear and complex data and suitability for predicting AT (Zhu et al., 2019; Yoo et al., 2018).

3.3 Prediction accuracy of RF Models

Figure 5 compares the measured AT of the high-density automatic stations in the training set or testing set and the predicted AT of the RF model in the five-fold CV. In general, a large number of scattered points of predicted and observed AT are clustered around the 1:1 line, indicating good performance of the model. In the training set, the average R^2 and RMSE of the three models are 0.955 and 0.325°C respectively. The R^2 and RMSE using data on 11 August 2013, 2 September 2015 and 21 July 2017 are 0.948 and 0.295°C, 0.954 and 0.310°C, and 0.963 and 0.369°C, respectively, indicating high model accuracy. The result of the testing set shows that the average R^2 and RMSE are 0.535 and 0.719°C, respectively. Among them, the prediction results achieved on 21 July 2017 are slightly less accurate than those obtained on the two other days. A smaller R^2 and larger RMSE were observed on 21 July 2017 (0.802, 0.468°C) compared to 11 August 2013 (0.655, 0.563°C) and 2 September 2015 (0.700, 0.574°C). Based on existing research (Oh et al., 2020; Venter et al., 2020) and follow-up discussion (section 4.2.1), it can be concluded that the model performs best outside of the summer months, when the spatial variation in AT is low and wind velocities are high, corresponding to the model from 2 September 2015. In contrast, during the summer months, the performance of the model constructed with a high spatial variation of AT or low wind speed conditions decreases slightly, corresponding to the datasets on 21 July 2017 and 11 August 2013.

Furthermore, we used %IncMSE and IncNodePurity to determine the contribution of each variable (Table 43) and to compare their importance. The NDVI, and the proportion of IS, vegetation and water body area all appeared in the three models, indicating that vegetation, water bodies and human activities have important and universal impacts on the AT distribution. The distance to the city center appeared in the model based on the data on 2 September 2015 and 21 July 2017, and ranked high, implying the impact of urbanization on the heat island.

The absolute error for RF prediction is defined as difference in predicted AT and observed AT at each weather station (See Figure S2). The relative error is defined as that absolute error divided by observed AT, which is shown in Figure 6. In general, the mean relative (absolute) errors by all stations are 0.07% (0.014°C), 0.04% (-0.025°C) and 0.05% (0.003°C) on 11 August 2013, 2 September 2015 and 21 July 2017, respectively. In detail, most of errors are concentrated between -0.49°C and 0.5°C over more than half of all stations for these three days (Figure S2), and more than 39.1%/71.7%/86.3% of the total stations exhibit predictions with relative errors <1%/2%/3% (Figure 6), indicating good performance of RF models for most areas.

3.4 Model Robustness

~~Based on experiment before, we find reliable variables and parameters that can map high-spatial-solution AT in Nanjing. While the part before mainly focuses on accuracy of the RF model on a specific day, ignoring To validate robustness of this RF framework and its the practicality on a long period of time, . Hence, the generality of the model in time needs to be investigated. With hourly meteorological observation AT observations data for during August 2013, September 2015 and~~

July 2017, and corresponding environment variables were chosen to establish target and data and time of observed AT added as independent variables. New RF model were established.

The temperature differences in a month isare greatlarger, which meansshowing more complicated situations. For five-CV validation, scatterplot of predicted and observed air temperature are given in Figure 7, showing thatHowever, with more samples, the model achieves better performance. The mean RMSE and R^2 are 0.62°C and 0.99 respectively, indicating higher accuracy compared with using an hour data (mean RMSE: 0.53 and R^2 : 0.72°C). tThe mean RMSE are 0.75°C, 0.52°C and 0.59°C, and R^2 are 0.98, 0.99 and 0.99 respectively in August 2013, September 2015 and July 2017. Scatterplot of predicted and observed air temperature are shown in Figure 7. We find In general, for one-month samples, the mean R^2 reached 0.986 and RMSE was 0.620°C. Note that most of the points are clustered around the 1:1 line and the performance is better than the model using only one-day data in a daysamples. TWhy the accuracy using data in August 2013 is the lowest is because that resolution the minimum division value of observed AT is 0.5°C in this month, while 0.1°C in other two times monthsis 0.1°C. Larger minimum division value may result in loss of information, so the performance is the worst among three times months.

4. Refined CUHII assessment in Nanjing

4.1 Refined AT and CUHII and comparison with LST distribution

After establishing the model, a 2-km buffer area was created for each 30-m-resolution pixel and the same 18 independent variables were calculated. The constructed RF model took these pixel-wise variables as input and output AT for each pixel, and hence we obtained the RF model-predicted AT map at 30-m resolution (Figure 87). LST is also a physical manifestation of surface energy and moisture flux exchange between the atmosphere and the biosphere. Some researchers believePrevious studies point out that there is a relationship between LST and AT (Mutiiibwa et al., 2015; Benali et al., 2012), sotherefore, figure 9 shows the LST (Figure 9) of Nanjing in the corresponding time-se days, which wasere invertedretrieved by using Google Earth EngineRadiative Transfer Equation to compare with predicted AT. The methods used for calculating LST are given in Text S3. CUHII is an important indicator to quantify the UHI effect, which is usually defined as the difference in AT at the same level between urban and rural areas (Yang et al., 2020c; Nganyiyimana et al., 2020)[7,32], as follows:

$$CUHII = T - T_{rural} \quad (3)$$

where T is the predicted AT in each pixel and T_{rural} is the average AT in the reference rural area. A square area of size 10 km \times 10 km was selected as the reference rural area in the northern part of Nanjing (Valmassoi and Keller, 2021). It was far from the city center and barely impacted by the UHI effect (Figure 87). The average AT in each reference rural area was 36.0 °C , 27.8 °C and 34.7 °C in these three days, respectively. Then, the CUHII distribution in Nanjing was calculated according to Eq. (3) (Figure 108).

285 Figure 87 shows that the AT on 11 August 2013 and 21 July 2017 was higher and that the AT ranges were 35.4–37.8°C and 33.6–36.4°C, respectively. The corresponding CUHI was strong, with more than 1.5°C in the downtown area (Figure 108). On 2 September 2015, the AT range was 26.8–29.1°C (Figure 87) and the CUHI was slightly weaker, with the maximum value at only 1.3°C (Figure 108). ~~While in contrast, the LST are higher, does not has the same corresponding relationship, with ranging from 26.192-44.081°C, 21.283-44.041°C and 23.899-42.081°C respectively on 11 August 2013, 2~~
290 ~~September 2015 and 21 July 2017, respectively (Figure 9).~~ The three images from different seasons and different weather backgrounds led to significant differences in CUHI, ~~while LST differences are marginal.~~ On 2 September 2015, the overall CUHI was the weakest among the three days. Consistent with a previous study (Wang et al., 2020b), the summer CUHI in Nanjing was found to be generally stronger than that in autumn and winter. The difference between the maximal heat island and cold island intensity on 21 July 2017 was 2.8°C, the largest among the three cases. Generally, the densely populated
295 central city area has a large proportion of IS area, large anthropogenic heat emissions, and higher AT ~~and LST~~, showing an obvious UHI phenomenon (Figures 8, 97 and 108). However, in urban areas with high vegetation coverage or large water bodies, the AT ~~and LST~~ decreases with weakened CUHI ~~(Figures 7 and 8)~~. The AT ~~and LST~~ gradually decreases from the city ~~center~~ centre to the suburbs. Suburban areas, which are covered by more vegetation and water bodies, have significantly lower AT ~~and LST~~ than central urban areas. At the boundary of the central city, high-AT areas and heat islands extend
300 outward along built-up areas and roads (Figures 8, 97 and 108).

Against different weather backgrounds, the spatial distributions of AT and CUHI exhibit heterogeneity in urban Nanjing on different days. The high-AT area on 11 August 2013 extended from the city center to a wide range, and the extreme value of AT was the highest (Figure 87a), corresponding to the strongest CUHI (Figure 108a). Combined with Figure 1, we can see only a small range of vegetation coverage and water bodies in the central urban area, so the CUHI decreased slightly. Only
305 in the suburban water body and farmland areas were there large cold island areas, ~~and only in this day, the distribution of LST is corresponding to that of AT.~~ Nanjing is traversed by the Yangtze River. On 2 September 2015, the high-AT area was relatively small to the north of the Yangtze River. The AT on the Yangtze River was the lowest (Figure 87b), with the strongest cold island here (Figure 108b). The high-AT area extended from the central city to the south, and the cold islands in the southern water body and vegetation covered areas were not significant. On 21 July 2017, the distribution of the heat
310 island was the opposite. There was a large area of high-AT to the north of the Yangtze River, and the cooling effect of the Yangtze River was weak (Figure 87c). Meanwhile, the AT in the southern suburbs dropped significantly, and cold islands widely spread in water body and cropland areas (Figure 108c). Compared with the distribution of CUHI on 11 August 2013, the AT over the water bodies and hills in the northeast of the central city was lower, forming a large and strong cold island area.

315 ~~However, note that the distribution of LST fromat thisese three times are similar, and they are all strongly related to urban form and LULC (Li et al., 2021), which are written in the last paragraph. This is Bbecause -different influencing factors caused different spatial distribution between LST and AT. Ground transfers heat to the air through radiation, conduction and convection after absorbing solar energy, which is the main source of heat in the air (Hong et al., 2018; Khan et al., 2020).~~

While LST is directly heated by solar energy, which is more sensitive to emissivity, surface material and humidity, which related to LULC, and tendings to have a greater temperature differences for different LULC type (Janatian et al., 2016; Long et al., 2020). The LULC in these periods are similar, so the LST difference are marginal.

To further explore the intensity and coverage of the CUHI on different days, the area (km²) occupied by different levels of CUHII on the three different days was calculated (Table 54). The CUHI area on 11 August 2013 accounted for 84.1%; and the area of the CUHII in the range of 1–1.5°C and 1.5–2°C was 1486.89 km² and 82.96 km², respectively. whereas that On 2 September 2015, the CUHI area and 21 July 2017 only accounted for 80.2% and the CUHII area at 0–0.5°C accounted for 57.0%, concentrating in this range, while that at 1–1.5°C was only 56.97 km². The strongest cold island was lower than –1°C, and the overall CUHI effect was relatively weak, 81.2%. Comparing the proportions by area of different CUHII levels, on 2 September 2015 the CUHII area at 0–0.5°C accounted for 57.0%, concentrating in this range, while that at 1–1.5°C was only 56.97 km², which was much lower than that of the other two days. The strongest cold island was lower than –1°C, and the overall CUHI effect was relatively weak. In contrast, on 11 August 2013, the area of the CUHII in the range of 1–1.5°C and 1.5–2°C was 1486.89 km² and 82.96 km², respectively, which far exceeded that on the other two days. On 21 July 2017, the CUHI area accounted for 81.2%, and the area where the CUHII was greater than 1.5°C was only 0.14 km². Therefore, the distributions of UHII on the three days were quite different and need to be discussed separately.

4.2 Potential drivers of CUHII

According to previous studies, three factors—the wind vector field (He, 2018), LULC (Cao et al., 2018; Wang et al., 2020b) and the urban structure (Shahmohamadi et al., 2011; Li et al., 2020)—are the most important influencing factors of CUHIs. In this section, we explore these three drivers of CUHI in Nanjing city.

4.2.1 Relationship between CUHII and the wind vector field

The horizontal air flow has a significant impact on the intensity and shape of the CUHI (He et al., 2021). Figure 119 shows the wind vector field observed by weather stations on the three days analyzed in our study.

On 11 August 2013, the average wind speed at the stations was 0.70 m/s, most of which recorded calm wind (0–0.2 m/s) or soft wind (0.3–1.5 m/s) (Figure 119a). The main reason for this was that Nanjing was continuously controlled by the western Pacific subtropical high at this time and was therefore experiencing a continuous heat wave (Jing et al.)—conditions that are usually associated with low wind speeds, descending motion and stable weather, leading to increased CUHI strength (Figure 108a) (Wang et al., 2021). On 2 September 2015, the average wind speed was 1.53 m/s, which was a significant increase (Figure 119b). The overall northwesterly wind direction led to the CUHII being lower than that on 11 August 2013. Indeed, it has been noted in previous work that the wind direction will significantly affect the position and shape of a heat island (Bassett et al., 2016), and in the present study the northwesterly winds resulted in the CUHI extending from the built-up area to the southeast (Figure 108b) whilst weakening significantly in the northwest. On 21 July 2017, the average wind speed

350 reached 3.07 m/s, with a southwesterly wind direction (Figure 119c). The CUHI effect weakened accordingly, extending to the northeast in the downward wind, and the CUHI was significantly weakened in the southwest (Figure 108c). ~~However, whatever the wind speed is, the distribution of LST hardly changed.~~

On all three days the wind speed in the suburban areas was higher than that in the central city, and this is because there is no shelter provided by tall and dense buildings in the suburban areas, which is conducive to cooling from air convection and therefore a weakening of the CUHI (Yang et al., 2020a). That said, records show that, surprisingly, the boundary-layer mean wind speed in a city can be higher than its rural counterpart. On the one hand, Nanjing is traversed by the Yangtze River, and the central city surrounds a large area of water, wherein the low surface roughness of the water is conducive to air convection. On the other hand, channeling/the Venturi effect might be an important factor. When the prevailing wind is parallel to the axis between buildings, it will be forced to enter between the buildings, resulting in higher wind pressure, which increases the wind speed (Droste et al., 2018).

In order to quantify the relationship, the average CUHI and standard deviation under different wind speeds at various meteorological stations were calculated (Figure 120). On 11 August 2013, the maximum wind speed was 2 m/s, which bore no significant relationship with the CUHI (Figure 120a). On 2 September 2015 and 21 July 2017, the maximum wind speed reached 5 m/s and 6 m/s, respectively, which showed a significant negative correlation with the CUHI (Figures 120b and 120c). The greater the wind speed, the more significant the negative correlation.

There are two aspects concerning the influence of air convection on CUHIs. On the one hand, air convection will facilitate horizontal advection cooling between urban and rural areas, thereby weakening the CUHI (T. Brandsma, 2003). The greater the wind speed, the more significant the cooling effect (Figure 120). On the other hand, horizontal convection transfers heat from the upwind to the downwind area, weakening the upwind CUHI and strengthening the downwind CUHI (Bassett et al., 2016) (Figures 108 and 119). Under different wind speeds, the synergy of these two aspects differs significantly. On 11 August 2013, the average wind speed was the smallest among the three days at only 0.7 m/s, and there was no uniform wind direction, corresponding to the strongest CUHI. The distribution of the CUHI was highly correlated with that of built-up areas (Figures 108a and 119a). On 2 September 2015 the average wind speed was 1.53 m/s. Due to the combined effect of horizontal advection cooling and heat transfer, an upwind cold island appeared and, meanwhile, the downwind area received heat from the upwind area and the CUHI increased significantly (Figures 108b and 119b). On 21 July 2017 the average wind speed was 3.07 m/s, and the upwind CUHI also weakened (Figures 108c and 119c). Downwind, however, the urban heat convection was the dominant factor, which reduced the CUHI in some areas.

~~In contrast, CUHI distribution is in good agreement with LST distribution on 11 August 2013, while large pattern difference during other two days (Figures 9 and 11). This is because clam wind on 11 August 2013 can not induce horizontal However, there is no sufficient evidence show that air convection of urban heat, can affect LST, and from Figure 9 and Figure 11, air convection can hardly influence LST. Therefore, spatial distributions of LST and AT- are well matched in this day have a good corresponding relationship when there is no wind. While under large wind conditions (e.g., larger wind speeds on both~~

2 September 2015 and 21 July 2017), there are obvious urban heat island advection (Bassett, et al., 2016), resulting in different patterns between CUHII and SUHI during these two days (Figures 9 and 11).

385 4.2.2 Relationship between CUHII, ~~LST~~ and LULC

LULC also has a significant impact on CUHII (Wang et al., 2020) and LST (Li et al., 2021). The average values and standard deviation of CUHII were calculated for each LULC type on the three days (Figure 13+). On 11 August 2013, the CUHII in the built-up area was the strongest, exceeding 1.1°C, and in the water body areas it was the weakest at only 0.22°C (Figure 13+a). On 21 July 2017, the CUHII in the built-up area was the strongest at 0.62°C, and in the vegetation areas it was the weakest at 0.24°C (Figure 13+b). The CUHII on these two days was highest in the built-up area, followed by cropland, and then water bodies and vegetation. On 2 September 2015 the CUHII in the built-up area was the strongest at 0.32°C, while it was the weakest at -0.06°C in the water body areas (Figure 13+c).

Different LULC types have different effects on AT owing to their own intrinsic physical properties, mainly reflected in three aspects:

395 (1) Due to the good thermal conductivity and small specific heat capacity of the surface material in the built-up area, the ability to absorb shortwave radiation during the day is stronger than that of other land uses. The LST is significantly higher than that of the suburbs, and therefore the atmosphere is easily heated (Hong et al., 2018).

(2) Due to sufficient water availability in cropland and vegetation-covered areas, evaporation will increase the latent heat flux and cooling effect (Zhao et al., 2020; Zheng et al., 2018). In contrast, the surface humidity of the built-up area is low, with low corresponding latent heat flux. The difference in latent heat flux will increase the difference in LST and AT between urban and rural areas. The latent heat flux of the water bodies is the largest, and the cooling effect is the most obvious.

405 (3) There is a significant correlation between LULC and wind speed (Chen et al., 2020). Areas with tall buildings in built-up areas have high surface roughness and low wind speed, whereas water bodies have low surface roughness and high wind speed. The surface roughness of vegetation-covered areas and cropland is somewhere between. The air convection will increase the sensible heat flux and reduce the AT (section 4.2.1). Therefore, LULC and air convection will jointly enhance or weaken the CUHII.

On 11 August 2013, the average wind speed and the difference in wind speed between different LULC types were small, and so was the difference in sensible heat flux. The difference in radiation and sensible heat flux was the main factor. On 21 July 2017, the average wind speed was the highest, and the synergy in the three aspects led to the CUHII over different LULC types being highest in the built-up area, followed by cropland, vegetation, and then water bodies. On 2 September 2015, the CUHII was highest in the built-up areas, followed by vegetation, cropland, and then water bodies. This was due to the influence of low wind speeds, which would have produced heat transfer and made the CUHII shift from the built-up area to other LULC types (section 4.2.1).

415 4.2.3 Relationship between CUHI and urban structure

Human activities and urbanization have a significant impact on the spatial distribution of UHI (Shahmohamadi et al., 2011; Li et al., 2020). To explore this influence, concentric rings with various radii (5 km, 10 km, 15 km, ..., 40 km) were created surrounding the city center. Within each ring, the average values and error ranges of AHF and CUHII, along with the average proportion of built-up area, were calculated. Figure 142 shows that the CUHII, AHF and proportion of built-up area all significantly decrease with increasing distance to the city center.

From a longitudinal perspective, the AHF and the proportion of built-up areas both increased year by year. The built-up areas of Nanjing on the three days were 982.78 km², 1076.19 km² and 1220.36 km², respectively. The proportion of built-up areas beyond 20 km to the city center increased, especially within the range of 20–25 km. The AHF also showed the same trend, which within the range of 20–25 km even exceeded that in the range of 15–20 km on 2 September 2015 and 21 July 2017. This shows that built-up areas and human influence were spreading from the city center to the surrounding areas during this period. However, the intensity and range of the CUHI did not increase with this trend, because the wind field and weather background have a stronger influence on CUHI than urbanization (Hong et al., 2018; Zong et al., 2021).

5. Discussion

Based on the RF model and combined with local environment and background weather data, the pattern and causes of CUHIs can be analyzed in detail. On 11 August 2013, Nanjing experienced a heat wave, with almost no horizontal convection of air (Figure 119a). In dry areas, such as built-up areas, the latent heat flux remained unchanged, but the high reflectivity of the surface raised the AT. In the heat wave period, the higher AT increased the latent heat flux in rural areas (Khan et al., 2020). For example, vegetation and water bodies alleviated the increase in AT in rural areas. This combined effect exacerbated the difference in AT between the urban and rural areas, making the overall CUHI the strongest (Nganyiyimana et al., 2020; Meili et al., 2021). In Figure 108a, it can be seen that the cooling efficiency of vegetation in the urban area was not high and the coverage of the cooling area was small. This is because the stomata of leaves would have been closed under high AT and dry weather, resulting in reduced evapotranspiration and increased AT (Manoli et al., 2019). On 2 September 2015, northwesterly winds prevailed (Figure 119b), and there was abundant water vapor over the hills of northeast Nanjing and over the Yangtze River. The increase in latent heat flux and horizontal convection cooling lowered the CUHII. Cold islands even appeared to the north of the Yangtze River. The CUHII in the southeast direction was strong (Figure 108b), which was mainly affected by the heat transport of the prevailing winds (Chuanyan et al., 2005), causing the CUHI to shift toward the downwind area. On 21 July 2017, southwesterly winds prevailed in Nanjing, with high wind speed, decreasing the CUHII in the upwind region (Figures 108c and 119c). However, there were large areas of vegetation coverage in the range of 10–20 km in the downwind region, which was affected by the combined effects of land use and horizontal advection cooling leading to lower CUHII than that of 20–30 km. This also confirms the conclusion (Bassett et al., 2016)

that the upwind horizontal advection cooling has the strongest correlation with the weakening of the CUHI effect, and that the downwind region is affected by the wind speed.

There are four main methods for retrieving AT for CUHII assessment:

450 (1) Statistical methods (Prihodko and Goward, 1997; Alonso and Renard, 2020; Li et al., 2021). Statistical models of environmental factors and temperature are established to evaluate the AT, such as multiple linear regression models, partial least-squares regression and GWR. In previous study (Alonso and Renard, 2020), two methods of AT prediction (namely, stepwise linear regression and GWR) were compared with the RF model. The RF model has the highest accuracy and effectively avoids the problem of autocorrelation by filtering variables, which is consistent with previous work (Yoo et al., 2018; Zhu et al., 2019) and our present work. While conventional statistical methods, in addition, cannot effectively solve 455 nonlinear problems (Oh et al., 2020).

(2) Temperature–vegetation index method (VTX) (Goward, 1997; Stisen et al., 2007; Vancutsem et al., 2010). This refers to inversion using the relationship between AT, LST and vegetation index under the premise that the temperature of a dense vegetation canopy is similar to the AT. While VTX only indicates the relationships between underlying surface, LST and AT. In fact, there are many factors that can affect AT, e.g., anthropogenic heat, altitude, and distance to city. Ignoring these 460 factors, therefore, the accuracy of VTX method was low (Stisen et al., 2007)). In contrast, our RF model input multi-variables, including more affecting AT factors.

(3) Machine learning methods (Venter et al., 2020). Predictions are made by establishing models of various variables and AT, such as RF models or neural networks. Compared with other machine learning methods such as neural networks (Astsatryan et al., 2021), the RF model has better noise immunity and is suitable for small sample sizes in this study. Other machine 465 learning methods usually require a lot of data with little noise, so the data cleaning before modeling will take more time. In future, we would like to compare different machine learning methods to come up with a consistently well-perform model, e.g., SVM and ANN. We will also use stacking ensemble strategy to combine the advantages of different models and get the best prediction results

(4) Physical model methods. This category mainly constitutes the energy balance method (Yang et al., 2018), which refers to 470 the study of AT inversion using the principle of energy balance. Physical model approach is relatively complex, and the performance is highly dependent on the understanding of the mechanism affecting AT, which can only address specific problems. While the RF framework in this paper is relatively simple, comprehensive, and suitable for different weather backgrounds.

475 Moreover, the RF prediction framework proposed in this work can not only can dynamically predict CUHII in detail and high frequency within highly heterogeneous cities, but can also can be built against different weather backgrounds, mainly because the environmental parameters entered into the model are relatively stable within a certain period (such as the same month or season). As long as the environmental parameters are acquired once, they can be combined with the AT data in real time to establish the RF model, and the spatial distribution characteristics of CUHII with high temporal and spatial resolution

480 can be obtained. For instance, we randomly predicted the 30-m-resolution AT and spatial distribution of CUHII (Figure 153) with the wind vector field (Figure S3) during the heat wave period of 12–14 August 2012, thereby supporting those involved in making decisions with respect to urban climate, urban planning and urban energy consumption. Particularly, The potential that our proposed model can be used cross a short period as most of the environmental parameters fed to the model probably can remain stable for some time, e.g., one month or even longer (See Figure S4).

485 ~~In addition, Due to changes in local weather conditions (e.g., precipitation and cloud cover), however, satellite-based LST samples are various and LST is usually dynamical in one month, leading to uncertainties in predicting AT, therefore, LST is not suitable to be as an input variable for our present model of CUHII under some circumstances, LST cannot be derived from used as a predictive factor for AT, such as when there is wind or cloud cover. It is worth mentioning that there are many factors that affect the CUHII. In addition to~~ Except for human activities and LULC, the background weather conditions

490 (such as heat waves, air pollution, atmospheric circulation and cloud cover) are also extremely important (Bassett et al., 2016; Yang et al., 2020a; Khan et al., 2020), which should be introduced to improve the RF model of CUHII.

6. Conclusions

Taking Nanjing as an example and using remote sensing data with data from local weather stations, parameters to

495 characterize the urban environment were constructed—namely, anthropogenic parameters (i.e., AHF), geometric parameters (distance from city center, proportions of LULC types by area, altitude, and latitude and longitude, slope and aspect), and physical parameters (proportion of IS, surface albedo, NDVI, NDBI, SAVI, gNDVI and NDMI). A 2-km buffer zone was created around the meteorological stations, and the observed environmental parameters were extracted. A refined assessment framework of CUHII was then established by using Random Forest Model with observed AT and environmental variables.

500 Results showed that the correlation coefficient between the predicted and observed AT was 0.731, and the average RMSE was 0.719°C, indicating accurate results. Based on one-month data samples, the R^2 reached 0.986 and RMSE was 0.620°C. Finally, the high-spatial-resolution (30m) CUHII distribution was analyzed. It was found that the shape of the CUHII was highly correlated with the spatial distribution of AHF and built-up area under calm wind conditions. Under the prevailing wind conditions, the CUHII should be discussed separately in upwind and downwind areas divided by the central city. In the

505 upwind area, there was a significant negative correlation between the wind speed and CUHII. The higher the wind speed, the more obvious the negative correlation. In the downwind area, horizontal convection cooling was found to be the leading factor under high wind speed weather, and heat transfer was the leading factor under low wind speed weather. The combined effects of built-up areas, heatwaves, and human factors can strengthen the CUHII, while the vegetation canopy and water bodies will weaken it. Vegetation and water bodies in the central urban area were found to have a significant cooling effect,

510 providing a reference for urban development. With increasing distance from the city center, the CUHII decreased sharply. ~~In some weather condition with wind or cloud, LST is not suitable for predict factor of AT.~~

In general, overlapping the refined CUHII with local environmental variables and weather conditions helps to explore the causes of CUHIs in more detail, instead of being limited to the location of meteorological sites and frequent changes in various types of weather. The new 30-m resolution CUHII evaluation framework developed in this study has strong portability, and important practical value. Our findings are helpful towards improving our understanding of the relationship between human activities and regional climate change, which can provide important guidance for urban development planning and allocation of public resources in the context of global warming and rapid urbanization.

Code availability

The model in this paper is based on the random Forest data package in the R language, and our implementation and analysis code are available upon request to the corresponding author (yyj1985@nuist.edu.cn).

Data Availability

Landsat 8 OLI datasets (<http://www.gscloud.cn/sources/index?pid=263&rootid=1&label=Landsat8&sort=priority&page=1> (access on 10 April 2021)) were used to retrieve IS area, LULC and NDVI. nighttime light satellite datasets (<http://ngdc.noaa.gov/eog/dmsp/downloadV4composites.html> (access on 10 April 2021)) were used to retrieve anthropogenic heat flux (AHF), surface meteorological observations were collected from the China Meteorological Data Service Center (<http://data.cma.cn/en>(access on 10 April 2021)), DEM were achieved from geospatial data

Supplement

The following are available online, Text S1: Specific inversion steps of related environmental variables. Table S1: band ranges and the main use of Landsat 8 OLI. Figures S1: The performance of the RF models under different variable combinations. Table 1: Independent variables with their sources and spatial resolution

	<u>Parameters</u>	<u>Source</u>	<u>Spatial resolution(m)</u>
<u>geometric parameters</u>	<u>Proportion of LULC area</u>	<u>Landsat 8 data</u>	<u>30</u>
	<u>Latitude and longitude</u>		
	<u>distance from the city center</u>	<u>LULC data</u>	
	<u>Altitude, Slope and aspect</u>	<u>DEM data</u>	
<u>physical parameters</u>	<u>Proportion of IS area</u>	<u>Landsat 8 data</u>	<u>30</u>
	<u>Albedo</u>		
	<u>NDVI, NDBI, gNDVI,</u>		
	<u>SAVI and NDMI</u>		
<u>anthropogenic parameters</u>	<u>AHF data</u>	<u>NOAA nighttime lighting data</u>	<u>1000</u>

Notes: DEM, digital elevation model; IS, impervious surface; NDVI, normalized difference vegetation index; NDBI, normalized difference built-up index; gNDVI, green normalized difference vegetation index; SAVI, soil-adjusted vegetation index; NDMI, normalized difference moisture index; AHF, anthropogenic heat flux.

800

Table 21: R^2 and RMSE of the RF model with different buffer sizes (500 m, 1000 m, 2000 m, 5000 m).

	500 m		1000 m		2000 m		5000 m	
	R^2	RMSE (°C)	R^2	RMSE (°C)	R^2	RMSE (°C)	R^2	RMSE (°C)
11/08/201 3	0.33	0.75	0.57	0.65	0.56	0.65	0.36	0.74
02/09/201 5	0.58	0.70	0.59	0.69	0.57	0.70	0.49	0.76
21/07/201 7	0.19	0.92	0.17	0.91	0.47	0.80	0.16	0.93

Table 32: R^2 and RMSE of stepwise regression, GWR (geographically weighted regression) and the RF model within a 2-km buffer zone.

	Stepwise regression		GWR		RF model	
	R^2	RMSE (°C)	R^2	RMSE(°C)	R^2	RMSE (°C)
11/08/2013	0.30	0.69	0.33	0.77	0.56	0.65
02/09/2015	0.47	0.74	0.44	0.82	0.57	0.70
21/07/2017	0.27	0.90	0.12	0.93	0.47	0.80

Table 43. Importance of input variables for the RF model of AT estimation on the three different days.

11/08/2013	%IncMSE	IncNodePurity
Water-body	9.23	4.71
NDVI	8.38	4.22
NDBI	7.15	7.13
IS	6.93	6.46
Built-up	4.19	2.05
Vegetation	2.35	1.38
AHF	0.89	2.91
Cropland	0.27	1.70

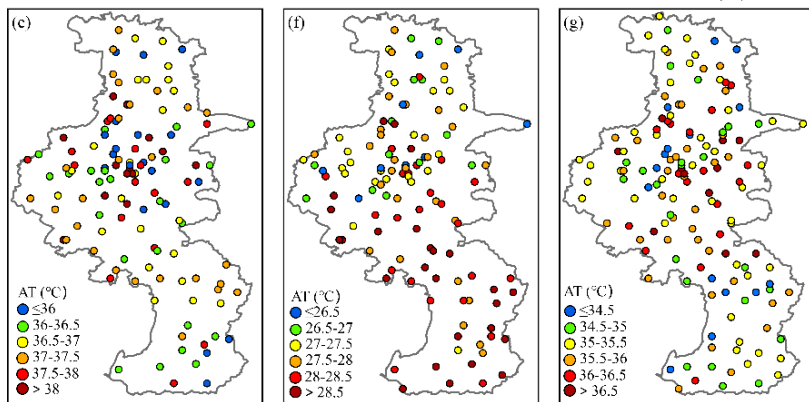

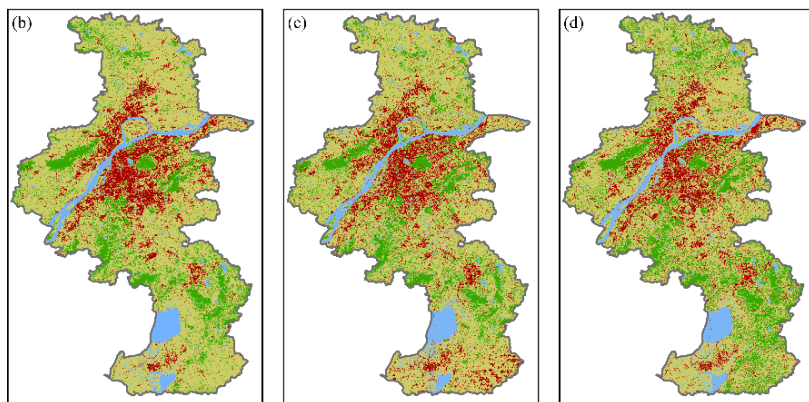

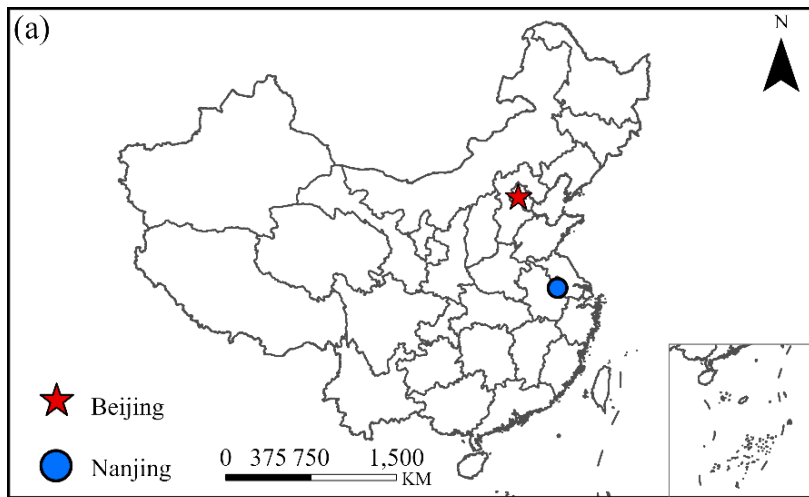

02/09/2015	%IncMSE	IncNodePurity
Cropland	5.10	9.45
Distance to city center	4.57	8.59
Water body	4.00	11.05
NDVI	3.18	5.34
NDBI	2.44	4.05
Built-up	2.41	2.78
SAVI	1.49	2.67
Vegetation	1.44	2.24
IS	0.40	2.59

21/07/2017	%IncMSE	IncNodePurity
Distance to city center	20.01	16.22
IS	18.36	15.75
Vegetation	11.52	8.08
NDVI	9.89	3.85
gNDVI	7.86	3.28
SAVI	6.78	2.38
Water-body	6.45	6.24

Notes: NDVI, normalized difference vegetation index; IS, impervious surface; AHF, anthropogenic heat flux; DEM, digital elevation model; NDBI, normalized difference built-up index; gNDVI, green normalized difference vegetation index; SAVI, soil-adjusted vegetation index.

Table 54. Area occupied by different levels of urban heat island intensity on different days (km²).

<u>CUHII level(°C)</u>	-1.5 to -1	-1 to -0.5	-0.5 to 0	0 to 0.5	0.5 to 1	1 to 1.5	1.5 to 2
11/08/2013	0.00	0.15	1047.43	1517.19	2446.03	1486.89	82.96

21/07/2017	0.23	232.52	1005.04	2670.11	2040.98	634.13	0.14

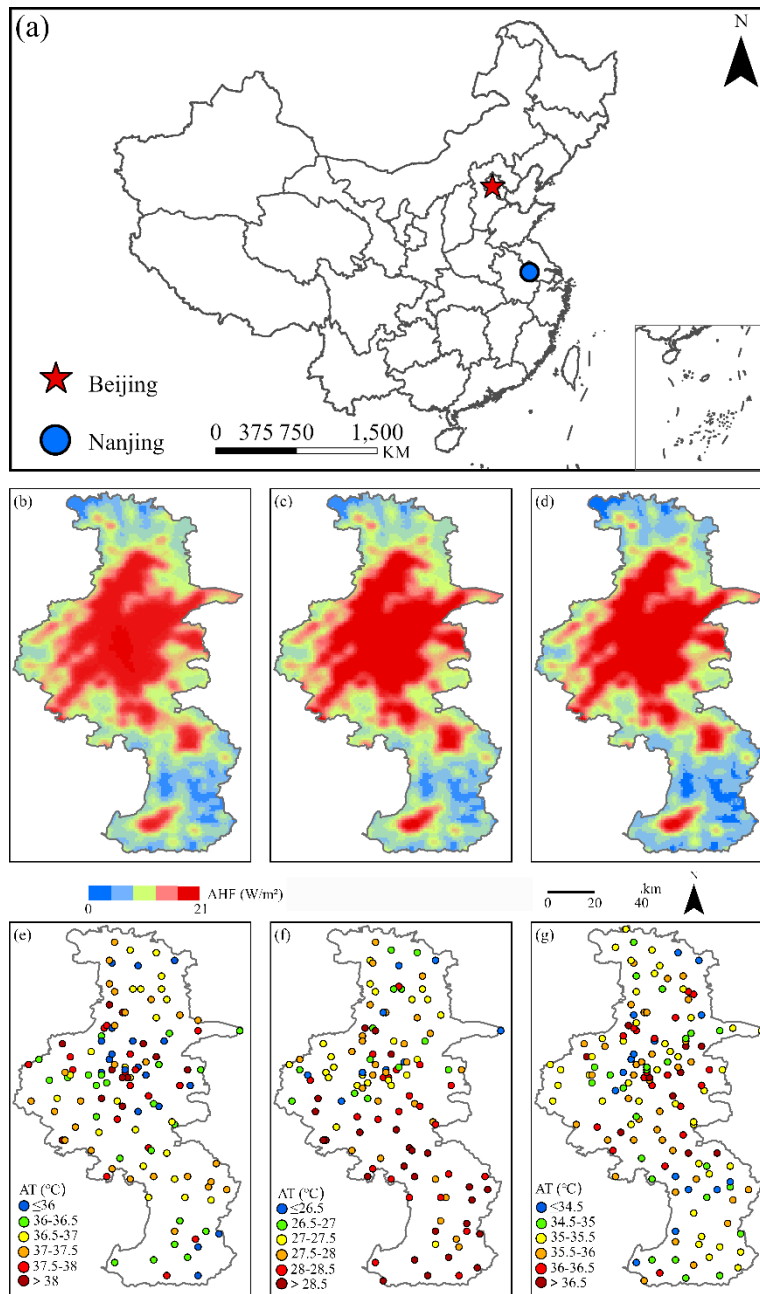

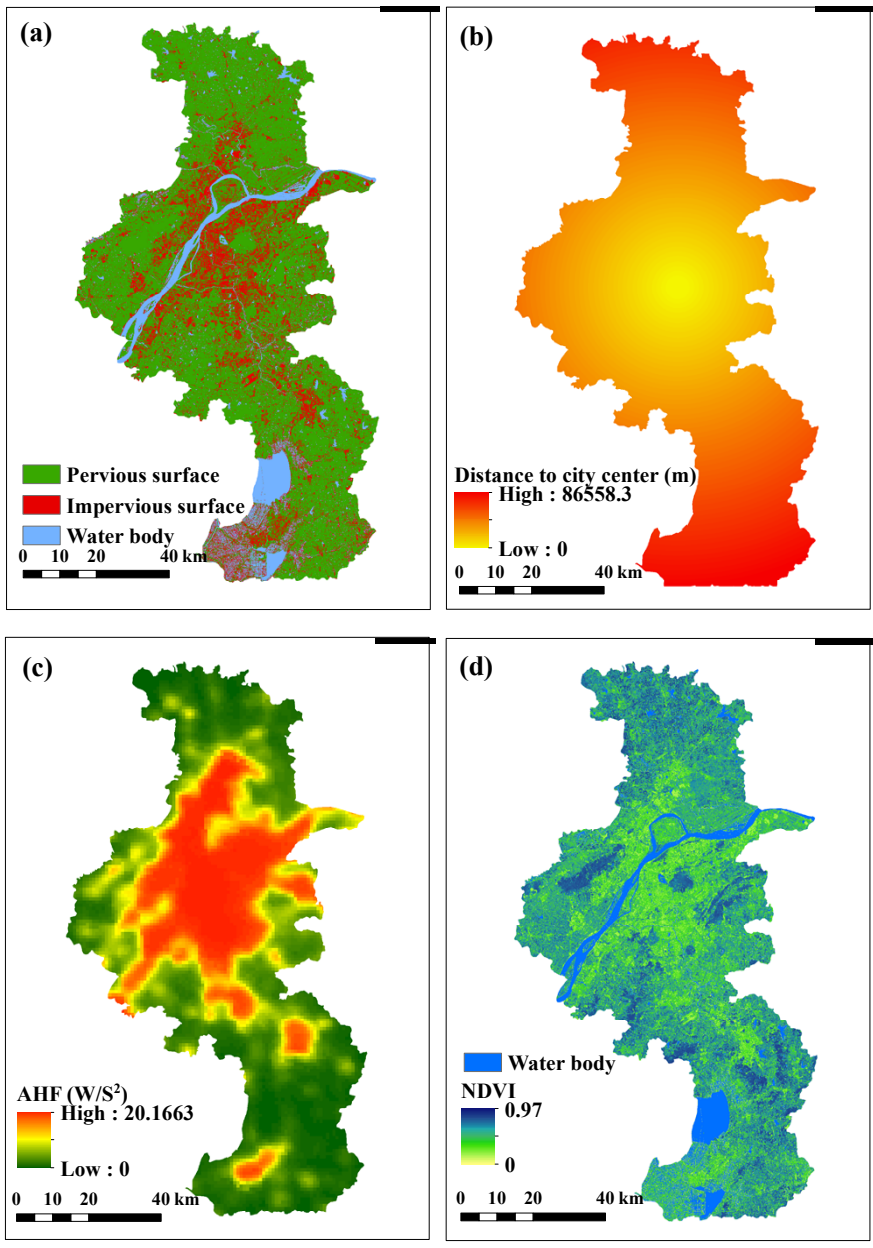

Figure 1: anthropogenic heat flux Land-use/land-cover of Nanjing city and locations of high-density automatic meteorological stations in Nanjing with recorded air temperature: (a) location map of Nanjing in China; (b, e) 11:00 local time (LT) 11 August 2013; (c, f) 11:00 LT 2 September 2015; (d, g) 11:00 LT 21 July 2017.

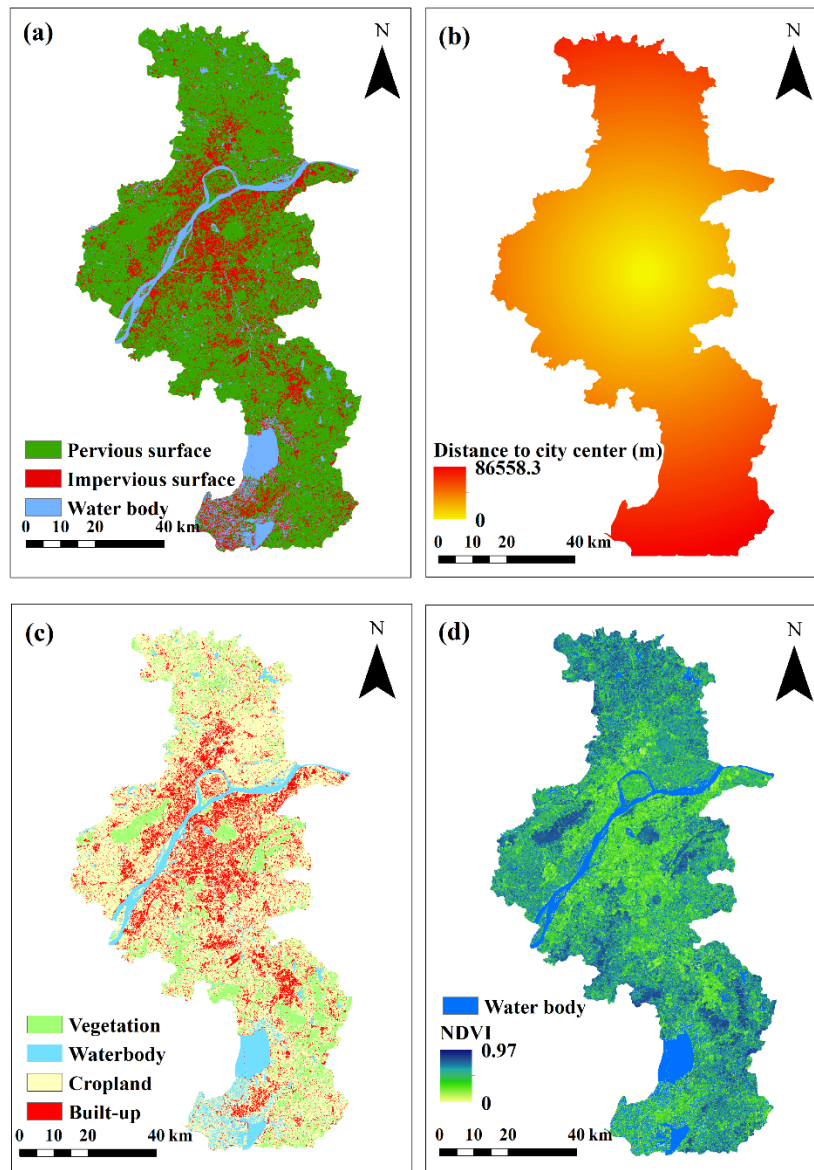

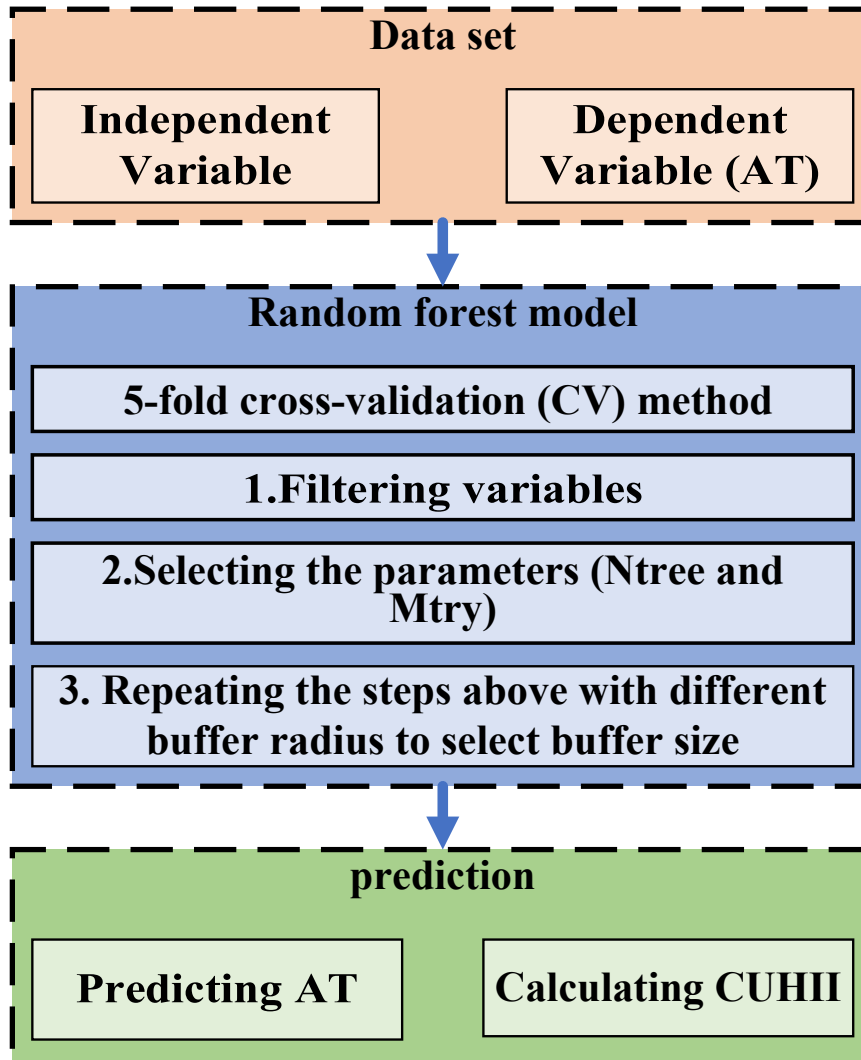

Figure 2: Spatial distribution of some typical environmental variables on 21 July 2017 in Nanjing city: (a) impervious surface; (b) distance from city center; (c) AHF (anthropogenic heat flux)LULC; (d) NDVI (normalized difference vegetation index).

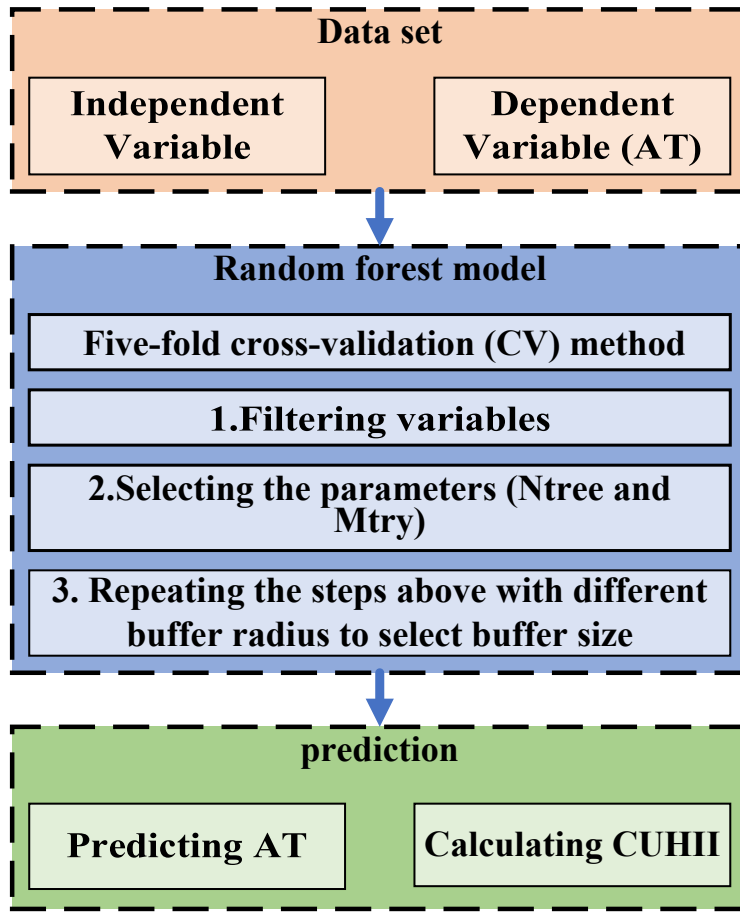

Figure 3: Flowchart for constructing the RF model and evaluating the CUHII (Canopy-urban layer urban heat island-intensity). Abbreviations: DEM, digital elevation model; AHF, anthropogenic heat flux; LULC, land use/land cover; IS, impervious surface; AT, air temperature; RF, Random Forest.

835

Figure 4. The (a–c) R^2 (coefficient of determination) and (d–f) RMSE (root-mean-square error) changes with the parameters Ntree and Mtry of the model using the dataset on (a, d) 11 August 2013, (b, e) 2 September 2015, and (c, f) 21 July 2017.

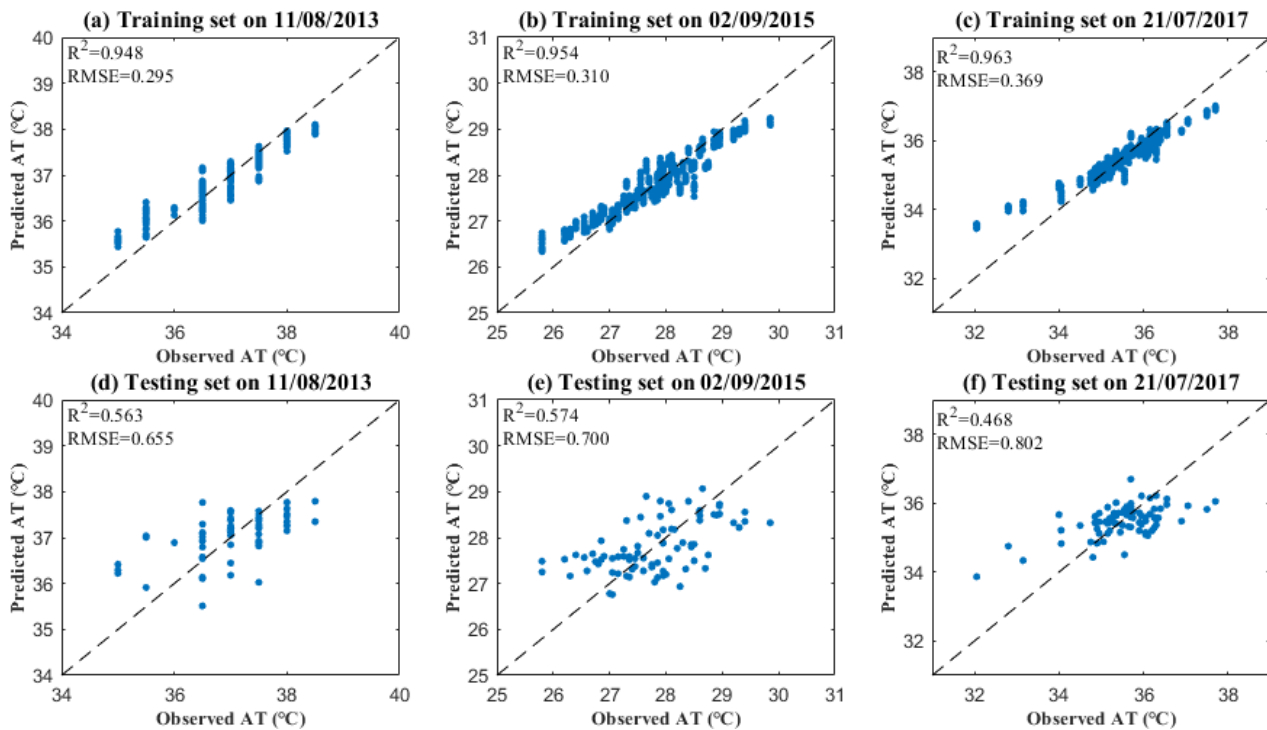

Figure 5: Scatterplot of predicted and observed air temperature: five-fold cross-validation (CV) for the training set on (a) 11 August 2013, (b) 2 September 2015 and (c) 21 July 2017; five-fold CV for the testing set on (d) 11 August 2013, (e) 2 September 2015 and (f) 21 July 2017.

845

Figure 6: the predicted relative error of the air temperature by random forest: (a) 11 August 2013; (b) 2 September 2015; (c) 21 July 2017.

Figure 7: Scatterplot of predicted and observed air temperature using data in a month five-fold CV for the testing set on (a) August 2013, (b) September 2015 and (c) July 2017.

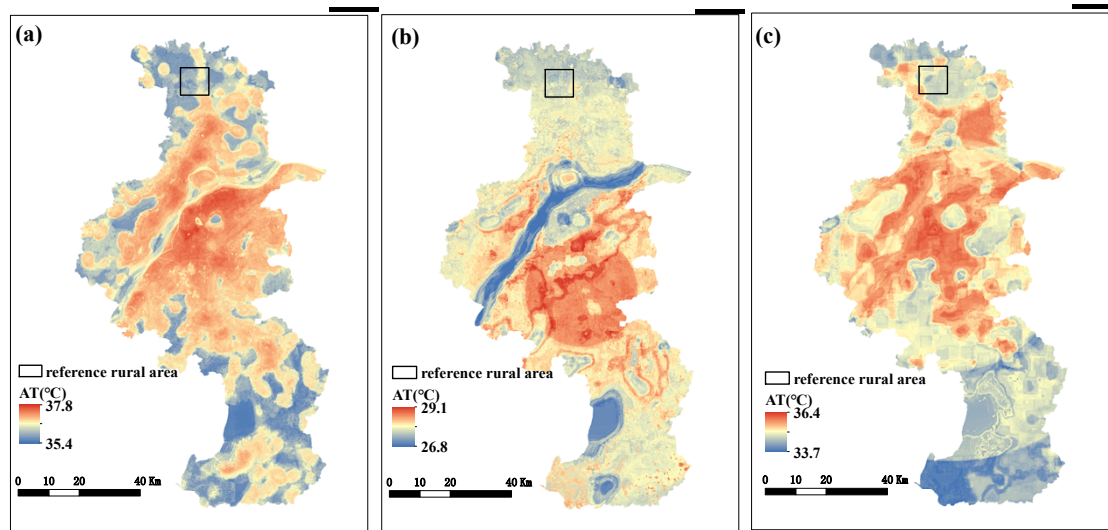

Figure 87: Spatial distribution of air temperature (AT) in Nanjing and the reference rural area: (a) 11 August 2013; (b) 2 September 2015; (c) 21 July 2017.

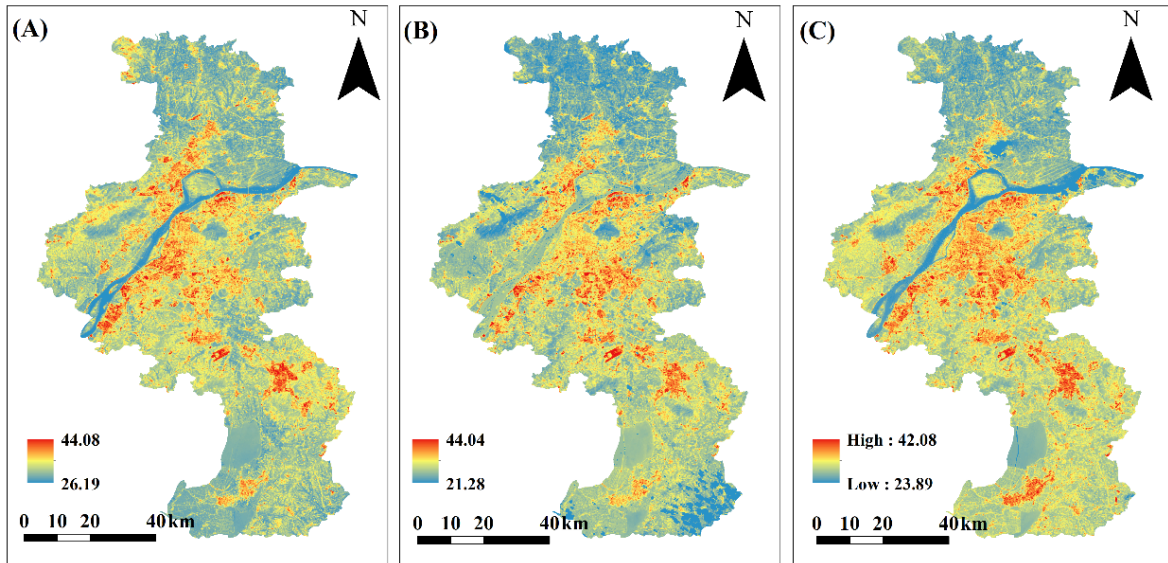

Figure 9: Spatial distribution of the LST in Nanjing: (a) 11 August 2013; (b) 2 September 2015; (c) 21 July 2017.

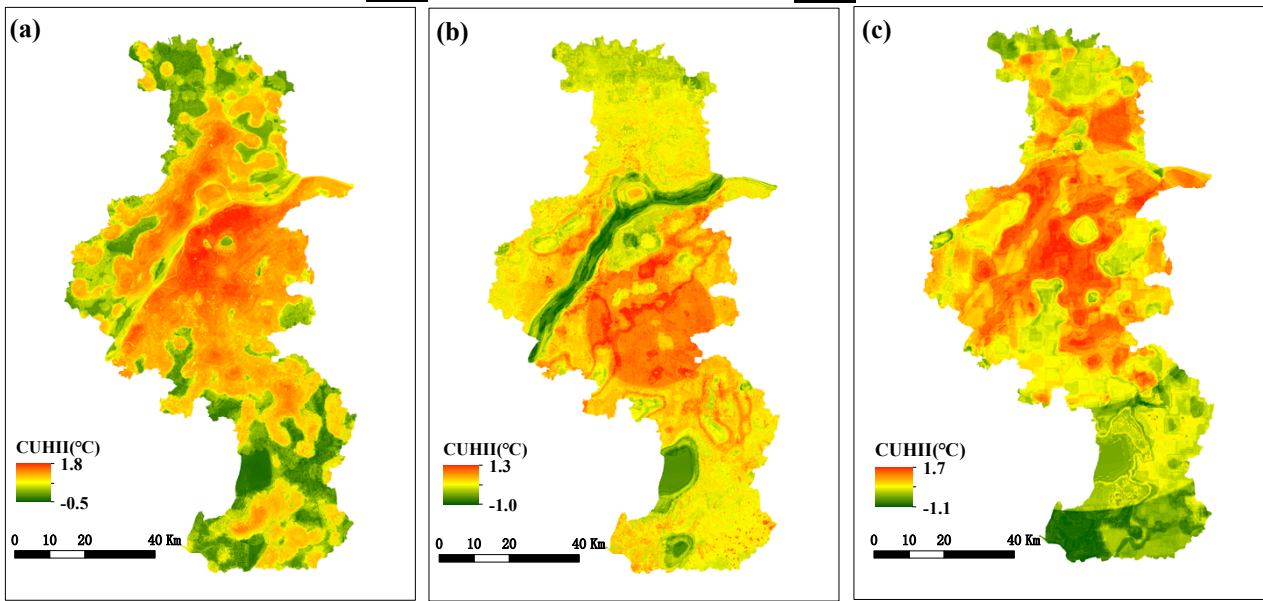

Figure 108: Spatial distribution of the CUHII in Nanjing: (a) 11 August 2013; (b) 2 September 2015; (c) 21 July 2017.

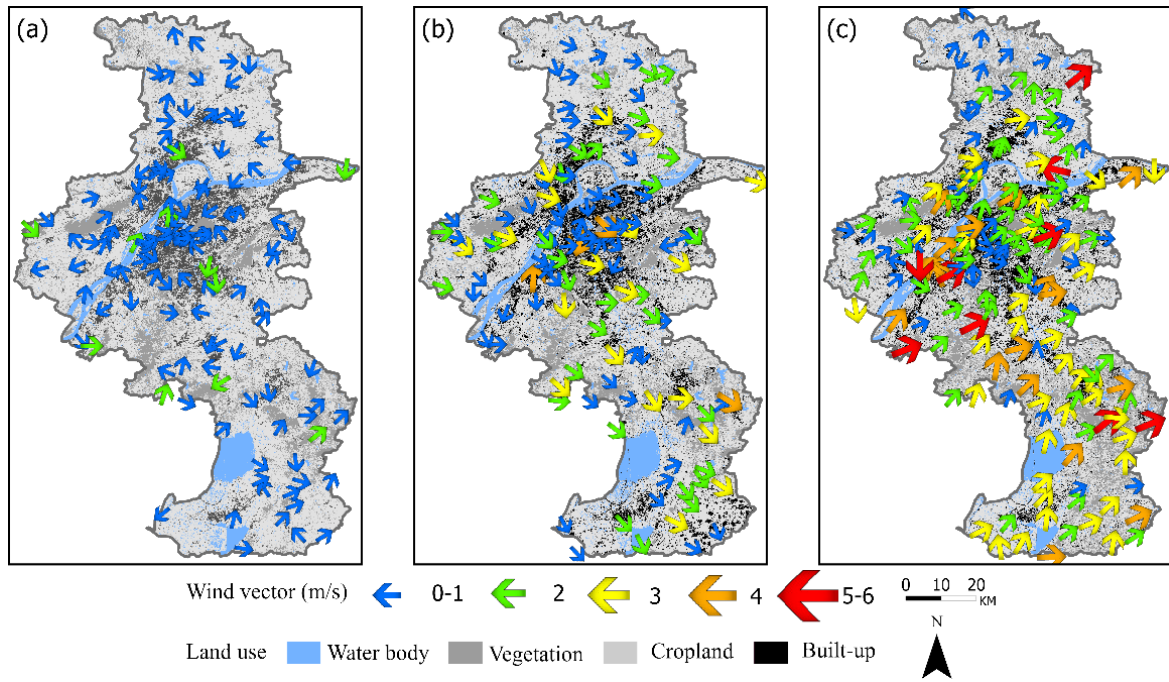

Figure 119: Wind vector field in Nanjing on (a) 11 August 2013, (b) 2 September 2015, and (c) 21 July 2017.

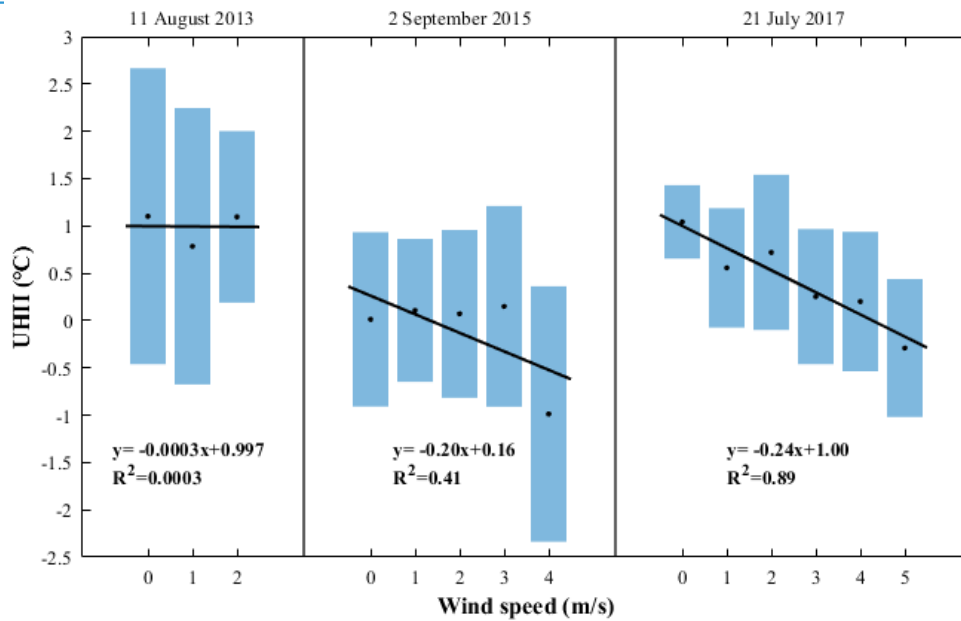

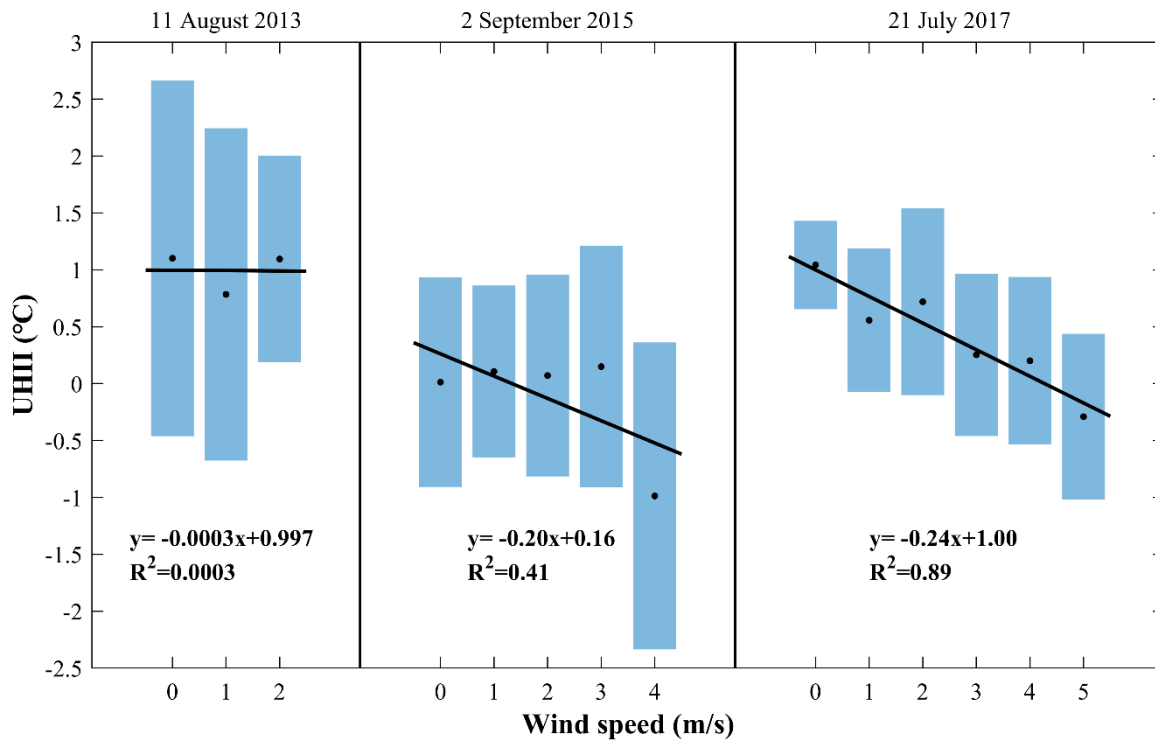

Figure 120: Relationship between canopy urban heat island intensity (UHII) and wind speed around all meteorological stations on (a) 11 August 2013, (b) 2 September 2015, and (c) 21 July 2017. The black dots represent the mean canopy UHII, while the bottom and top edges of the box indicate the uncertainties of one standard deviation value

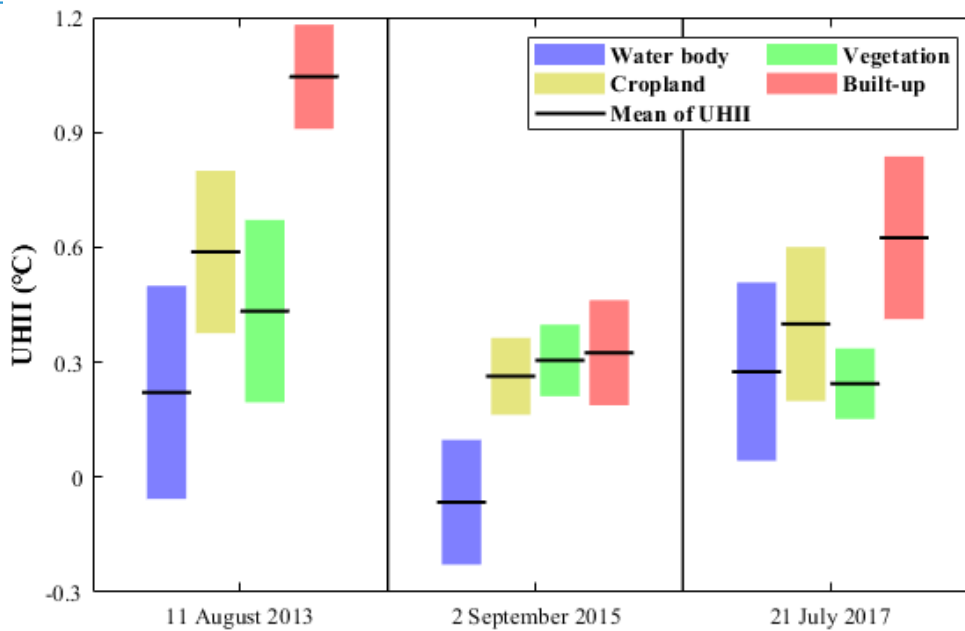

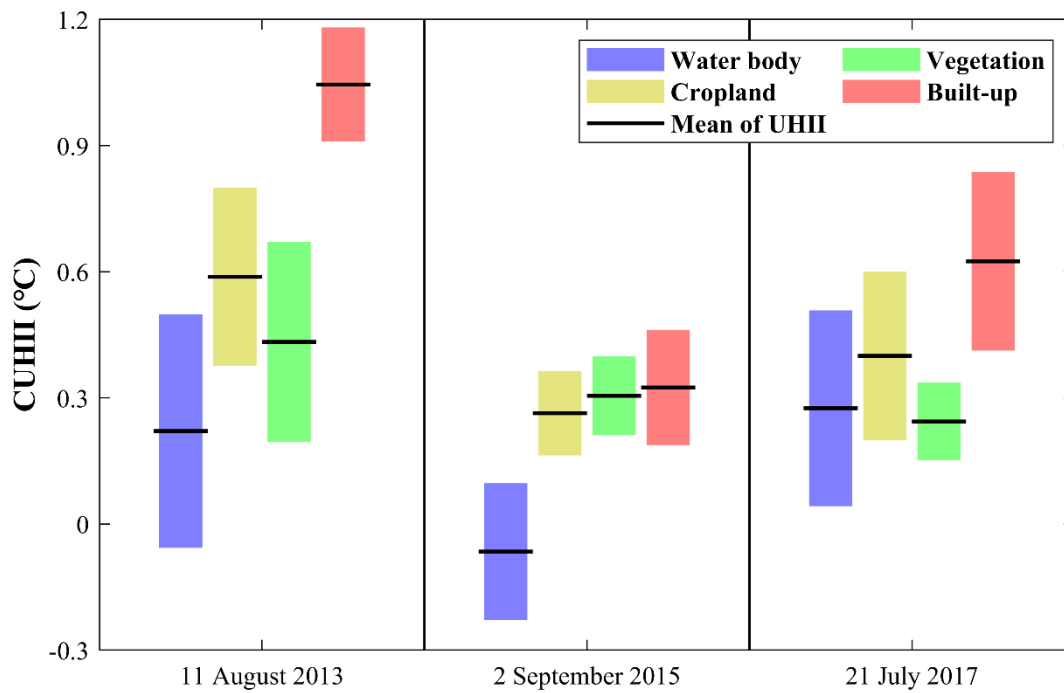

Figure 134: Histogram of canopy urban heat island intensity (CUHII) over different land use/land cover on (a) 11 August 2013, (b) 2 September 2015, and (c) 21 July 2017. Horizontal lines represent the mean intensity, while shaded regions are the uncertainties of one standard value from the mean.

Figure 142: Changes in air temperature, anthropogenic heat flux (AHF) and the proportion of built-up areas with distance from the city center on (a) 11 August 2013, (b) 2 September 2015, and (c) 21 July 2017. Thick lines represent mean values, while shaded regions are the uncertainties of one standard value from the mean.

Figure 153: Spatial distribution of canopy urban heat island intensity (CUHII) in Nanjing during a heat wave period: (a) 12 August 2013; (b) 13 August 2013; (c) 14 August 2013.
