Abstract. Three-dimensional (3D) cloud structures may impact atmospheric trace gas products from ultraviolet-visible (UV-VIS) sounders. We used synthetic and observational data to identify and quantify possible cloud-related bias in NO₂ tropospheric vertical column densities (TVCD). The synthetic data were based on high-resolution large eddy simulations which were input to a 3D radiative transfer model. The simulated visible spectra for low-earth orbiting and geostationary geometries were analysed with standard retrieval methods and cloud correction schemes that are employed in operational NO₂ satellite products. For the observational data the NO₂ products from the TROPOspheric Monitoring Instrument (TROPOMI) were used while the Visible Infrared Imaging Radiometer Suite (VIIRS) provided high spatial resolution cloud and radiance data. NO₂-profile shape, cloud shadow fraction, cloud top height, cloud optical depth, solar zenith and viewing angles, were identified as the metrics being the most important in identifying 3D cloud impacts on NO₂ TVCD retrievals. For a solar zenith angle less than about 40° the synthetic data show that the NO₂ TVCD bias is typically below 10%, while for larger solar zenith angles the NO₂ TVCD is low-biased by tens of %. The horizontal variability of NO₂ and differences in TROPOMI and VIIRS overpass times makes it challenging to identify a similar bias in the observational data. However, for optically thick clouds above 3000 m a low bias appears to be present in the observational data.

1 Introduction

Operational retrievals of tropospheric trace gases from space-borne spectrometers are based on the use of 1D radiative transfer models. To minimize cloud effects, generally only cloudless and partially cloudy pixels are analysed using simplified cloud contamination treatments based on radiometric cloud fraction estimates (e.g. Grzegorski et al., 2006; Stammes et al., 2008) and photon path length corrections based on oxygen collision pair (O₂-O₂) (Acarreta et al., 2004; Veeffkind et al., 2016) or O₂-A absorption band measurements (for example the FRESKO and OCRA/ROCINN algorithms, see Koelemeijer et al., 2001; Wang et al., 2008; Loyola et al., 2018; Liu et al., 2021). In reality however the impact of clouds can be much more complex, involving unresolved sub-pixel clouds, scattering of clouds in neighbouring pixels and cloud shadow effects. In a model study

Merrelli et al. (2015) showed that 3D radiation scattering from unresolved boundary layer clouds may give significant biases in Orbiting Carbon Observatory-2 (OCO-2) retrievals of CO₂ concentration. Massie et al. (2017, 2020) provided observational evidence of 3D cloud effects in OCO-2 CO₂ retrievals and found them consistent with 3D radiative transfer simulations. For airborne and ground-based remote sensing Schwaerzel et al. (2020, 2021) have shown the importance of accounting for 3D radiative transfer in air mass factor calculations when the atmosphere cannot be assumed to be horizontally homogeneous and when buildings are present.

In general, space-borne measurements of trace gases may be cloud contaminated and the presence of clouds may result in both positive and negative biases. It is thus vital to quantify the impact of clouds on trace gas retrievals and, if possible, envisage correction methods. To exclude cloud contaminated pixels from analysis is not a viable option as this, for example, may give bias in long-term averages, as shown by Geddes et al. (2012) for NO₂. Furthermore, the loss in data coverage when excluding partially cloudy scenes may become critical, especially for low/medium resolution sensors and for regions where the probability of cloud occurrence is high (e.g. Germany and other western European countries).

This paper is one of a series of three papers discussing the impact of 3D cloud structures on the atmospheric trace gas products from ultraviolet-visible (UV-VIS) sounders. The first paper by (Emde et al., 2021) describes the synthetic data which is based on 3D radiative transfer model simulations utilizing realistic 3D clouds as input and is designed for validation of remote sensing trace gas retrievals. In the second paper, Yu et al. (2021) discuss trace gas retrieval and mitigation strategies in the presence of 3D cloud structures. In this paper, the bias due to 3D clouds is quantified using both synthetic and observational data.

We chose to study NO₂, as it is an important measure of air quality and a key tropospheric trace gas measured by the atmospheric Sentinels (sentinel.esa.int). The synthetic data, which ignore stratospheric NO₂, were used to identify the cloud situations that give bias in tropospheric NO₂ retrievals. The observational satellite data from TROPOMI were used to investigate the presence of 3D cloud radiative transfer effects in real data. While focus is on tropospheric NO₂, the results are expected to be valid for other UV-VIS derived trace gas products.

The paper first discusses the synthetic and observational data sets, section 2. This is followed by a description of the various metrics used to identify cloud impacts, section 3. In section 4 the results are presented and discussed before the paper ends by some concluding remarks and an outlook in section 5.

2 Data

From the HD(CP)2 (hdcp2.eu) project large eddy simulations (LES) based on the ICOSahedral Non-hydrostatic atmosphere model (ICON Dipankar et al., 2015; Zängl et al., 2015) are available for a region including Germany, the Netherlands and parts of other surrounding countries. The model results were validated against ground and satellite-based observational data by Heinze et al. (2017). This unique synthetic data set provide realistic input for 3D radiative transfer modelling. Hence, we adopted the study region to be the area covered by the LES. This region also covers part of the footprints of the upcoming Sentinel-4 and Sentinel-5 missions.

2.1 Synthetic satellite data

The synthetic satellite data comprise results from three sources: 1) high-resolution LES cloud data; 2) 3D radiative transfer modelling of satellite radiances with the LES cloud data as input; and 3) NO₂ retrieval using the synthetic satellite radiances.

5 Within the HD(CP)2 project the ICON model simulated realistic liquid and ice clouds with a horizontal spatial resolution of approximately $1.2 \times 1.2 \text{ km}^2$. Several weeks of simulations are available including all kinds of weather situations in Europe. We, however, utilize only one from 29 July 2014, 12:00 UTC, due to the computational burden of the radiative transfer simulations. The simulated scene includes all cloud types that are typical for Europe, such as shallow cumulus, cirrus, stratus, and also convective clouds. While focus is on Europe, the results/methods are expected to be general and thus applicable elsewhere.

10 The LES results were input to the 3D MYSTIC Monte Carlo radiative transfer model (Mayer, 2009; Emde et al., 2011) run within the libRadtran package (Mayer and Kylling, 2005; Emde et al., 2016) to generate synthetic observation spectra in the visible spectral range from 400–500 nm and in the O₂-A band region from 755–775 nm (for further details see: Emde et al., 2021; Yu et al., 2021). The spatial resolution of the simulated sensor was set to approximately $7 \times 7 \text{ km}$, corresponding to 98×104 pixels for the full LES domain. Note that each simulated sensor pixel includes 36 cloud pixels, hence the simulations include sub-pixel cloud inhomogeneity. The synthetic spectra were input to a NO₂ retrieval algorithm which included two steps: first
15 a differential optical absorption spectroscopy (DOAS) fit was performed using the QDOAS retrieval algorithm (Blond et al., 2007; De Smedt et al., 2008) to get the NO₂ slant column densities; second the slant column densities were converted to vertical column densities using layer air mass factors (AMF) based on the VLIDORT 1D radiative transport model (Spurr, 2006). The fitting window was between 425 and 495 nm, similar to the one used by Richter et al. (2011). The air mass factor was calculated at the middle of the fitting window, that is 460 nm. Cloud corrections were made using both O₂-O₂ and O₂-A band (FRESCO,
20 OCRA/ROCINN) based methods (Yu et al., 2021). An example of retrieved NO₂ TVCD for a synthetic case is shown in Fig. 1a. Note that the “true” NO₂ is constant over the scene with column density of $1.6 \times 10^{16} \text{ molec/cm}^2$ corresponding to an European tropospheric polluted NO₂ profile from Levelt et al. (2009). Thus any differences between the retrieved and “true” NO₂ TVCDs are due to the presence of clouds, Fig. 1b. The NO₂ retrieval is further discussed by Yu et al. (2021).

While we discuss our synthetic results in connection with observational results from satellites in low-earth-orbit (LEO),
25 simulations were also made for a geostationary orbit (GEO). Azimuth and zenith viewing and solar angles were chosen to resemble geometries for the study region when viewed by the TROPOspheric Monitoring Instrument (TROPOMI, Veeffkind et al., 2012) and the future Ultra-violet Visible Near-infrared (UVN, <https://sentinel.esa.int/web/sentinel/missions/sentinel-4>) instrument to be in geostationary orbit. In total 15 and 36 combinations of viewing and solar angles were simulated for the GEO-case and LEO-case, respectively (Emde et al., 2021). The surface was assumed to be snow free and with constant albedo
30 to simplify the interpretation of the results. In the visible (400-500 nm) simulations were made with albedos of 0, 0.05 and 0.2, while in the O₂-A band region an additional albedo of 0.5 was included to account for the potentially larger albedo in this part of the spectrum. Combining the sun-sensor geometries and visible albedo values our simulated data set thus include a total of 45 GEO-cases and 108 LEO-cases.

Figure 1. (a) The retrieved NO_2 TVCD for the low-earth orbit geometry case with albedo=0.05, solar zenith angle= 60° , solar azimuth angle= 13° , satellite viewing angle= 0° , and satellite azimuth angle= 282° (identical for all pixels). (b) The difference between the retrieved and the true NO_2 TVCD. (c) The cloud shadow index, see section 3.3 for details. The units on the axes are in pixel numbers. White pixels are cloudy regions for which the retrieval was not performed.

2.2 Observational satellite data

Both observational satellite spectrometer and imager data were utilized to investigate the presence of 3D cloud radiative transfer effects in real data. NO_2 TVCD data were taken from the TROPOMI/S5P operational L2 NO_2 tropospheric column product (van Geffen et al., (last access 21 March, 2022). TROPOMI/S5P was launched 2017-10-13 and L2 NO_2 data are available from 2018-06-28. It passes the equator at 1330 local time. S5P does not include an imager for cloud information. However, it flies in tandem with the Suomi National Polar-orbiting Partnership (S-NPP) satellite. The S-NPP payload includes the Visible Infrared Imaging Radiometer Suite (VIIRS) instrument which may be used as an imager for TROPOMI. The difference in overpass time is slightly more than four minutes and care must be taken to for example movement of clouds when combining data from the two platforms (e.g. Trees et al., 2021). We used both VIIRS L1b and L2 data. The L1b reflectances were used for RGB plots and to produce various metrics, see section 3. The L2 data include various cloud products of which we used the cloud mask, cloud shadow, cloud optical thickness and cloud top height products. The TROPOMI data includes the latitude and longitude of the corners of each TROPOMI pixel. This information was used to identify VIIRS pixels within each TROPOMI pixel.

Data within the study region roughly covering Germany and parts of neighbouring countries were collected for the periods 28 June 2018 - 15 October 2018 and 1 March 2019 - 30 June 2019 when the sun was sufficiently high on the horizon to avoid problems with NO_2 retrievals for low sun (solar zenith angle $< 60^\circ$). The NO_2 and cloud situations generally vary a lot for this region. In Fig. 2 an example of NO_2 data from TROPOMI, (Fig. 2b,c) and cloud optical depth (Fig. 2d), cloud top height (Fig. 2e) and cloud shadow fraction (Fig. 2f) from near simultaneous and VIIRS overpasses of Germany, is shown. A distinct cloud shadow band is seen in Fig. 2a,d,e starting at about 50°N , 3°E and extending in the east/north-east direction.

Figure 2. (a) RGB composite of VIIRS bands M3, M4 and M5 (centred at 0.488, 0.555 and 0.672 μm). (b) The tropospheric NO₂ vertical column density from TROPOMI. Only pixels with data quality value > 0.95 are displayed. (c) The percentage difference of the NO₂ column from the median over the study area. (d) The VIIRS cloud optical thickness. (e) The VIIRS cloud top height. (f) The VIIRS cloud shadow mask.

3 Methods

Several metrics were calculated to quantify cloud features and their possible connection with NO₂-biases due to 3D cloud effects.

3.1 Cloud geometric and radiance fractions

- 5 Cloud fractions may be defined in several ways. We calculate the geometric cloud fraction, CF_g , the radiometric cloud fraction, CF_r , and the weighted radiometric cloud fraction, CF_w .

The geometric cloud fraction for a TROPOMI pixel is defined as

$$CF_g = \sum CM_i / N, \quad (1)$$

where the sum is over all N VIIRS pixels within the TROPOMI pixel and CM_i is the VIIRS cloud mask where $CM_i = 1$ for pixels identified as cloudy and $CM_i = 0$ otherwise.

The radiometric cloud fraction is the fraction of measured radiance reflected from clouds in a pixel (see also Grzegorski et al., 2006)

$$5 \quad CF_r = \begin{cases} 0 & R \leq R_s \\ \frac{R-R_s}{R_c-R_s} & R_s < R < R_c \\ 1 & R \geq R_c \end{cases} \quad (2)$$

Here R is the observed reflectance, R_s is the reflectance for a cloudless sky and R_c the reflectance for an opaque cloud. For the O₂-O₂ cloud correction, CF_r is calculated based on the reflectance at 460nm which is in the middle of the DOAS fitting window for NO₂. For the FRESKO algorithm, CF_r is determined by the reflectance in the 758-759nm window band. Further details are described by Yu et al. (2021). We also define an average radiometric cloud fraction CF_r^{VIIRS} using the average of
 10 CF_r calculated for each VIIRS M3 band pixel, centred at 0.488 μ , within a TROPOMI pixel:

$$CF_r^{VIIRS} = \sum CF_{r,i}/N, \quad (3)$$

where the sum is over all N VIIRS pixels within the TROPOMI pixel.

Finally, the weighted radiometric cloud fraction is defined as (Yu et al., 2021)

$$CF_w = \frac{CF_r R_c}{CF_r R_c + (1 - CF_r) R_s} \quad (4)$$

15 3.2 Cloud mask

No cloud mask was available for the LES based synthetic data. In principle this may be calculated from the cloud optical thickness assuming some treshold. However, we chose to calculate a cloud mask similar to how it is done for several operational satellite products. We thus assume that pixels with reflectance larger than some threshold, $R > R_t$, are cloudy. The cloud mask was calculated from high spatial resolution radiance simulations at 0.55 μ m of the synthetic cases described by Emde et al.
 20 (2021). A threshold of $R_t = 0.25$, similar to Heinze et al. (2017), was adopted. It is noted that Barker et al. (2017) used $R_t = 0.15$ for the GOES-13 0.65 μ m band. Yang and Di Girolamo (2008) has shown that there may be overlap between clear and cloudy pixels and hence some mis-classification is unavoidable. Our slightly higher value of R_t potentially includes more cloud contaminated pixels, but also reflects that we are mainly working over land where surface albedo is higher than over ocean.

25 3.3 Cloud shadow fraction and cloud shadow index

The VIIRS cloud shadow mask algorithm is geometry-based and described by Hutchison et al. (2009). They compared the MODIS MOD35 product which uses spectral signatures to identify cloud shadows with geometry-based approaches and states that the latter “are far superior to those predicted with the spectral procedures”. A cloud shadow detection algorithm using TROPOMI data only have been described by Trees et al. (2021). It was, however, not available for this study.

The cloud shadow fraction, CSF , for a TROPOMI pixel is defined as

$$CSF = \sum CSM_i / N, \quad (5)$$

where the sum is over all N VIIRS pixels within the TROPOMI pixel and CSM_i is the VIIRS cloud shadow mask where $CSM_i = 1$ for pixels identified as cloud shadow and $CSM_i = 0$ otherwise.

5 For the LES we define the cloud shadow index (CSI) as a surrogate for a cloud shadow product as follows:

$$CSI = E_0 - E_{\theta, \phi} / \cos(\theta) \quad (6)$$

Here $E_0 = 1$ is the direct transmittance at the surface for an atmosphere with no molecular absorption nor clouds or aerosol. The direct transmittance, $E_{\theta, \phi}$, at the surface for a solar zenith angle of θ and solar azimuth angle ϕ , was calculated with the MYSTIC model. It also does not include molecular absorption nor aerosol, however, it includes clouds, which are fully
 10 accounted for in 3D geometry and with the 3D cloud fields in higher spatial resolution than the TROPOMI pixel size. The CSI is zero for pixels with no cloud shadow and 1 if a pixel is fully in the cloud shadow. The CSI clearly and unambiguously identify cloud shadow regions as it is based solely on sun, cloud and surface geometry. An example of the CSI is given in Fig. 1c.

3.4 H-metric

15 For a TROPOMI pixel the H-metric is the standard deviation of VIIRS band reflectances divided by the mean of the VIIRS reflectances within the TROPOMI pixel. It is an estimate of the variation of radiance within the TROPOMI pixel and has been used earlier by for example Massie et al. (2017) as metric for the impact of 3D clouds on CO_2 retrievals. In the presence of sub-pixel clouds the H-metric is expected to increase as the horizontal cloud inhomogeneity increase. In the absence of clouds the H-metric is expected to be small. However, for cloud free pixels with large variations in surface albedo the H-metric may
 20 still be large, and conversely, for a completely cloudy pixel the H-metric may be small. Thus, it may not be used without care to unambiguously identify cloud inhomogeneity. From the VIIRS data we calculate the H-metric for the M3, M4 and M5 bands centred at 0.488, 0.555 and 0.672 μm respectively.

3.5 Absorbing aerosol index

Clouds have an effect on the UV absorbing aerosol index (AAI). It is thus of interest to investigate possible relationships
 25 between the AAI and the cloud shadow fraction and the NO_2 TVCD. The AAI is a measure of the UV color of a cloud-, aerosol- and shadow-free 1-D atmosphere-surface model with respect to the measured UV color (de Graaf et al., 2005). When absorbing aerosols are present, the AAI tends to be positive, while the AAI is approximately zero or negative in the presence of clouds (see e.g. Kooreman et al., 2020; Penning de Vries et al., 2009a). We use the TROPOMI AAI product to investigate relationships between the AAI and the NO_2 TVCD.

Figure 3. The difference between the retrieved and “true” NO₂ TVCDs versus the cloud shadow index for three low earth-orbiting-geometry cases. Results are shown for cloud filtered pixels and solar zenith angles of (a) 20, (b) 40 and (c) 60°, albedo=0.05, solar azimuth angle=13°, satellite azimuth angle=0°, and satellite viewing angle=282°. The black lines are linear fits and the fit parameters and R^2 are given in the individual plots. The data in (c) are for the case presented in Fig. 1.

4 Results

For both the synthetic and observational data the aim is to compare the NO₂ TVCD for cloud affected cases with the true NO₂ TVCD and identify potential biases. This is straightforward for the synthetic data as the true NO₂ TVCD is known. For the observational data the true NO₂ TVCD unaffected by clouds is in general not known and is difficult to estimate due to the horizontal variability of NO₂. An attempt to estimate the true NO₂ TVCD from the observational data is discussed in section 4.2, which also include the analysis of the observational data.

4.1 Synthetic satellite data

For the synthetic data the fully cloudy pixels were not simulated due to the computational burden, see Emde et al. (2021) for details. To further filter for the presence of clouds the NO₂ TVCDs were retrieved for pixels where the radiometric cloud fraction $CF_r < 0.3$ for all LEO and GEO cases. The retrieval tries to correct for the presence of remaining clouds by including a standard photon path length correction based on absorption by the oxygen collision pair O₂-O₂ or the O₂-A band as described by Yu et al. (2021). An example of the retrieved NO₂ TVCD and the bias is shown in Figs. 1a and b, while the cloud shadow index is shown in Fig. 1c.

For three LEO cases the difference between the retrieved and “true” NO₂ TVCDs versus the cloud shadow index is shown in Fig. 3. The cloud shadow impact is seen to increase as the solar zenith angle increases. The number of pixels with NO₂ TVCD differences $< -20\%$ is 0.2% for a solar zenith angle of 20° (Fig. 3a), 4.1% for 40° (Fig. 3b) and 20.1% for 60° (Fig. 3c). As the solar zenith angle increases a linear relationship appears between the NO₂ TVCD difference and the CSI as indicated by the black lines and corresponding R^2 values. The increase of the cloud shadow impact with increasing solar zenith angle is

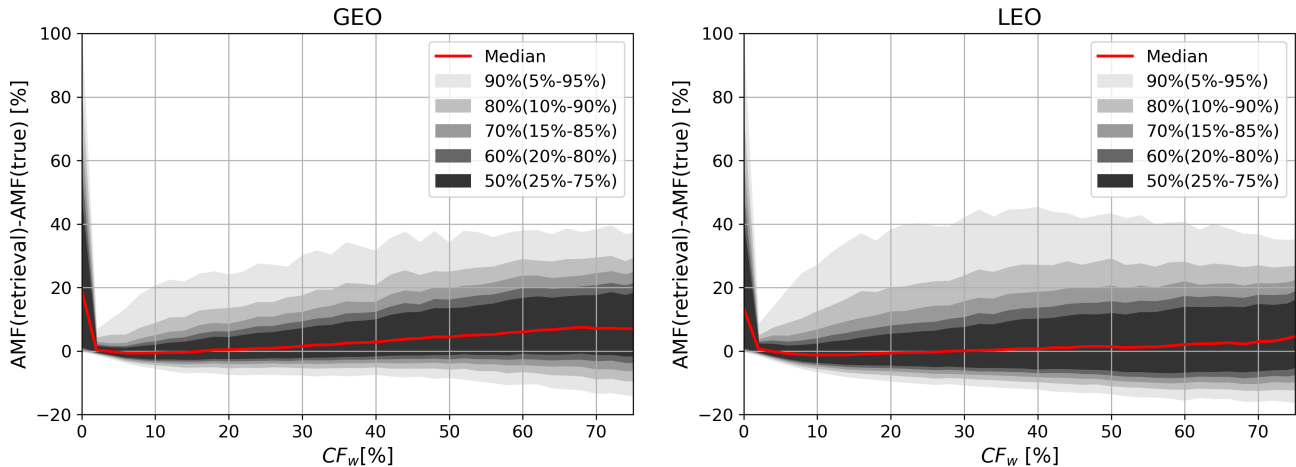

Figure 4. Distribution of the NO₂ AMF bias as a function of the weighted radiometric cloud fraction, CF_w , for geostationary and low earth orbiting geometries. Results are shown for the retrieval using the O₂-O₂ cloud correction. Results are similar for the O₂-A band based cloud correction.

due to the increase in cloud shadow size for larger solar zenith angles from geometrical reasons, see Emde et al. (2021) for a detailed discussion.

For the cloud correction of the AMF the weighted radiometric cloud fraction, CF_w , is used as described by Yu et al. (2021). The effect of increasing CF_w is shown in Fig. 4 where the NO₂ AMF bias (1D AMF - 3D AMF) is plotted as a function of CF_w for all GEO and LEO geometries. The retrieval bias is binned in CF_w bins with 2% steps which gives more than 5000 pixels in each bin when the $CF_w < 75%$. The bias may be due to several causes. The NO₂ profile and surface albedo input gives differences between the LIDORT, used in the retrieval, and MYSTIC RTM, used for the 3D simulations, on the order of 1% (Emde et al., 2021; Yu et al., 2021). As discussed by Yu et al. (2021), the NO₂ retrieval error due to the use of a simple cloud correction scheme is generally less than 20% for nearly cloud-free cases ($CF_w < 50%$). Therefore, pixels with a NO₂ retrieval bias $> 20%$ are likely to be affected by cloud shadow effects. For both geometries the NO₂ AMF bias is high (median of 20%) and with a large range (0-65%) for $CF_w < 1%$. For these clear pixels there is a significant number of pixels with the retrieval bias $> 20%$ and this is attributed to cloud shadow effects. The bias decreases to 0% when the CF_w is between 1-3%. The bias range increases slightly with increasing CF_w : about 75% of the pixels have a positive bias for large CF_w for GEO geometry, while there are comparatively more pixels with a negative bias for LEO geometry. The solar zenith angle is the same for the LEO and GEO cases. However, the solar azimuth angle and the sensor viewing zenith and azimuth angles are different. For the LEO and GEO geometries studied, see Emde et al. (2021) for details, the sun is to the south of the study region. This implies that a relatively large portion of cloud shadows are on the northern sides of the clouds. These cloud shadows are partly hidden from GEO satellites but may be visible from LEO satellite instrument with a nadir view of Earth, thus giving different

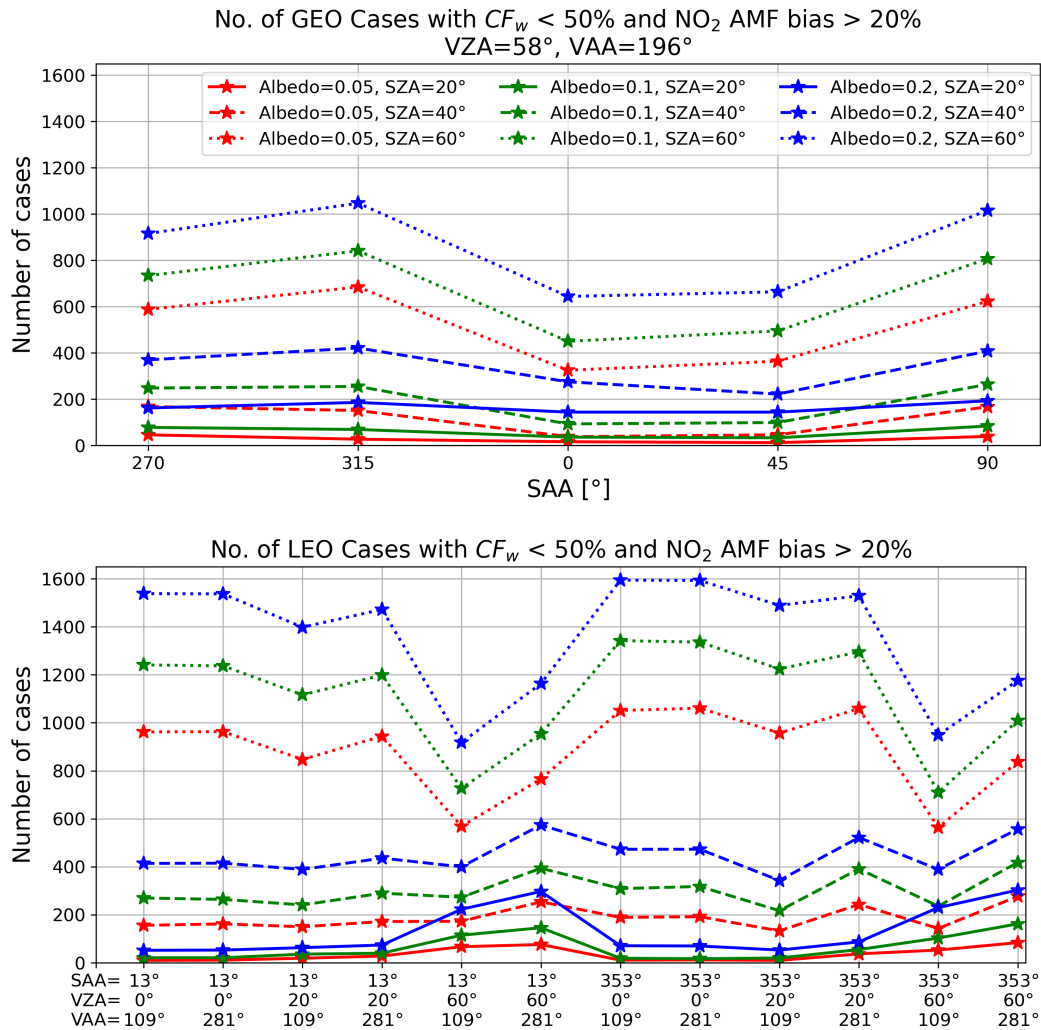

Figure 5. Number of pixels with weighted radiometric cloud fraction $CF_w < 50\%$ and NO_2 AMF bias $> 20\%$ for geostationary (top) and low earth orbiting (bottom) geometries. The data points are connected by lines for increased readability. Different line styles indicate different SZA while line color are used for the surface albedo as given in the annotation. For the geostationary geometry the solar azimuth angle (SAA) for each case is given on the x-axis label, while for the low earth orbiting geometry the viewing zenith angle (VZA) and viewing azimuth angle (VAA) are given in addition. The total number of pixels for a single case is 9400.

sensitivity to cloud shadows for LEO and GEO geometries. More than 15% of the pixels have a bias larger than 20% for $CF_w > 50\%$ for both GEO and LEO geometries.

Figure 5 shows the number of pixels that satisfy these conditions for all the LEO and GEO geometries. For the geostationary geometry, the number of pixels with retrieval bias $> 20\%$ is up to about 1000 or 10.6% (out of 9400 pixels for a single case).

Figure 6. The number of cases with $CF_w < 50\%$ and NO_2 AMF bias $> 20\%$ for each pixel for GEO (left) and LEO geometries (right). The x- and y-axes represent pixel number in the longitude/latitude direction. Grey shaded pixels indicate cloudy pixels.

This number increases with surface albedo and SZA, the difference between surface albedos of 0.05 and 0.2 is about 150 to 400 pixels. As discussed above the increase with solar zenith angle is due to larger cloud shadow due to geometrical reasons. With respect to the albedo dependence, Emde et al. (2021) showed that the relative 3D-1D difference in reflectance increase with increasing surface albedo. Furthermore, Yu et al. (2021) showed that this gives increased differences in $\text{O}_2\text{-O}_2$ and FRESCO cloud-corrected AMFs with increasing surface albedo. This number also strongly depends on the solar azimuth angle (SAA), and the difference between SAAs of 315° and 45° is more than 25%. For low earth orbiting geometry, the number of pixels with bias $> 20\%$ increases with surface albedo and SZA as well, and it is up to 1600 (17%) for high surface albedo of 0.2 and SZA of 60° .

To identify the localisation of the pixels with NO_2 AMF bias $> 20\%$, maps of the number of cases with NO_2 AMF bias $> 20\%$ were made as shown in Fig. 6. Generally, the majority of pixels with large NO_2 AMF bias are found in cloud free regions close to cloud edges. For a solar zenith angle around 40° most pixels will have an AMF bias below 20% if the distance to the cloud edge is more than about 10 km. For a solar zenith angle of 60° this distance increase to about 20 km. The distance depends on a number of factors such as cloud top height, cloud optical depth and surface albedo. This is further discussed and quantified for box clouds in the accompanying paper by Yu et al. (2021). Figure 7 shows maps of the maximum retrieval bias for each pixel. As above, cloudy data ($CF_w > 50\%$) are excluded from the analysis. The maximum bias is usually less than 60% over the northwest region ($x=30-50$, $y=70-100$) where there is an ice cloud with small optical thickness (< 10). In the center of the map, the bias is often higher than 100%, the pixels around are covered by a convective cloud with large vertical extent and optical thickness > 100 . Fig. 8 shows under which geometry the maximum bias is observed. Pixels with maximum

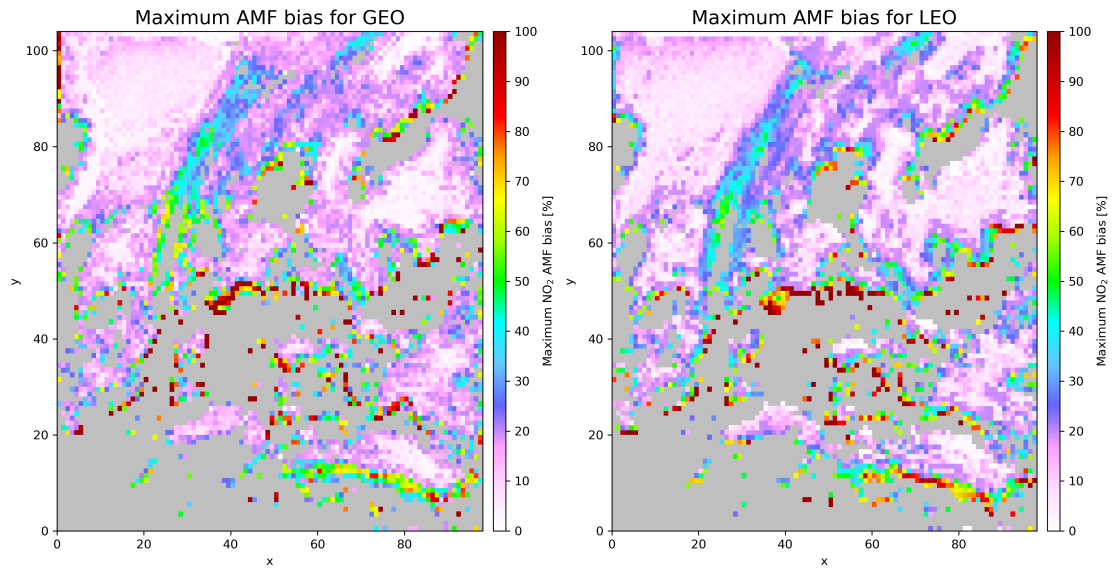

Figure 7. Maximum NO₂ AMF bias for each pixel (left: geostationary geometry; right: low earth orbiting geometry).

Figure 8. Geometry for the largest AMF bias for each location (left: geostationary geometry; right: low earth orbiting geometry). Only the pixels with maximum bias > 20% are shown.

biases < 20% are not shown. In general, the maximum bias is obtained at high SZA (60°), and for GEO cases, the bias also depends on the solar azimuth angle. Maximum biases are found on the east/west side of the cloud when the sun is in the west (SAA=-90°)/east (SAA=90°). Note that this dependency for GEO geometry is particular for the region, and thus solar and viewing conditions, studied. This dependency is not seen for the LEO geometry as for LEO geometry the local daily revisit
5 time is the same and thus also the solar azimuth. A further summary of the LEO and GEO cases is provided in S1.

These results show that the solar zenith angle is of prime importance for 3D cloud impacts and that the impact increases with increasing solar zenith angle. This is due to geometry reasons which cause the cloud shadow to increase as the solar zenith angle increases. Also, as the viewing zenith angle increases a larger, potentially cloud shadow impacted, horizontal surface area will be viewed due to geometry reasons and thus the cloud shadow effect increase with increased viewing zenith angle. Both
10 under- and over-estimates of the NO₂ TVCD occur in pixels close to clouds. The underestimates are due to cloud shadows, thus the cloud shadow fraction is a cloud feature metric that may be used to identify affected pixels, Fig. 3. However, while for large solar zenith angles pixels affected by cloud shadows are mostly underestimated, overestimates occur for all solar zenith angles and is mostly present for low cloud shadow fractions (Fig. 3) and increase for large surface albedo (blue dashed lines Fig. S1). Thus, cloud features in neighbouring pixels, such as cloud top altitude and cloud optical thickness, are also of
15 importance (Emde et al., 2021).

According to box cloud simulations presented by Emde et al. (2021) and Yu et al. (2021), the cloud enhancement effect is of similar magnitude as the cloud shadow effect. For the synthetic data the enhancement effect is present, but is smaller in magnitude than the cloud shadow effect, see blue lines Fig. S1. This is most likely due to cloud enhancement affected pixels being identified as cloudy and thus not analysed. Also the synthetic data indicate that the smaller the solar zenith angle is, the
20 larger are the chances for cloud enhancements between 5-10% for low earth orbit satellites (data not shown). The differences are largest for large satellite viewing angles (60°) and may thus indicate enhancement due to the satellite partly viewing sun-illuminated cloud sides. For geostationary geometry this effect is not present. This is due to differences in the solar azimuth angles for the two geometries. However, in magnitude, this effect has a much smaller impact than cloud shadows.

For large SZA (60°) and low albedo the number of pixels with NO₂ TVCD underestimated by more than <-20% is 12.0 and
25 18.3% for GEO and LEO geometries, respectively. For comparison Lorente et al. (2017) estimated the structural uncertainty (differences in retrieval methodology) in the tropospheric NO₂ AMF to be 42% over polluted regions and 31% over unpolluted regions. These differences are mostly driven by the uncertainty in the a-priori NO₂ profile, cloud properties and surface albedo. Thus, while smaller than the structural uncertainty, 3D cloud impacts constitute an additional significant error source for polluted conditions and large SZA. Note that the different cloud correction schemes (O₂-O₂ and O₂-A band) are normally
30 within 10% (not shown) and this number may be interpreted as the level of uncertainty of the uncertainty introduced by these correction schemes.

4.2 Observational satellite data

As shown in section 2.1 for the synthetic data, the NO₂ bias may be on the order of tens of percent and are largest for large solar zenith angles. We thus searched TROPOMI and VIIRS data for cases with cloud shadows and large solar zenith angles.

While the true NO₂ TVCD is known for the synthetic data, for the observational data the true NO₂ TVCD unaffected by clouds is not known. In order to have a reference or true NO₂ TVCD to compare with, we look at neighbour pixels in a 3×3 pixel matrix where the pixel of interest is in the centre. The true NO₂ TVCD is then taken to be the average of cloudfree neighbours with NO₂ retrieval quality value > 0.95. Obviously this choice of true NO₂ TVCD has its problems including that
5 neighbours may also be affected by clouds and that NO₂ TVCD may have large spatially gradients, see for example Fig. 2b which shows the NO₂ TVCD, and Fig. 2c which shows the percentage difference of the NO₂ TVCD to the area median NO₂ TVCD.

For specific cloud band cases and associated cloud band shadows the NO₂ TVCD appears low-biased when the cloud is optically thick and the cloud shadow fraction > 0.0 compared to when the cloud shadow fraction is zero, see S2.

10 For general cases, we looked for NO₂ TVCD biases due to clouds for the months of October 2018 and March 2019 when the solar zenith angle is between 50-60° for the study region (covering approximately Germany, the Netherlands and parts of other surrounding countries, see section 2). A total of 1,023,081 TROPOMI pixels and 45,926,808 VIIRS pixels were collected for the study region and October 2018 and March 2019. To quantify possible cloud shadow effects and factors that impact it, TROPOMI pixels with NO₂ retrieval data quality value >0.95 and cloud shadows were selected for further analysis. A NO₂
15 retrieval with the data quality value >0.95 was reported for 367,584 (36%) of the pixels. The VIIRS cloud mask identified 70.7% of the VIIRS pixels to be cloudy, indicating that clouds were the main reason for reducing the NO₂ retrieval quality for the majority of the TROPOMI pixels. Of the 367,584 pixels with high NO₂ retrieval data quality, a total of 129,180 (35%) were affected by cloud shadows according to the VIIRS cloud shadow product. Of the 45,926,808 VIIRS pixels 1,3438,968 (29.3%) were cloud free. Of these cloud free VIIRS pixels 17.8% contained cloud shadows. This number is lower than the
20 number of TROPOMI pixels affected by cloud shadows as is to be expected due to the higher spatial resolution of VIIRS. Note that this number pertains to months of the year where we expect cloud shadow effects to be large due to the large solar zenith angles. For months of the year with smaller solar zenith angles this number may well be smaller. The pixels affected by cloud shadows were further analysed to understand which parameters that have the largest impact on the NO₂ TVCD. In order to have a reference NO₂ TVCD to compare the centre pixel value with, only centre pixels which have one or more cloudfree
25 neighbours with NO₂ retrieval quality value > 0.95, were included. This restriction reduced the number of TROPOMI pixels to be analysed from 129,180 to 39,011. For these pixels the difference between the centre pixel NO₂ TVCD and the average of the NO₂ TVCD in the cloud free neighbours (ΔNO_2) is shown as a function of cloud height maximum of neighbour pixels in Fig. 9. For this data subset clouds are mostly found at high (about 10,000 m) and low (about 1,900 m) altitudes, with relatively more clouds at the higher altitudes. This is qualitatively in agreement with Noel et al. (2018). They reported cloud fractions as
30 estimated from a lidar on board the International Space Station. For Europe (their Fig. 5b) they report a similar cloud vertical behaviour, albeit for a different time of year (July, June and August). The subset of TROPOMI pixels presented in Fig. 9 shows both high and low NO₂ TVCD biases with a median NO₂ TVCD bias of -1.4% and maximum of the Gaussian kernel density probability density function estimate maximum of -0.7%. Thus, for this subset of TROPOMI pixels no significant cloud shadow effect is visible in the NO₂ TVCD. As stated above, no true observational NO₂ TVCD is available as for the synthetic data.

Figure 9. The difference between the centre pixel NO_2 TVCD and the average of the NO_2 TVCD in the cloudfree neighbours as a function of cloud height maximum of neighbour pixels. The median of the difference is given in the legend together with the maximum of a Gaussian kernel-density probability density function estimate of the data points. The size of the data points illustrates the maximum cloud optical thickness in neighbour pixels (NCOTM). It varies between the minimum and maximum NCOTM values given in the legend.

Table 1. Binning of parameters used to quantify the cloud shadow effect.

Parameter	Bin borders
Maximum cloud height of neighbour pixels (NCH)	0, 3000, 9000, 20000
Maximum slant cloud optical thickness of neighbour pixels (SCOT)	0, 3, 5, 7, 10, 15, 300

Furthermore, clouds and thus cloud shadows may have moved between VIIRS and TROPOMI overpasses. This may be reasons for the lack of a clear cloud shadow effect in this data subset.

This subset of data were further binned according to the maximum cloud height of neighbour pixels and the maximum slant cloud optical thickness ($\text{SCOT} = \text{COT} / \cos(\theta)$, where COT is the VIIRS cloud optical thickness) of neighbour pixels as given in Table 1. Furthermore, only TROPOMI pixels where the maximum slant cloud optical thickness and maximum cloud top height are in the same neighbour pixel were included. This reduced the data set to 18,029 pixels.

The NO_2 TVCD bias density as a function of the cloud shadow fraction for the SCOT bins and maximum cloud heights is shown in Fig. 10. As the cloud height increases (from bottom row to top row in Fig. 10) the cloud shadow fraction increases

Figure 10. The NO_2 -bias density as a function of the cloud shadow fraction. The data are binned into slant cloud optical thickness bins for high (a), medium (b) and low (c) clouds. See text for further details.

because generally the cloud shadow within a pixel geometrically increases with cloud height when the cloud is larger than the pixel size. For the low clouds the median NO₂ TVCD bias varies between -1.2 to 0.2% for SCOT<15. For SCOT>15 the median NO₂ TVCD bias is -2.9%. For the medium height clouds the median NO₂ TVCD bias for SCOT>15 increase in magnitude to -5.8%. For smaller SCOT the median NO₂ TVCD bias is negative and varies between -0.8 and -3.4%. For the
5 high clouds the median NO₂ TVCD bias is between -0.3 and 1.6% for SCOT<7. For larger SCOT the median NO₂ TVCD bias is -0.9, -8.7 and -15.1% (7<SCOT<10, 10<SCOT<15, 15<SCOT<300).

For all cloud heights the median NO₂ TVCD bias is negligible for SCOT<7. For low and medium clouds there is a negative bias for the largest SCOT. For the high clouds the bias is pronounced for SCOT>10. Thus, the median NO₂ TVCD bias increases with cloud height and with slant cloud optical thickness. It is noted that for individual pixels the bias may be larger
10 and both positive and negative. We use a neighbour pixel as the true NO₂-value. This assumes that only the cloud shadow effect is the reason for the NO₂ TVCD bias. In reality there are horizontal gradients in the NO₂ TVCD for numerous other causes as well, including local emissions, wind transport and differences. Also, the difference in overpass time between VIIRS and TROPOMI, may give differences in the clouds and cloud shadows viewed by the two instruments.

Finally it is noted that for the 129,180 pixels which were affected by cloud shadows, the number of pixels with cloud free
15 neighbours where $|\Delta\text{NO}_2| > 20\%$ is 45.7%. Under the assumption that this number is applicable to all TROPOMI pixels affected by cloud shadows, about 16% of TROPOMI pixels for which NO₂ TVCD retrievals with a high quality value were made, may be impacted by cloud effects larger than 20% for solar zenith angles between 50-60°. Of these about half of the NO₂ TVCD are overestimated and half underestimated. The underestimate is clearly linked to cloud shadow effects. The overestimate may be due to in-scattering or horizontal gradients in NO₂ concentrations and thus wrong cloud shadow free NO₂
20 TVCD true value. These two processes may, however, not be distinguished in the observed data set.

5 Conclusions

In this study we have investigated the impact of 3D clouds on NO₂ TVCD retrievals from UV-VIS sounders. Both synthetic and observational data have been used to identify and quantify possible biases in NO₂ TVCD retrievals. The synthetic data were based on high-resolution LES results which were input to the MYSTIC 3D radiative transfer model. The simulated visible
25 spectra for low-earth orbiting and geostationary geometries were analysed with standard NO₂ retrieval methods including operational cloud corrections. Profiles of NO₂ for polluted conditions, with increased NO₂ in the lower atmosphere below cloud tops, were considered as cloud shadow effects are not important for background NO₂ conditions where the amount of NO₂ below the cloud top is relatively small compared to the total column. For the observational data the NO₂ products from TROPOMI were used while VIIRS provided high spatial resolution cloud data. Both single cases and overall statistics were
30 calculated. The main findings are:

- The following metrics were identified as being the most important in identifying 3D cloud impacts on NO₂ retrievals: NO₂-profile shape, cloud shadow fraction, cloud top height, cloud optical thickness, solar zenith and viewing angles.

- Analysis of the synthetic data show that for low-earth and geostationary orbit geometries, 89 and 93%, respectively, of the retrieved NO₂ TVCD are within 10% of the actual column for small solar zenith angles. For large solar zenith angles the numbers decrease to 53 and 61%.
- The synthetic data shows that in general the NO₂ TVCD bias is slightly larger for low-earth orbiting geometries than for geostationary geometries. This is due to differences in viewing geometry where, for the mid-latitude targets studied here, the sun-target-detector geometry overall sees fewer cloud shadows for geostationary geometry.
- For a solar zenith angle less than about 40° the synthetic data show that the NO₂ TVCD bias is typically below 10%, while for larger solar zenith angles the NO₂ TVCD is low-biased by tens of %. The horizontal variability of NO₂ and differences in TROPOMI and VIIRS overpass times makes it challenging to identify a similar bias in the observational data. However, for optically thick clouds above 3000 m a low bias appears to be present in the observational data.
- For clearly identified cloud shadow bands from optically thick clouds in the observational data, the NO₂ TVCD appears low-biased when the cloud shadow fraction > 0.0 compared to when the cloud shadow fraction is zero. If it is assumed that the clouds are the main reason for the variations in the NO₂ TVCD over the cloud shadow band, i.e. the NO₂ field is assumed to be horizontally homogeneous, then these cloud shadow band cases are examples of how cloud shadows give underestimates of NO₂ TVCD, in agreement with the theoretical findings.

The above conclusions suggest that further work is required on 3D cloud radiative impacts. For this future work the following topics may be considered:

- As shown in this study, 3D radiative simulation of high-resolution satellite instrument spectra with realistic 3D cloud input is fully achievable. However, to cover all possible atmospheric situations on Earth, more high-spatial resolution LES results may be needed. Furthermore, 3D RT modelling is demanding on computer resources and requires careful interpretation and analysis of the output. It is expected that such modelling efforts may prove useful not only for trace gas retrieval algorithm studies, but also for cloud detection and cloud microphysics retrievals and more.
- For future missions, including the Meteosat Third Generation (MTG) Flexible Combined Imager (FCI) and the Meteorological Operational Satellite Second Generation METImage (formerly known as VII-Visible and Infrared Imager), a cloud shadow product is needed for assessing and mitigating 3D cloud impacts. Experience with the VIIRS cloud shadow product (large changes between versions¹) suggests that independent verification with ground measurements may be of use. Such validation is non-trivial and possibly require new experimental approaches for measurements of both cloud shape and trace gas spatial variation at sub-pixel resolution.

¹The VIIRS L2 product changed version from v1r1 to v1r2 between 13 and 14 Aug 2018, see https://www.star.nesdis.noaa.gov/jpss/documents/AMM/N20/Cloud_CBH_Provisional.pdf. Large changes in the cloud shadow product was seen between versions with v1r1 given unrealistic large number of pixels with cloud shadow. Realistic numbers were found with v1r2.

Code availability. The libRadtran software used for the radiative transfer simulations is available from www.libradtran.org. The QDOAS software for DOAS retrieval of trace gases is available from uv-vis.aeronomie.be/software/QDOAS.

Data availability. VIIRS data were accessed through the NOAA Comprehensive Large Array-Data Stewardship System (CLASS, <https://www.class.noaa.gov>). TROPOMI data were downloaded from <https://s5phub.copernicus.eu/>
