20 **Abstract**

21 The Nimbus 7 limb infrared monitor of the stratosphere (LIMS) instrument operated from  
22 October 25, 1978, through May 28, 1979. Its Version 6 (V6) profiles and their Level 3 or zonal  
23 Fourier coefficient products have been characterized and archived in 2008 and in 2011,  
24 respectively. This paper focuses on the value and use of daily ozone maps from Level 3, based  
25 on a gridding of its zonal coefficients. We present maps of V6 ozone on pressure surfaces and  
26 compare them with several rocket-borne chemiluminescent ozone measurements that extend into  
27 the lower mesosphere. We illustrate how the synoptic maps of V6 ozone and temperature are an  
28 important aid in interpreting satellite limb-infrared emission versus local measurements,  
29 especially when they occur during dynamically active periods of northern hemisphere winter. A  
30 map sequence spanning the minor stratospheric warmings of late January and early February  
31 characterizes the evolution of a low ozone pocket (LOP) at that time. We also present time  
32 series of the wintertime tertiary ozone maximum and its associated zonally varying temperatures  
33 in the upper mesosphere. These examples provide guidance to researchers for further  
34 exploratory analyses of the daily maps of middle atmosphere ozone from LIMS.

35

36 **1 Introduction and objectives**

37 The historic Nimbus 7 Limb Infrared Monitor of the Stratosphere (LIMS) experiment provided  
38 data on middle atmosphere ozone from October 25, 1978, through May 28, 1979, for scientific  
39 analysis and for comparisons with atmospheric models (Gille and Russell, 1984). Ozone is an  
40 excellent tracer of stratospheric transport in the high latitude stratosphere. As an early example,  
41 Leovy et al. (1985) showed how daily maps of the LIMS ozone fields correlate well with  
42 geopotential height (GPH) fields on the 10-hPa pressure surface. They also reported on the  
43 rapidly changing effects of wave activity on ozone, which led to a better understanding of  
44 stratospheric transport processes within models. Hitchman et al. (1989) also analyzed the  
45 temperature fields from LIMS and reported on Arctic observations of an elevated stratopause in  
46 late autumn to early winter that they associated with momentum forcings from gravity waves.

47

48 Current research focuses on the 3-dimensional character of ozone in the upper stratosphere and  
49 mesosphere, based on more recent satellite datasets. Several studies consider how temperature  
50 and ozone vary in association with sudden stratospheric warming (SSW) events (Smith et al.,  
51 2009; de la Camara et al., 2018; Kim et al., 2020; Shams et al., 2021). Manney et al. (1995) and  
52 Harvey et al. (2008) describe the development of low ozone pockets (LOPs) in the region of the  
53 Aleutian anticyclone during winter. Siskind et al. (2005; 2021) explain the occurrence of a  
54 mesospheric cooling associated with SSWs and the role of gravity waves for modeling ozone in  
55 the upper mesosphere, respectively. Chandran et al. (2013) provide a climatology of the Arctic  
56 elevated stratopause, and Sofieva et al. (2021) analyze for regional trends in stratospheric ozone.  
57 Smith et al. (2011; 2018) report on monthly changes of the tertiary ozone maximum at high  
58 latitudes of the upper mesosphere during winter.

59

60 The LIMS (Level 2) profiles were retrieved with an improved Version 6 (V6) algorithm. They  
61 were archived in 2008 and include ozone, temperature, and GPH that extend from 316 hPa to  
62 ~0.01 hPa. Co-located V6 profiles of water vapor (H<sub>2</sub>O), nitric acid vapor (HNO<sub>3</sub>), and nitrogen  
63 dioxide (NO<sub>2</sub>) extend through the stratosphere. Lieberman et al. (2004) analyzed the V6  
64 temperature profiles and found evidence for non-migrating tides in the mesosphere, due to the  
65 interaction of the diurnal tide and planetary zonal-wave 1, especially in late January 1979. Holt  
66 et al. (2010) analyzed the descent of V6 NO<sub>2</sub> from the lower mesosphere to within the polar  
67 stratospheric vortex, where it interacts with ozone. Remsberg et al. (2013) assimilated V6 ozone  
68 profiles in a reanalysis model and gained improved estimates of column ozone, especially in  
69 Arctic winter. Such reanalysis studies assimilate temperature and ozone profiles within a model  
70 framework. However, the models only approximate the effects of small-scale variations, so it is  
71 also useful to consider observed variations of the LIMS parameters without resort to a model.  
72 Keep in mind that smaller-scale atmospheric variations also contribute to the analyzed  
73 intermediate and large-scale fields from V6. This paper further explores several instances of  
74 those larger-scale variations of Arctic ozone, temperature, and GPH.

75

76 The SPARC Data Initiative (SPARC-DI) includes monthly zonal averages of V6 ozone up to the  
77 0.1-hPa level (see Tegtmeier et al., 2013; SPARC, 2017; and Remsberg et al., 2021). In Section

78 2 we show January zonal averages of V6 ozone and temperature profiles that extend even higher  
79 or to near the mesopause. The V6 Level 3 (map) product provides a 3-dimensional context for  
80 those zonal mean data. Daily V6 maps are also an aid in interpreting individual V6 profiles  
81 versus correlative data, especially during dynamically disturbed periods. Specifically, in Section  
82 3 we compare several nighttime V6 ozone profiles with those obtained with a rocket-borne  
83 chemiluminescent technique (Hilsenrath et al., 1980). Those profile comparisons are for  
84 December 15 and for January 27 and 28, when the temperature and ozone fields were affected by  
85 planetary wave forcings. There is a corresponding cooling and variations of ozone in the winter  
86 lower mesosphere associated with the warming in the upper stratosphere. Section 4 presents  
87 variations of ozone and GPH at northern extratropical latitudes during the minor SSW events of  
88 late January and early February 1979, as a complement to the more comprehensive findings of  
89 Harvey et al. (2008) on the occurrence of LOPs within anticyclones determined from satellite  
90 solar occultation data. Section 5 considers the variability of the tertiary ozone maximum in the  
91 upper mesosphere during that same period, as an adjunct to monthly zonal average values  
92 reported by Smith et al. (2018). Section 6 notes that the maps of V6 ozone contain more details  
93 about ~~the gradients of atmospheric in temperature and ozone during disturbed periods, but~~  
94 ~~also~~ and cautions users about occasional, pseudo-ozone features in the tropical lowermost  
95 stratosphere. Section 7 concludes that the V6 Level 3 product ~~represents~~ is an important resource  
96 for studies of the effects of transport and chemistry on Arctic ozone.

97

## 98 2 Characteristics of V6 Level 3 data

### 99 2.1 LIMS measurements and analyses

100 Nimbus 7 was in a near-polar orbit, and LIMS made measurements at ~1 pm local time along its  
101 ascending (A or south-to-north) orbital segments and at ~11 pm on its descending (D or north-to-  
102 south) segments. A-D time differences are of the order of 10 hours at most latitudes because  
103 LIMS viewed the atmosphere 146.5° clockwise of the spacecraft velocity vector, as seen from  
104 above. The A-D differences narrow from 10 to about 6 hours from 60°N to 80°N, due to the  
105 orbital geometry of Nimbus 7. The V6 processing algorithm accounts for low-frequency  
106 spacecraft motions that affect the LIMS view of the horizon. As a result, its measured radiance  
107 profiles are well registered in pressure-altitude (Remsberg et al., 2004). Retrieved V6 ozone,

108 temperature, and GPH profiles extend from 316 hPa to ~0.01 hPa and have a vertical point  
109 spacing of ~0.88 km with an altitude resolution of ~3.7 km. Retrieved profile pairs are spaced  
110 every 144 km along the orbital track or at every 1.3°, but closer together at the high, turn-around  
111 latitudes of the orbital viewing geometry (Remsberg et al., 1990). LIMS made measurements  
112 with a duty cycle of about 11 days on and 1 day off over its planned observing lifetime. The  
113 LIMS algorithms (Remsberg et al., 2007) do not account for non-local thermodynamic  
114 equilibrium (NLTE) effects in ozone (Solomon et al., 1986; Mlynczak and Drayson, 1990) and  
115 in CO<sub>2</sub> (Edwards et al., 1996; Manuilova et al., 1998), so there are positive biases in the retrieved  
116 V6 ozone throughout the mesosphere during daylight. However, the V6 nighttime ozone is more  
117 nearly free of NLTE effects below about the 0.05-hPa level, except at times of SSWs (see e.g.,  
118 Funke et al., 2012).

119

120 A sequential-estimation (SE) algorithm was used to generate daily, zonal Fourier coefficients  
121 (zonal mean and up to six cosine and sine values or 6-zonal wavenumbers) for Level 3 at every  
122 2° of latitude and at up to 28 vertical levels (Remsberg and Lingenfelter, 2010). The V6 SE  
123 algorithm uses better estimates of data uncertainty and its zonal wave coefficients have a  
124 memory of ~2.5 days, or about half that of the SE algorithm used by Remsberg et al. (1990).  
125 The SE analysis is insensitive to the very few large, unscreened ozone profiles values found in  
126 the lower stratosphere, as noted in Remsberg et al. (2013, their Fig. 1a). The SE algorithm  
127 combines the coefficients from both the separate A and D orbital segments and effectively  
128 interpolates the profile data in time to provide a continuous, 216-day set of daily zonal  
129 coefficients versus pressure-altitude at 1200Z for each of the retrieved LIMS parameters.

130

### 131 *2.2 Monthly average V6 data*

132 One can generate monthly average distributions from the daily Level 3 files of temperature,  
133 GPH, and species (ozone, H<sub>2</sub>O, HNO<sub>3</sub>, and NO<sub>2</sub>); zonal averages for the V6 species were  
134 supplied to SPARC-DI (SPARC, 2017; Hegglin et al., 2021). Tegtmeier et al. (2013) compared  
135 the V6 monthly ozone distributions with ones from other satellite-based, limb sensors and  
136 reported good agreement throughout the stratosphere. Although the species cross sections for

137 SPARC (2017) extend only up to the 0.1-hPa level (~64 km), V6 average ozone extends higher  
138 or to about 0.015 hPa (~75 km). Figure 1 shows the latitude-pressure cross section for January  
139 from just the descending (D) orbital profiles, which avoids the larger NLTE biases that affect  
140 daytime ozone in the mesosphere. Stratospheric ozone mixing ratios in Fig. 1 have largest  
141 values at about 10 hPa near the Equator ( $> 9.2$  ppmv), and they decrease sharply above and  
142 below that level. Maximum mixing ratios for the middle to high latitudes occur between 3 to 5  
143 hPa, due to the larger zenith angles and longer paths of the ultraviolet light for production of  
144 atmospheric ozone. There is a nighttime ozone minimum of  $\sim 1.2$  ppmv across most latitudes of  
145 the middle mesosphere. A tertiary ozone maximum is present in the upper mesosphere near the  
146 winter day/night terminator zone in the LIMS measurements for January (at about  $67^\circ\text{N}$ ), in  
147 accordance with the interpretation of Marsh et al. (2001). The location ( $\sim 0.02$  hPa) and  
148 magnitude ( $\sim 3.5$  ppmv) of the NH maximum are somewhat higher and larger than those reported  
149 by Smith et al. (2018, their Fig. 4) from more recent satellite datasets. ~~On the other hand,~~  
150 ~~while~~ ~~Although~~ the V6 ozone poleward of  ~~$\sim 5055^\circ\text{S}$~~  is also from descending orbital profiles, it  
151 corresponds to daylight conditions at the high southern latitudes in January. Thus, the decrease  
152 of mesospheric V6 ozone at 0.1 hPa and poleward of  ~~$5055^\circ\text{S}$~~  ~~in Fig. 1~~ indicates merely a change  
153 from night to day values and agrees with findings of Lopez-Puertas et al. ~~(2018);(2018)~~. ~~On the~~  
154 ~~other hand, the rather large ozone values in the upper mesosphere at about  $45^\circ\text{S}$  are not found in~~  
155 ~~other data sets and are not expected from theory. We consider that ozone anomaly further in~~  
156 ~~Section 6.~~

157

158 Radiances from two 15- $\mu\text{m}$   $\text{CO}_2$  channels are used for retrievals of V6 temperature versus  
159 pressure or  $T(p)$ , and they are free of NLTE effects below about the 0.05-hPa level (~70 km)  
160 (Lopez-Puertas and Taylor, 2001). To first order, the V6  $T(p)$  retrievals account for the effects  
161 of horizontal temperature gradients in the stratosphere (Remsberg et al., 2004). Single profile  
162 root-sum-squared (or RSS) errors for  $T(p)$  vary from 1 K at 10 hPa to  $\sim 2.5$  K in the upper  
163 mesosphere, but they do not include possible temperature gradient errors. RSS error from  $T(p)$  is  
164 the primary source of bias error for ozone, growing to about 16% in the middle mesosphere  
165 (Remsberg et al., 2021, Table 1). Random errors become large for single ozone profiles in the  
166 upper mesosphere. As a complement to the V6 ozone of Fig. 1, we show the descending

167 (~nighttime) V6 T(p) distribution for January in Figure 2, which extends to near the 0.01-hPa  
168 level. The large-scale features of the T(p) distribution compare well with climatological values  
169 from the late 1970s (Fleming et al., 1990), having a maximum value of about 285 K at the SH  
170 high latitude stratopause and minimum values of < 200 K at the tropical tropopause and near the  
171 SH summer mesopause. There is also some elevation of the Arctic zonal-average stratopause.

172  
173 Figure 3 shows the monthly-average, zonal (wave) standard deviations (SD) about daily zonal  
174 means of the combined-mode (A+D) V6 ozone for January, where the SD values are derived  
175 from the zonal-wave amplitudes of V6 Level 3. There are relatively small SD values at low  
176 latitudes from 7 to 10 hPa; it is assumed that they are a result of smaller-amplitude Kelvin and  
177 Rossby-gravity waves. Effects of more vigorous, planetary wave activity are most apparent at  
178 high northern latitudes of the stratosphere during winter. Gravity waves also contribute to SD in  
179 the uppermost mesosphere (Siskind et al., 2021). Ozone shows little zonal variation in the SH  
180 upper stratosphere of Fig. 3, due to constraints on the upward propagation of planetary waves  
181 through the summer zonal easterlies (Andrews et al., 1987). SD values near the tropical  
182 tropopause are due mostly to residual effects of emissions from thin cirrus and represent spurious  
183 ozone variations (see Section 6).

184

### 185 **3. V6 comparisons with rocket-borne chemiluminescent ozone measurements**

186 In this section we consider V6 comparisons with three nighttime, rocket-borne chemiluminescent  
187 ozone soundings of Hilsenrath (1980)—one at White Sands, NM, (32.4°N, 253.5°E) on  
188 December 15, 1978, and two more at Poker Flat, AK, (65.1°N, 212.5°E) on the successive days  
189 of January 27 and 28, 1979. The estimated total, rocket ozone error is 14% (precision plus  
190 accuracy), according to Hilsenrath and Kirschner (1980).

191

192 Ozone comparisons for December 15 are in Figure 4 (top); we plot every other V6 profile and  
193 those four profiles have spacings of 2.6° in latitude. The short-dashed V6 profile is at 29.2°, and  
194 the long-dashed profile is at 37.2°. The solid curve is the V6 profile at 31.8° (at 0611Z) or

195 closest to the rocket sounding from White Sands (at 0541Z). Horizontal bars on the profiles are  
196 estimates of ozone error; they overlap between V6 and rocket, except in the upper stratosphere.  
197 LIMS ozone is larger than rocket ozone in through the upper stratosphere. The corresponding  
198 V6 ozone map at 4.6 hPa in Fig. 4 (bottom) reveals an ozone maximum just south of White  
199 Sands (WS—blue dot), along the descending orbital segment of the satellite at (6°N, 265°E—  
200 white dot) or viewing in the NNW direction toward White Sands. Note that while zonal  
201 variations in the map are from a gridding of the Level 3 coefficients (2° latitude and 5.625°  
202 longitude), there is no smoothing of the gridded field in the meridional direction; there is good  
203 continuity across latitudes, nonetheless. The rocket profile is a local measurement and has a  
204 vertical resolution that ranges from 1.5 km at 60 km to 0.1 km at 20 km; the nearby V6 profiles  
205 have a lower vertical resolution of ~3.7 km and are an average over the finite horizontal length  
206 (~300 km or ~3° latitude) of the LIMS tangent layer. There is an ozone maximum along the  
207 LIMS view path just to the south of White Sands, which may account for the profile differences.  
208 We also note that the ozone field of two days earlier has the region of sharp gradients positioned  
209 over White Sands with ozone at only 8 ppmv. Thus, an ozone field that varies in both space and  
210 time can lead to additional uncertainties for comparisons of the localized rocket and limb-  
211 viewing satellite profiles in Fig. 4.

212

213 Because V6 ozone is obtained from retrievals of the measured V6 ozone radiance profiles, the  
214 LIMS retrieved temperature profile must be representative of the atmospheric state for the  
215 forward model of ozone radiance. Figure 5 (top) shows the corresponding temperature  
216 comparisons between V6 and a separate rocket Datasonde instrument. Agreement between them  
217 is very good throughout the upper stratosphere, indicating that the temperature variations are  
218 well determined along the LIMS view path for the forward radiance calculations of V6 ozone  
219 and that the retrieved V6 ozone should be nearly unaffected by temperature bias error. The map  
220 of V6 temperature (Fig. 5—bottom) shows zonal variations on December 15, although their  
221 meridional gradients are relatively weak above White Sands. Conversely, the ozone profiles  
222 agree well near 0.68 hPa in Fig. 4, where there are apparent biases between the T(p) profiles.  
223 There are significant horizontal gradients near White Sands in the maps of T(p) at 0.68 hPa, but  
224 not in ozone (not shown). In fact, the V6 ozone field at that level has a nearly constant value,

225 and ozone is less sensitive (by half) to changes in  $T(p)$  at 0.68 hPa than at 4.6 hPa (Remsberg et  
226 al., 2007). Co-location is more important for the V6 versus rocket comparisons of  $T(p)$  than of  
227 ozone in the lower mesosphere.

228

229 The two comparisons above Poker Flat, AK, occurred at the time of a stratospheric, zonal wave-  
230 1 warming event. Leovy et al. (1985) provide a detailed discussion of the advective changes for  
231 ozone in the middle stratosphere during January 1979. Figure 6 (top) shows three V6 ozone  
232 profiles from along an ascending orbital segment on January 27. The LIMS instrument was  
233 viewing from its satellite location (80.7°N, 113°E) at 2204Z, and the rocket ozone launch was  
234 two hours earlier or at 2005Z at a solar zenith angle of 84° or near the terminator; there is good  
235 agreement of the structure between them, even in the mesosphere. A second rocket launch  
236 followed at 0833Z of January 28 (Hilsenrath, 1980). Since the separate V6/rocket ozone and  
237  $T(p)$  comparisons are similar for the two days, Fig. 6 contains results for January 27 only. The  
238 rocket sounding recorded two ozone maxima, one near 15 hPa and another at about 0.6 hPa. The  
239 ozone maximum at about 15 hPa is primarily due to advection of ozone of higher mixing ratios  
240 from lower latitudes just prior to the warming event. The local maximum at 0.6 hPa was  
241 unexpected, based on findings from a larger set of rocket ozone soundings. There is a relative  
242 minimum for both V6 and rocket ozone through the upper stratosphere, although V6 ozone is  
243 larger. The map of V6 ozone at 4.6 hPa in Fig. 6 (bottom) indicates that the rocket measurement  
244 occurs at the center of the minimum, whereas the V6 profiles are averages across it. The ozone  
245 profiles in Fig. 6 (top) indicate the relative minimum in a low-ozone pocket (LOP) that extends  
246 from about 7 hPa to 2 hPa.

247

248 Figure 7 (top) shows the V6 temperature profile comparisons;  $T(p)$  from the Datasonde has more  
249 vertical structure, as expected from a localized measurement. V6  $T(p)$  values reach a maximum  
250 of order 250 K at about 3 to 4 hPa. They agree reasonably with the Datasonde values, given that  
251 there is significant horizontal structure in the temperature field surrounding Poker Flat. The  
252 apparent V6 minus Datasonde bias of order 5 K at 3 hPa ought to lead to a V6 minus rocket  
253 ozone bias of -40%, according to error estimates for retrieved V6 ozone. However, Fig. 7  
254 (bottom left) indicates that LIMS was viewing Poker Flat across an area of higher temperatures,

255 such that it is likely that there is a spatial mismatch for V6 and Datasonde T(p) values. The  
256 much smaller and positive ozone differences in Fig. 6 support that likelihood. There may also be  
257 co-location differences between the rocket temperature and ozone soundings in this instance.

258

259 Figure 7 also shows a map of NH GPH at 4.6 hPa on January 27 for comparison with the ozone  
260 map in Fig. 6. Lowest ozone values are in the polar vortex, where the GPH field is asymmetric  
261 about the Pole. A second, low value of ozone is associated with the anticyclone over the  
262 Alaskan sector. One can determine horizontal winds from gradients of GPH on the 4.6-hPa  
263 surface and thereby estimate the transport of ozone to first order. Qualitatively, the direction and  
264 strength of the large-scale transport follows from the character of the cyclonic and anticyclonic  
265 features on the GPH map. The large-scale cyclonic circulation about the vortex transports air  
266 from middle latitudes to across the Pole on January 27. The vortex region has low ozone and is  
267 relatively cold, whereas stratospheric temperatures over Alaska show a maximum (the SSW),  
268 and the rocket profile above Poker Flat, AK, was near the center of the anticyclone and in the  
269 region of relatively low ozone (or LOP).

270

271 Ozone is an approximate tracer of transport processes and reveals dramatic changes with altitude  
272 associated with this SSW event, even through the winter lower mesosphere. As an example,  
273 Figure S1 (in Supplemental Materials) shows a concurrent cooling at 0.46 hPa above the Alaskan  
274 anticyclone on January 27, where the co-located ozone field exhibits a local maximum. There is  
275 also a major temperature increase above the polar stratospheric vortex over northern Europe at  
276 0.46 hPa, or where ozone values remain low. In summary, Figs. 4 through 7 and S1 indicate the  
277 utility of daily maps from LIMS for analyses of the ozone fields during dynamically disturbed  
278 conditions.

279

#### 280 **4. Variation of a low ozone pocket (LOP) from LIMS Level 3**

281 The polar vortex on January 27 was located over northern Europe and Asia; it was centered off  
282 the Pole because of effects of large-scale, planetary waves in the development of the SSW

283 (Andrews et al., 1987, Chapter 6). In this section, we show sequences of polar plots of both  
284 stratospheric GPH and ozone for February 1979. Manney et al. (1995) and Harvey et al. (2004,  
285 2008) provide comprehensive analyses about the occurrence of polar anticyclones and their  
286 associated LOPs from studies of GPH and ozone fields from several different satellites. They  
287 determined the extent and character of the polar vortex based on meteorological data from the  
288 UK Met Office or as obtained from relatively low vertical resolution radiance profiles from  
289 operational, nadir temperature sounders. The V6 GPH profiles are derived from and have the  
290 same vertical resolution as the T(p) profiles. Manney et al. (1995) showed that water vapor is a  
291 useful tracer of the meridional transport of air, and the V6 H<sub>2</sub>O fields at 6.8 and 10 hPa indicate  
292 that low latitude air was transported to the region of the LOP in late January. But the V6 H<sub>2</sub>O  
293 fields are noisy at 4.6 hPa (not shown). Even so, the V6 Level 3 ozone, T(p), and GPH data  
294 offer useful details about the occurrence of LOPs in the upper stratosphere.

295

296 Harvey et al. (2004) reported that LOPs occur nominally at about the 5-hPa level. Accordingly,  
297 the three panels of Figure 8 show three daily NH maps of V6 GPH from February 3 to February  
298 17 at 4.6 hPa; each successive map is spaced one week from the previous one. This sequence  
299 shows that both the vortex and anticyclone weaken during the three weeks following January 27  
300 at this level. The vortex re-centers on the Pole by February 17, and the anticyclone is nearly  
301 absent at 4.6 hPa following the two minor warming events. The map sequence of GPH indicates  
302 that there were significant changes in the horizontal transport of ozone in late January/early  
303 February. The corresponding three panels of ozone in Figure 9 show the further evolution of  
304 ozone, following that of January 27 (in Fig. 6). Even though the anticyclone had weakened  
305 during the first week, there was a deepening of the LOP from January 27 to February 3 and a  
306 filling of it thereafter.

307

308 Was there some chemical loss of ozone from January 27 to February 3 in the region of the LOP?  
309 Morris et al. (1998) and Nair et al. (1998) conducted model calculations to show how that could  
310 happen. Ozone reactions are affected by changes with latitude of solar insolation, temperature,  
311 and loss via NO<sub>x</sub>. Nair et al. (1998) reported on the effect of a decrease in the production of  
312 ozone for the development of LOPs, as air parcels in the middle stratosphere move from low to

313 high latitudes or to higher solar zenith angles in winter. Remsberg et al. (2018) analyzed air  
314 parcel trajectories that included chemistry, and they showed that there was some loss of ozone in  
315 the middle stratosphere, due to reactions with NO<sub>x</sub>. However, Holt et al. (2012) analyzed V6  
316 NO<sub>2</sub> in the winter polar vortex, and they did not find enhanced values at 4.6 hPa due to energetic  
317 particle precipitation (EPP) by late January.

318  
319 Figure 10 (left) is a map of the V6 descending orbital (nighttime) NO<sub>2</sub> for January 27 at 4.6 hPa.  
320 Based on the corresponding map of GPH in Fig. 7, one can trace the horizontal advection of high  
321 NO<sub>2</sub> toward higher latitudes and toward the polar vortex as well as the advection of low NO<sub>2</sub> out  
322 of the vortex and about the anticyclone. ~~Fig. 10 (right) is a map of HNO<sub>3</sub> at 4.6 hPa. It has a~~  
323 ~~weak, relative maximum above the anticyclone that appears as a residual from the advection of~~  
324 ~~much higher vortex values from several days before. A closer inspection in time reveals that the~~  
325 ~~NO<sub>2</sub> values in the LOP were a bit lower by January 31, when ozone had already declined to near~~  
326 ~~its February 3 value. Thus, while an excess of HNO<sub>3</sub> in the region of the LOP is consistent with~~  
327 ~~a conversion of NO<sub>2</sub> to HNO<sub>3</sub> above the isolated anticyclone, there is no clear evidence from the~~  
328 ~~V6 map products that such chemistry led to significant changes in the ozone. One must conduct~~  
329 ~~trajectory studies that include chemistry and that rely on the V6 species profiles as input for~~  
330 ~~better, quantitative estimates. Unfortunately, the profiles of V6 NO<sub>2</sub> and HNO<sub>3</sub> become noisy in~~  
331 ~~the upper stratosphere. At a minimum though, one can follow the evolution of the LOP using the~~  
332 ~~daily maps of V6 ozone and GPH. 10 (right) is a map of HNO<sub>3</sub> at 4.6 hPa, and it shows a weak,~~  
333 ~~relative maximum above the anticyclone.~~

334  
335 The formation of the LOP at 5hPa near Poker Flat region in January is studied with the help of  
336 photochemical calculations along a trajectory. A full description of the trajectory and  
337 photochemical models is given in Remsberg et al (2018). For this study, we generated backward  
338 trajectory starting at 5 hPa and 212° E and 64°N. The starting time of the back trajectory is 0900  
339 Z on January 28,1979. This is close to local time of LIMS descending mode observation of  
340 around 11:00 pm on January 27. Figure 11 shows the back trajectory with the day numbers  
341 illustrating the progress of the air parcel. Between January 22 and 28, the air parcel remains  
342 confined within a small region at high latitude. Results of a time dependent photochemical

343 calculation conducted along this trajectory in the forward direction are shown in Figure 12 as a  
344 function of time. The model initialization uses the mixing ratios of O<sub>3</sub>, NO<sub>2</sub>, and HNO<sub>3</sub> from  
345 LIMS descending mode observations. Figure 12 shows that the parcel was at 3 hPa on January  
346 15 and descended steadily to 5 hPa by late January. The decrease in ozone during the last 8 days  
347 is mainly caused by the daytime odd oxygen loss due to the catalytic cycle involving NO<sub>x</sub>.  
348 Production of odd oxygen is minimized since the air parcel is confined to high latitudes. Large  
349 diurnal variations in NO<sub>2</sub> and a small increase in HNO<sub>3</sub> are as expected for this pressure level.  
350 The LOP formation is a result of the interplay between transport and photochemistry in the high  
351 latitude upper stratosphere in the winter.

## 353 5. Variations of the tertiary ozone maximum

354 Smith et al. (2018) describe the changing monthly, zonally averaged character of the wintertime  
355 tertiary ozone maximum of the polar upper mesosphere. They point out that the low latitude  
356 edge of the tertiary ozone maximum is where HO<sub>x</sub> radicals and the chemical loss of ozone due to  
357 reactions with them are reduced. V6 ozone radiance profiles have low signal-to-noise in the  
358 upper mesosphere; the precision estimate is 0.32 ppmv for retrieved ozone profiles. We show a  
359 map in Figure 4+13 of the combined V6 ozone for December 15 at 0.022 hPa (~72 km), where  
360 its distribution in the subpolar region is based on fewer than 13 zonal coefficients because some  
361 profiles do not extend to that pressure altitude. The corresponding map of temperature is also in  
362 Fig. 4+13, and one can see that there is significant non-zonal structure in its field at the latitudes  
363 where ozone is enhanced. While both V6 ozone and temperature are not highly accurate due to  
364 NLTE effects in the upper mesosphere, their maps reveal significant relative spatial structures  
365 indicating advective transport and its likely effects on ozone.

366  
367 Figures S2 and S3 in the Supplemental Materials show additional panels at 0.022 hPa of ozone  
368 and temperature, respectively, for January 13, February 10, and March 1. Elevated values of  
369 ozone occur at higher latitudes on February 10 and March 1 than on December 15 and January  
370 13, which is consistent with the more northward position of the terminator away from winter  
371 solstice and the consequent effects for the chemical loss of ozone. The temperature fields are

372 also perturbed on January 13 and February 10, but they are more nearly zonal by March 1.  
373 However, there are meridional gradients of temperature on all three days in the region of the  
374 tertiary ozone maximum. On January 13 there is also a well-defined mesospheric vortex in GPH  
375 (not shown), and the highest values of ozone correlate reasonably with it. The vortex is most  
376 disturbed and tertiary ozone maximum has largest values on February 10, perhaps in response to  
377 the upward propagation of wave activity following the minor SSW of late January.

378

379 Figure 12.14 shows time series of peak zonal mean ozone at 0.022 hPa and its latitude location  
380 for each week from November through mid-March. The separate time series are for peak ozone  
381 (bottom two series) and their latitude locations (top two). Dashed red curves represent zonal  
382 mean results for combined (A+D) ozone; solid black curves are results for nighttime (D) only.  
383 Blue horizontal lines represent the approximate latitude position of the terminator. Peak  
384 nighttime ozone values are based on just the ‘zonal mean’ and the cosine and sine coefficients  
385 for waves 1 and 2 because not all profiles reach to the 0.022-hPa level. Peak ozone occurs at  
386 lower latitudes (~65°N) in December, increasing to ~75°N in early November and early February  
387 and to near 80°N by early March. The latitude time series of peak ozone values is reasonably  
388 coincident with the changing location of the terminator. Peak combined (A+D) ozone increases  
389 slowly from a minimum of 2.2 ppmv in November to 3.6 ppmv in late February and March.  
390 Descending (or nighttime only) ozone varies from 3.3 ppmv in November, to ~4.5 ppmv in  
391 January, to a maximum of 6.3 ppmv in mid-February, and then declining to 3.5 ppmv by mid-  
392 March, although the time series shows rather large variations. Those maximum V6 values are  
393 larger than reported by Lopez-Puertas et al. (2018, [their Fig. 15](#)), perhaps due to biases from V6  
394 T(p) and/or ozone at 0.022 hPa.

395

396 The ~~increasing~~increase of V6 ozone ~~in Fig. 12~~ during winter ~~in Fig. 14~~ disagrees with that of  
397 Smith et al. (2018), who found decreasing ozone ~~in~~by February. They reported that, in most  
398 years, there is a slow descent of relatively dry air into the vortex region in [the upper mesosphere](#)  
399 [during](#) late autumn and early winter ~~in the upper mesosphere~~, and that the reduction in water  
400 vapor implies that there are fewer HO<sub>x</sub> radicals for the destruction of ozone near the terminator  
401 zone, leading to accumulations of ozone. However, there were two minor warmings and

402 associated lower mesospheric cooling events during late January and early February 1979  
403 (Hitchman et al., 1989). The enhanced V6 ozone of February 1979 follows those SSW events.  
404 ~~It may be that, and~~ there ~~were~~ wave-driven disturbances and ~~a~~-dissipation of their energy in  
405 the upper mesosphere at ~~higher latitudes at~~ that time (e.g., Siskind et al. 2005); ~~Smith et al.,~~  
406 ~~2009~~. One ~~should be able to~~ gain more ~~information~~ details about the evolution of the tertiary  
407 ozone maximum in the winter of 1978-79 from the daily maps of V6 ozone, T(p), and GPH (as  
408 in Figs. S2 and S3).

409

## 410 **6. Other aspects of V6 Level 3 ozone**

411 The combined (A+D) Level 3 coefficients are the basis for a gridding of daily synoptic maps at  
412 1200Z of ozone and related parameters. The Level 3 product also contains coefficients from its  
413 separate A and D profiles; their ‘zonal mean’ values correspond to the local time-of-day of their  
414 respective measurements. Remsberg et al. (2007) noted that maps from V6 reveal more details  
415 about the variations of ozone. In Figure S4 of the Supplemental ~~Material~~ Materials we compare a  
416 map of V6 ozone at 10 hPa on 27 January with a similar map for V5 of Leovy et al. (1985). The  
417 ozone gradients are more pronounced with V6 than with V5 at both the subtropical and vortex  
418 edges of the ozone field. The V6 maps make use of all profiles along the orbit, and the SE  
419 mapping algorithm was applied to them every 2° of latitude. However, the tighter gradients were  
420 also achieved with the V6 algorithm because it has a relaxation time (or memory) that is half that  
421 of V5. This means that the V6 maps are more representative of the rapidly changing  
422 atmospheric ozone fields on that day. Similar version differences are evident throughout winter,  
423 when the so-called ‘stratospheric surf zone’ develops and expands (Leovy et al., 1985).

424

425 Significant exchanges of air and ozone occur from the extratropical stratosphere to the  
426 troposphere in winter and spring (Gettelman et al., 2011). There are large zonal variations about  
427 the daily zonal means of ozone in the Arctic region of the lower stratosphere in Fig. 3. There are  
428 similar variations in GPH (and derived winds) and in zonal wave activity that lead to ozone  
429 transport. Zonal variations are resolved in the daily ozone maps down to the 146-hPa level.  
430 Notably, Shepherd et al. (2014) integrated the V6 monthly zonal mean ozone above the

431 tropopause and subtracted it from observed total ozone, as part of their assessment of long-term  
432 trends of tropospheric ozone from models. Their determination of extratropical tropospheric  
433 ozone based on LIMS agrees with that obtained from other ozone datasets.

434

435 There is also a relative excess of SD ozone values in Fig. 3 centered at 68 hPa at tropical  
436 latitudes, and similar anomalies occur in other LIMS months (not shown). As an example,  
437 Figure 4315 shows a map of V6 ozone at 68 hPa (~18 km) on December 15, to give more insight  
438 about the source of the tropical variations. Ozone mixing ratio values in Fig. 4315 are of order 2  
439 to 3 ppmv at high latitudes, becoming much smaller in the subtropics. However, there is also an  
440 unexpected, high value of 2 to 3 ppmv at about 15°N, 150°E. Limb measurements in the ozone  
441 channel include radiance effects from cirrus particles that can occur along the tangent view path,  
442 although the retrieved ozone mixing ratio profiles were screened of those effects to first order  
443 (Remsberg et al., 2007). Even so, we note that ozone is easily affected by any excess radiance  
444 because of highly non-linear effects for retrievals of ozone in the lower stratosphere. It is very  
445 likely that the anomalous ozone at 68 hPa is a result of residual effects from subvisible cirrus,  
446 which is nearly ubiquitous over the western tropical Pacific region (see SPARC, 2006, Fig. 1.8).  
447 While individual V6 ozone profiles may include such spurious features in the tropics, the Level 3  
448 ozone product at 68 hPa is affected mainly when there is an organized convection and outflow of  
449 air that persists for several days. The adjacent map of ozone at 46 hPa appears unperturbed in  
450 that region (not shown), and tropical ozone at 100 hPa approaches zero. There are much smaller  
451 anomalies in maps of nitric acid, as its mixing ratio retrieval is very nearly linear. Anomalies are  
452 also not so apparent in maps of V6 H<sub>2</sub>O at 68 hPa because the cloud screening algorithm for H<sub>2</sub>O  
453 accounts for the larger vertical field-of-view and extent in altitude for measurements in the water  
454 vapor channel of LIMS. ~~To summarize~~ Thus, one must be mindful that the Level 3 product may  
455 indicate excess, but spurious ozone at 68 hPa in the tropics.

456

457 Finally, in our earlier description of descending orbital ozone in Fig. 1, we noted that there are  
458 anomalously high values near 45°S in the upper mesosphere. Fig. S5 of the Supplemental  
459 Materials shows distributions of temperature and ozone from descending orbital measurements at  
460 0.032 hPa on January 15. Zonal wave activity is very weak in both. The descending orbital

461 views of the tangent layer at 45°S are located just in front of the region of large temperature  
462 gradients at 40°S. Although we showed in Section 3 that taking account of temperature  
463 gradients is important for accurate retrievals of ozone, such gradients were not employed for  
464 calculations in the mesosphere of tangent layer radiance in the V6 algorithms. If such  
465 temperature biases persist through the upper mesosphere, they will also affect the registration of  
466 the observed ozone radiance versus pressure at those altitudes. Therefore, we judge that it is  
467 very likely that the enhanced ozone mixing ratios near 45°S in Fig. 1 are an artifact because the  
468 associated, retrieved tangent path temperatures are not weighted properly, are too cold, and do  
469 not account for enough of the observed ozone radiance. Ozone mixing ratio anomalies are not  
470 apparent along the ascending orbital segment because their LIMS views are in a near-zonal  
471 direction.

472

## 473 7. Conclusions

474 This report provides guidance to researchers for their use of the LIMS V6 Level 3 product and  
475 for their generation of daily gridded distributions of its temperature, ozone, and GPH on pressure  
476 surfaces. H<sub>2</sub>O, NO<sub>2</sub>, and HNO<sub>3</sub> are also available for the stratosphere from the Level 3 product.  
477 The V6 dataset represents an early baseline for considering possible changes in the middle  
478 atmosphere from 1979 to today and into the future. LIMS made measurements at a time when  
479 stratospheric effects from volcanoes were minimal and when catalytic effects of chlorine on  
480 ozone were relatively small. Accordingly, Stolarski et al. (2012) found small, but significant  
481 changes in the distribution of upper stratospheric ozone for recent decades compared with 1978-  
482 1979. The LIMS measurements were taken near solar maximum and when atmospheric  
483 concentrations of the greenhouse gases (GHG), CO<sub>2</sub>, CH<sub>4</sub>, and CFCs, were smaller than today.  
484 Middle atmosphere T(p) distributions were warmer in 1978-1979.

485

486 The LIMS measurements in the winter Arctic region occurred when there was a lot of wave  
487 activity for the transport and mixing of ozone. As a result, ozone varied dramatically in winter,  
488 particularly during times of stratospheric warming events. There was a so-called Canadian  
489 warming in early December 1978, two minor SSW events in late January and early February,

490 and a final warming in late February 1979. We showed V6 comparisons with temperature and  
491 ozone profile data obtained using rocket borne Datasonde and chemiluminescent instruments,  
492 and we pointed out how an examination of changes in their nearby fields is valuable for the  
493 interpretation and validation of V6 profiles against those correlative measurements. The Level 3  
494 dataset provides daily details on variations of ozone with latitude, longitude, and altitude, along  
495 with related variations in temperature, geopotential height, NO<sub>2</sub>, and HNO<sub>3</sub>. We noted also that  
496 there are instances of spurious, excess ozone from the Level 3 coefficients at 68 hPa in the  
497 tropics but not in the extratropical stratosphere.

498

499 We displayed evidence of a low ozone pocket (LOP) and its chemical properties at 5 hPa above  
500 the Aleutian anticyclone during the minor SSW of late January ~~above the Aleutian anticyclone~~,  
501 and we followed its evolution into mid-February. The V6 nighttime ozone is relatively accurate  
502 through the mesosphere in Arctic winter. We provided time series of the wintertime, tertiary  
503 ozone maximum of the upper mesosphere from V6 data. Its ozone reached maximum values in  
504 February, perhaps as a response to enhanced wave activity in the mesosphere following several  
505 SSW events. Together with V6 maps of T(p) and GPH, one may explore further the daily  
506 evolution of that ozone maximum throughout the NH winter of 1978-1979.

507

#### 508 **Data Availability**

509 The LIMS V6 Level 3 product is at the NASA EARTHDATA site of EOSDIS and its website:  
510 [https://disc.gsfc.nasa.gov/datacollection/LIMSN7L3\\_006.html](https://disc.gsfc.nasa.gov/datacollection/LIMSN7L3_006.html) (Remsberg et al., 2011). The  
511 SPARC-Data Initiative data are located at <https://doi.org/10.5281/zenodo.4265393> (Hegglin et  
512 al., 2021). We acknowledge the individual instrument teams and respective space agencies for  
513 making their measurements available, and the Data Initiative of WCRP's (World Climate  
514 Research Programme) SPARC (Stratospheric Processes and their Role in Climate) project for  
515 organizing and coordinating the compilation of the chemical trace gas datasets used in this work.

516

517 *Author Contributions.* ER ~~wrote~~led the manuscript and prepared most of the figures with  
518 contributions from his co-authors. MH conducted the trajectory study and generated its figures.  
519 EH provided his rocketsonde data on ozone and temperature along with their error estimates.

520

521 *Competing interests.* The authors declare no competing interests for this study.

522

523 *Acknowledgements.* The authors appreciate John Gille and Jim Russell III and members of the  
524 LIMS Science Team for their leadership in the development of the LIMS instrument and for their  
525 processing of its historic data products. The authors are grateful to John Burton, Praful Bhatt,  
526 Larry Gordley, B. Thomas Marshall, and R. E. Thompson for producing the V6 Level 2 dataset.  
527 They acknowledge Gretchen Lingenfelter for her work in generating and archiving the V6 Level  
528 3 coefficient dataset. They appreciate especially the constructive comments from the two  
529 anonymous referees. They also thank V. Lynn Harvey for her comments on an early draft of the  
530 manuscript. EER and MN carried out their work while serving as Distinguished Research  
531 Associates of the Science Directorate at NASA Langley.
