10 **Abstract.** Formaldehyde (FM) and glyoxal (GL) are important atmospheric species of indoor and outdoor  
11 environments. They are either directly emitted in the atmosphere or they are formed through the oxidation of organic  
12 compounds by indoor and/or outdoor atmospheric oxidants. Despite their importance, the real-time monitoring of  
13 these compounds with soft ionization mass spectrometric techniques, e.g. proton transfer mass spectrometry (PTR-  
14 MS), remains problematic and is accompanied by low sensitivity. In this study, we evaluate the performance of a  
15 multi-ion selected ion flow tube mass spectrometer (SIFT-MS) to monitor in real-time atmospherically relevant  
16 concentrations of FM and GL under controlled experimental conditions. The SIFT-MS used is operated under standard  
17 conditions (SC), as proposed by the supplier, and custom conditions (CC), to achieve higher sensitivity. In the case of  
18 FM, SIFT-MS sensitivity is marginally impacted by RH, and the detection limits achieved are below 200 ppt.  
19 Contrariwise, in the case of GL, a sharp decrease of instrument sensitivity is observed with increasing RH when the  
20  $\text{H}_3\text{O}^+$  ion is used. Nevertheless, the detection of GL using  $\text{NO}^+$  precursor ion is moderately impacted by moisture with  
21 an actual positive sensitivity response. Therefore, we recommend the use of  $\text{NO}^+$  precursor for reliable detection and  
22 quantitation of GL. This work evidences that SIFT-MS can be considered as an efficient tool to monitor the  
23 concentration of FM and GL in laboratory experiments and potentially in indoor or outdoor environments, capable of  
24 identifying their primary emission or secondary formation through (photo)oxidation processes. Furthermore, SIFT-  
25 MS technology still allows great possibilities for sensitivity improvement and high potential for monitoring low proton  
26 transfer affinity compounds.

27  
28 **Keywords:** SIFT-MS; PTR-MS; Formaldehyde; Glyoxal;  $\text{H}_3\text{O}^+$ ;  $\text{NO}^+$ ; charge transfer reaction;  
29 quantification.

## 31 1. Introduction

32 Formaldehyde (CH<sub>2</sub>O, FM) is the lightest aldehyde. It is a ubiquitous chemical compound in outdoor and  
33 indoor environments. FM is a toxic and carcinogenic air contaminant with adverse health effects to humans  
34 (Bernstein et al., 1984; Kim et al., 2011). In the open atmosphere, FM is mainly formed by the oxidation of  
35 volatile organic compounds (VOCs), (Kefauver et al., 2014). Fuel combustion, forest fires and agricultural  
36 activities are also important sources of FM outdoors (Kaiser et al., 2015; Lee et al., 1997; Luecken et al.,  
37 2012). FM plays an important role in atmospheric photochemistry since it is photolysed, producing  
38 hydroxyl (OH) and hydroperoxy (HO<sub>2</sub>) radicals which drive ozone (O<sub>3</sub>) production, (Atkinson, 2000). Thus,  
39 it enhances the formation of secondary organic aerosol (SOA) (Li et al., 2011). In indoor environments,  
40 FM can be emitted directly from wood-based materials, construction materials, paintings, anthropogenic  
41 activities such as smoking, cooking, cleaning, or by the oxidation of indoor VOCs, especially terpenes, with  
42 high yields (Salthammer, 2019). Indoor concentrations of FM can reach significantly higher levels than  
43 outdoors (Crump et al., 1997; Langer et al., 2015; Liu et al., 2006).

44  
45 Glyoxal (C<sub>2</sub>H<sub>2</sub>O<sub>2</sub>, GL) is the lightest  $\alpha$ -dicarbonyl compound. GL has been identified as precursor of  
46 secondary organic aerosol (SOA) outdoors (Fu et al., 2008; Liggió et al., 2005; Volkamer et al., 2007;  
47 Rossignol et al., 2014). GL is formed in the atmosphere by the oxidation of biogenic and anthropogenic  
48 VOCs, such as isoprene (the highest emitted VOC in the atmosphere), and acetylene (Fu et al., 2008; Xiao  
49 et al., 2007; Myriokefalitakis et al., 2008). The oxidation of aromatic compounds in the presence of NO<sub>x</sub>  
50 (NO, NO<sub>2</sub>) also produces GL. Other sources of GL are biomass burning, fossil and biofuel combustion,  
51 (Grosjean et al., 2001; Hays et al., 2002; Kean et al., 2001) as well as oceans, but literature studies report a  
52 high variability (Mahajan et al., 2014; Sinreich et al., 2010). In literature it has also been reported that the  
53 photochemical oxidation of GL in the troposphere leads to HO<sub>x</sub> radical formations (Salter et al., 2013). In  
54 indoor environments, to the best of our knowledge, there are no studies reporting the direct emission or  
55 secondary formation of GL, but, considering emerging research activities dealing with indoor air quality,  
56 this should not be excluded.

57  
58 Due to their important role in the chemistry of outdoor and indoor environments, the monitoring of the FM  
59 and GL in laboratory experiments (e.g. simulation chamber experiments, photochemical reactors) or in field  
60 (indoor and outdoor) is of significant importance in order to evaluate and understand the underlying  
61 chemistry. Nevertheless, the real time measurement of FM and GL is not a trivial process. The sensitivity  
62 of the classically used proton transfer mass spectrometry (PTR-MS) technique for these compounds is quite  
63 limited and is strongly impacted by relative humidity (Inomata et al., 2008; Stönnner et al., 2017; Vlasenko  
64 et al., 2010; Yuan et al., 2017). Limitations are mainly due to the low proton transfer affinities (PA) of both  
65 compounds of interest :  $PA_{FM} = 713 \text{ kJ mol}^{-1}$  and  $PA_{GL} = 675\text{-}690 \text{ kJ mol}^{-1}$  (Wróblewski et al., 2007), and  
66 thus very close to the PA of water,  $PA_{H_2O} = 691 \text{ kJ mol}^{-1}$ . Quite recently, electron attachment reaction  
67 (EAR) ionization mass spectrometry has been used for real-time measurements of GL in ambient air.  
68 Nevertheless, this technique does not seem to be sensitive enough for other volatile organic compounds  
69 (VOCs) (Lu et al., 2019). It should be noted that mass spectrometric techniques are widely applied in  
70 atmospheric science for three main reasons. First, they are sensitive tools, able to monitor simultaneously  
71 and in real-time a wide range of VOCs. Second, they are robust, user-friendly and mobile systems. Third,  
72 they require a relatively low sampling flow (in the order of hundred cm<sup>3</sup> min<sup>-1</sup>) and can be easily coupled  
73 to “small scale” laboratory experiments or with other instrumentation without a significant extra demand  
74 on air sampling flow.

75  
76 Alternatively, the monitoring of FM and GL is achieved using VOC-selective spectroscopic techniques  
77 such as Fourier transform infrared spectroscopy (FTIR) (Catoire et al., 2012), differential optical absorption  
78 spectroscopy (DOAS) (Coburn et al., 2014), tunable-diode laser absorption spectrometer (TDLAS) (Catoire  
79 et al., 2012), or incoherent broadband cavity-enhanced absorption spectrometer (IBBCEAS) (Liu et al.,  
80 2019; Lu et al., 2019). FTIR spectroscopy is mostly used in lab experiments (Catoire et al., 2012) deployed  
81 in-situ or in line configuration inside atmospheric simulation chambers or photoreactors (Wisthaler et al.,  
82 2008). However, the sensitivity is relatively poor and even long optical path FTIR systems achieve detection  
83 limits (DL) in the order of several parts per billion (ppb). In addition, long path FTIR systems are not  
84 mobile, or of limited mobility, and the selective detection of FM and GL is relatively difficult due to the  
85 complex IR pattern in the presence of other VOCs. Other VOC-selective spectroscopic tools such as DOAS  
86 and IBBCEAS, are mostly used in outdoor field studies (Coburn et al., 2014; Lu et al., 2019). These are  
87 expensive and delicate systems that can achieve detection limits in the sub-ppb level. However, these  
88 techniques require a high volume sampling flow of several liters per minute ( $\text{L min}^{-1}$ ) (Coburn et al., 2014;  
89 Lu et al., 2019). Thus, they are not commonly deployed in laboratory studies or indoor field measurements.  
90 Therefore, low time resolution techniques such as off-line analytical approaches are used for the selective  
91 determination of FM and GL. In particular gas chromatography and mass spectrometry (GC-MS), or high-  
92 performance liquid chromatography (HPLC) are used for off line analysis of sampling cartridges (Ban-  
93 Weiss et al., 2008; Gómez Alvarez et al., 2012; Wisthaler et al., 2008).

94  
95 A response to the need for real-time, selective and sensitive monitoring of FM and GL could be the selected  
96 multi-ion flow tube mass spectrometry (SIFT-MS). SIFT-MS is a soft ionization analytical technique,  
97 mainly used for the real time monitoring (identification and quantification) of a wide diversity of VOCs,  
98 and some inorganic species (e.g.  $\text{NO}_2$ , HONO). SIFT-MS attains the advantages of typical mass  
99 spectrometric techniques described above. SIFT-MS is essentially a double quadrupole chemical ionization  
100 mass spectrometer using simultaneously  $\text{H}_3\text{O}^+$ ,  $\text{NO}^+$ , and  $\text{O}_2^+$  precursor ions for the ionization and the  
101 subsequent detection of the analytes. SIFT-MS has extensively been used for breath analysis, and in food  
102 science, but it is not commonly used in atmospheric science, where traditionally, PTR-MS is widely applied.  
103 Nevertheless, in the last decade, the application of SIFT-MS technology for the study of atmospheric  
104 relevant processes became more frequent, where SIFT-MS is either coupled to experimental chambers with  
105 various volumes for indoor studies (Caron et al., 2016; Caron et al., 2020; Thevenet et al., 2021), or  
106 atmospheric simulation chambers for the study of VOC degradation (Osseiran et al., 2020; Allani et al.,  
107 2021).

108  
109 Quite recently, Lacko et al. (2020) have reported for the first time the detection of FM and GL deploying a  
110 custom made SIFT-MS. In their study, authors mainly focus on the ion chemistry occurring inside the flow  
111 tube of the instrument and how it is impacted by humidity. These authors have also applied chemical  
112 modeling in an attempt to interpret their experimental results. Nevertheless, Lacko et al. (2020) used a  
113 custom-made SIFT-MS instrumentation that was operated in a tailored mode, injecting the corresponding  
114 VOC in a humidified air flow of helium bath gas. Their measurements were carried out at low levels of  
115 relative humidity, never exceeding 10 %, and using constant concentrations of VOCs in the ppm range.  
116 Therefore, authors did not evaluate the response of the instrument in a VOC concentration span of sub-ppm  
117 range, typical of indoor and outdoor environments, and they did not report the corresponding detection  
118 limits (DL). Furthermore, their study was solely focused on the chemistry of  $\text{H}_3\text{O}^+$  precursor ion.

119  
120 In this paper, we present a series of calibration experiments of FM and GL deploying a commercially  
121 available SIFT-MS Voice 200 Ultra instrument. The main objective of this work is to evaluate the  
122 sensitivity of SIFT-MS towards FM and GL, and elucidate whether it can (i) be used to monitor the  
123 concentrations of the title compound in laboratory scale or ambient indoor / outdoor air conditions and (ii)  
124 overcome the limitations encountered in conventional PTR-MS studies as highlighted above. In addition,  
125 for the first time in literature, we aim to emphasize the importance of  $\text{NO}^+$  charge transfer reactions on the  
126 detection of GL. To meet these objectives, FM and GL calibration measurements are carried out under  
127 dynamic flow conditions using a wide range of VOC concentrations in the ppb level, varying the relative  
128 humidity (RH) from dry to 70 %. Within that framework we assess the impact of RH and the instrument  
129 operational conditions (i.e. pressure and temperature) to its performance.

130  
131 The structure of the article is as follows: first we present a detailed description of the experimental set up,  
132 the methods deployed and protocols followed in this work. Thereafter, in the results and discussion section  
133 we provide (i) literature and experimental evidences that impact charge transfer reactions in SIFT-MS and  
134 PTR-MS, and (ii) the actions made in the framework of our study to improve SIFT-MS performance.  
135 Subsequently, results and discussion on FM and GL are presented separately in two different sections. Each  
136 of the two subsections include the presentation of our experimental observation, and a thorough discussion  
137 that contains comparison with PTR-MS or other SIFT-MS studies, and comprehensive assessment of the  
138 charge transfer reactions involved in the detection of the compound of interest.

## 140 2. Experimental Section

### 141 2.1 Materials

142 **Formaldehyde source.** A gas cylinder of FM purchased from praxair (12 ppm in  $\text{N}_2$ ) is used as a source  
143 for the calibration experiments. The purity and stability of the gas mixture is regularly tested by sampling  
144 FM gas on DNPH cartridges (Waters) eluted and analyzed off-line using UltiMate 3000 HPLC instrument  
145 (Thermo Scientific) coupled with an ultraviolet detector.

146 **Glyoxal source.** The monomer of pure GL is synthesized applying a similar method with the literature  
147 (Volkamer et al., 2005). In particular, equal amounts (ca. 0.6 g) of GL trimer dihydrate (purity  $\geq 97$  %  
148 Sigma-Aldrich) and di-phosphorous pentoxide (purity  $> 98$  %, VWR Chemicals) are mixed in a glass bulb  
149 and are progressively heated up under vacuum ( $1.5 \times 10^{-3}$  Torr) from room temperature to 453 K. The  
150 evolving gas is collected in a glass trap immersed into liquid nitrogen where the bright yellow pure GL  
151 solid crystals appear. Subsequently, after synthesis, the cold trap containing the monomer of GL is placed  
152 in a liquid nitrogen/ethanol bath maintained at 230 K, and is degassed under vacuum several times to  
153 remove volatile by-products (purification process). The vapors of pure GL are collected in a 10 L Pyrex  
154 glass bulb, darkened to minimize exposure of the sample to room light. The purity of the gas is verified by  
155 FTIR spectroscopy deploying an Antaris FTIR spectrophotometer equipped with a 2 L optical gas cell with  
156 10 m optical path length. The temperature of the optical cell is maintained at 353 K. The FTIR spectra  
157 collected are of high quality and identical to those presented in literature for pure GL monomers (Volkamer  
158 et al., 2005). The thermal stability of the GL is also verified, and we evidence that no thermal decomposition  
159 occurs, in accordance with the literature (Feierabend et al., 2008; Saito et al., 1984). Considering the  
160 detection limits of the instrument for CO,  $\text{CO}_2$  (in the order of 0.1 ppm), and FM (in the order of 1 ppm),  
161 the purity of GL is greater than 99 %. After the quality control experiments, dilutions of GL gas in He are

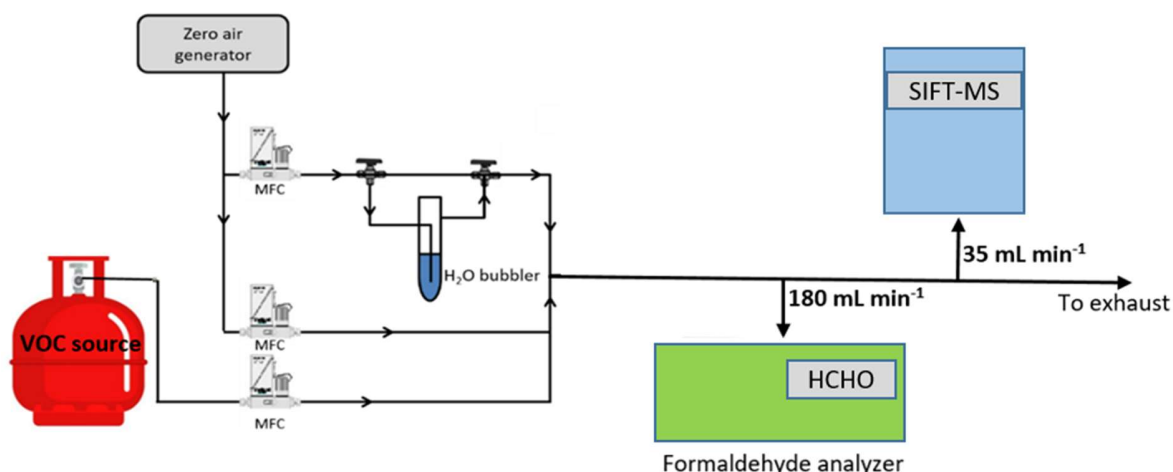

162 prepared manometrically in another glass bulb, with mixing ratios of ca. 1 % for a total pressure of 400  
163 Torr. For the sake of simplicity it will be referred to as mixture 1 (GL diluted in He) in the following.  
164 Mixture 1 is used as a source to prepare more diluted GL/He gas mixtures (in the range of 50 to 120 ppm)  
165 with total pressure of 1550 Torr inside a 6 L silonite treated canister. The exact concentration of GL in the  
166 canister is determined with FTIR spectroscopy using the well-defined broad band IR absorption cross  
167 section coefficients provided in literature for the characteristic band of GL between 2724-2940  $\text{cm}^{-1}$   
168 (Volkamer et al., 2005). These mixtures are used for the calibration of the SIFT-MS instrument and their  
169 stability is evaluated on a daily basis. It should be noted that two different GL syntheses were carried out  
170 and 4 different GL+He canister mixtures are used for the calibration experiments to evaluate uncertainties  
171 related to GL concentration.  
172

## 173 2.2 Experimental Setup

174

### 175 General Description

176 The experimental set up used in the current study is reported in Fig. 1. The gas flow generation lines are  
177 made of Teflon. Calibrated mass flow controllers (MFC) are used to mix the flow of the target VOC (i.e.  
178 FM or GL) with dry or humid zero air (impurity levels: VOCs < 0.1 ppb,  $\text{CO}_2$  < 10 ppb, and  $\text{CO}$  < 80 ppb,  
179 moisture level: ca. 2 ppm). The total gas flow rates in the calibration measurements are in the order of 1000  
180  $\text{mL min}^{-1}$ . Nevertheless, experiments are also performed varying the flow rate between 300 to 1600  $\text{mL min}^{-1}$   
181 aiming to evaluate the possible loss of compounds on gas lines. The total concentration of the target  
182 VOCs in the diluted gas flow are between 40 to 1200 ppb. In the case of FM, the diluted gas stream is  
183 sampled by an ap2e ProCeas FM analyzer (sampling rate 180  $\text{mL min}^{-1}$ ) and the SIFT-MS (sampling rate  
184 35  $\text{mL min}^{-1}$ ) connected in parallel. Concerning GL calibration experiments, the FM analyzer and the long  
185 path FTIR were occasionally used to evaluate possible impurities in the canister or transformation of GL in  
186 the gas lines, but the majority of the measurements are carried out by-passing them.

187

188 **Figure 1.** Experimental set-up used in the framework of the current study.

189

### 190 **Formaldehyde analyzer ap2e ProCeaS**

191 The real time measurement of FM in the gas flow is achieved deploying an ap2e ProCeaS gas analyzer. The  
192 gas flow is sampled through a sonic orifice with a diameter of few micrometers. Then, the gas is driven to  
193 an optical cell and analyzed employing patented laser optical feedback cavity enhanced absorption infrared  
194 spectroscopy. The instrument response is ca. 2 seconds and the detection limit ( $3\sigma$ ) of FM is 1 ppb for an  
195 integration time of 1 minute.

196

### 197 **SIFT-MS**

198 The SIFT-MS voice 200 ultra (Syft technology) is a double quadrupole chemical ionization mass  
199 spectrometer. A microwave discharge generates simultaneously three precursor ions,  $\text{H}_3\text{O}^+$ ,  $\text{NO}^+$  and  $\text{O}_2^+$ ,  
200 which are sequentially selected by a first quadrupole mass filter (Smith and Španěl, 2005). Then, under a  
201 flow of He, used as carrier gas, the precursor ions are driven inside a low pressure flow tube reactor. At the  
202 same time, the sampling flow is injected at the upstream-end of the reactor. The precursor ions react with  
203 the analytes along the flow tube to form characteristic ionized molecules as reaction products (Smith and  
204 Španěl, 2005). The temperature of the sampling port and the flow tube are temperature regulated (293 – 393  
205 K) to avoid contaminations of the sampling line and adsorption of reactants along the flow tube.  
206 Subsequently, the gas stream passes through a skimmer, located at the downstream end of the flow tube  
207 reactor, and finally is injected in a high vacuum chamber where both the precursor and reaction product-  
208 ions are focused, via electrostatic lenses, into a second quadrupole for mass analysis and ion counting. At  
209 this point it should be noted that the simultaneous presence of the three precursor ions allows the real-time  
210 monitoring of several VOCs eliminating the effect of mass peak overlapping due to the use of a quadrupole  
211 mass filter with a low mass resolution. Interestingly, this multi-ion chemistry allows SIFT-MS to  
212 discriminate isobaric compounds (Guimbaud et al., 2007), which is not a trivial task even for time of flight  
213 (TOF) techniques (Stönnner et al., 2017; Yuan et al., 2017).

214

### 215 **FTIR**

216 The purity of the glyoxal is verified by FTIR spectroscopy deploying an Antaris FTIR spectrophotometer  
217 equipped with a 2 L optical gas cell with 10 m optical path length and zinc selenide transmission windows.  
218 The temperature of the optical White-cell is maintained at 353 K. A liquid- $\text{N}_2$  cooled mercury cadmium  
219 telluride (MCT) detector was attached and 64 co-added IR spectra were recorded between 650 and 4000  
220  $\text{cm}^{-1}$ , with 1  $\text{cm}^{-1}$  resolution, using Result-3 software. Quantification and data processing were performed  
221 using a thermos scientific software, TQ-Analyst™.

222

223

## 224 **2.3 Experimental Procedure and Detection Limits**

225

226 Figure 2 displays the experimental strategy followed in the framework of the current study to calibrate the  
227 SIFT-MS. In a typical calibration experiment, initially the background of the VOC of interest is monitored  
228 for at least 20 min under a stream of zero air at the selected RH. Then the desired level of VOC is introduced  
229 in the gas stream and its concentration is monitored in real time. In each calibration step the flows are kept  
230 constant for around 20 min. In case of FM, the stabilization of its concentration in the gas flow is achieved

231 within the first 10 min after its introduction in the gas flow while in case of GL, its concentration is  
 232 stabilized almost instantaneously. Typically 4 to 6 different concentration levels of the VOC of interest are  
 233 set in each calibration experiment. At the end, the background is recorded again. This experimental  
 234 procedure is repeated for each level of RH and for each VOC individually. In the case of FM the calibration  
 235 factor is determined by plotting the SIFT-MS response (in counts) versus the concentration reported by the  
 236 FM analyzer; while in the case of GL by plotting the SIFT-MS response as a function of GL concentration  
 237 determined by the measured flow rate and the sample mixing ratio.

238  
 239 The time resolution of the SIFT-MS instrument in the calibration experiments is set to 1 second. FM is  
 240 monitored at the mass peak  $m/z = 31$  ( $\text{CH}_3\text{O}^+$ ,  $\text{FM-H}^+$ ) arising from  $\text{H}_3\text{O}^+$  precursor ion, while in the case  
 241 of GL the mass peaks  $m/z = 59$  ( $\text{C}_2\text{H}_3\text{O}_2^+$ ) and  $m/z = 88$  ( $\text{C}_2\text{H}_2\text{O}_2\cdot\text{NO}^+$ ), originating from  $\text{H}_3\text{O}^+$  and  $\text{NO}^+$   
 242 respectively are used.

243 To determine the detection limits ( $DL$ ) of the SIFT-MS Eq. (1) is used:

244 
$$DL = \frac{3.3 \times SD}{\text{calibration factor}} \quad \text{Eq. (1)}$$

245 where  $SD$  is the standard deviation of the background signal. Similar criterion has been used in literature to  
 246 determine the detection limits of PTR-MS instruments for FM and GL. Therefore, it will allow to make a  
 247 direct comparison between the instrument sensitivities.

248

249 **Figure 2.** Strategy followed during a typical calibration experiment. At first, the background of the VOC at  
 the corresponding mass peak(s) is recorded. Then its concentration is progressively increased and monitored  
 with SIFT-MS. Typically, 4 to 6 different concentrations of the VOC of interest are set before returning to  
 background monitoring.

### 250 3. Results and Discussion

251 Results and discussion section is divided in three parts. In the first one, we discuss the optimization of  
 252 operational parameters and conditions of the SIFT-MS and the strategy followed to improve the method  
 253 and the performance of the instrument. The second and the third subsections are dedicated to the calibration

254 measurements of FM and GL respectively, as a function of RH under standard and custom SIFT-MS  
255 operational conditions.  
256

### 257 **3.1 From Standard to Custom Method for SIFT-MS Determination of FM** 258 **and GL**

259 The standard operational conditions (SC) of the SIFT-MS, as recommended by the supplier, correspond to:  
260 (i) temperature of 393 K for the sampling plate and the flow tube, (ii) He flow rate of 380 mL min<sup>-1</sup> as bath  
261 gas, (iii) sampling flow rate of 35 mL min<sup>-1</sup>, resulting in a total pressure inside the flow tube of 0.65 Torr  
262 (Table 1). Table 1 summarizes other characteristic parameters of the SIFT-MS such as carrier gas ( $v_g$ ) and  
263 ions flow ( $v_i$ ) velocities, reaction time inside the flow tube of the instrument ( $t_r$ ), mean kinetic energy  
264 between reactants ( $KE_{cm}$ ). However, literature studies have reported that FM and GL detection is highly  
265 sensitive to operational conditions of soft ionization mass spectrometers (Lacko et al., 2020; Stönnner et al.,  
266 2017; Yuan et al., 2017). In particular, the detection of FM and GL is based on association reactions, (Lacko  
267 et al., 2020; Michel et al., 2005; Stönnner et al., 2017; Yuan et al., 2017) and thus the pressure and  
268 temperature of the flow tube can play a dominant role since association reactions are favored at higher  
269 pressures. Furthermore, in literature the fragmentation of GL has been reported, leading to reduced  
270 sensitivity and a more complex chemistry inside the reaction tube of the corresponding mass spectrometer  
271 (Lacko et al., 2020; Stönnner et al., 2017). Crucial role for the detection of both FM and GL is also played  
272 by the  $KE_{cm}$  (Hansel et al., 1997).  
273

274 Considering the abovementioned challenges related to the sensitive detection of FM and GL, to improve  
275 the sensitivity of the SIFT-MS we modified the pressure and temperature conditions of the SIFT-MS  
276 compared with SC. In particular, we indirectly increased the pressure inside the flow tube, by increasing  
277 He flow to its maximum value of 500 mL min<sup>-1</sup>, under constant pumping. This increase in He flow results  
278 in a 23 % higher pressure compared with SC. The temperature of the flow tube and sampling plate has been  
279 decreased to 323K. The temperature decrease results in lower  $KE_{cm}$ . Combined with increasing pressure, it  
280 leads to lower gas and ion flow velocities, and longer reaction times in the flow tube. Based on the literature  
281 (as described below, experimentally validated in our study), these modifications are anticipated to increase  
282 the sensitivity of the instrument. These modified operation conditions of the SIFT-MS are summarized in  
283 Table 1. In the following of the manuscript, they are referred to as custom conditions (CC). In order to  
284 assess the relevance of CC, calibration experiments described in the following of the manuscript are carried  
285 out under both SC and CC conditions.  
286

287 **Table 1.** SIFT-MS parameters and conditions used in the framework of the current study.

Parameters	Standard operation conditions (SC)	Custom operation conditions (CC)
Flow tube length, <sup>a</sup> $L$ (cm)	34	
Flow tube internal diameter, $D$ (cm)	4.1	
Sample plate temperature (K)	393	323

Flow tube temperature, $T_g$ (K)	393	323
Flow tube pressure (Torr)	0.65	0.85
Molecular density in the flow tube, $N$ (molecule $\text{cm}^{-3}$ )	$1.6 \times 10^{16}$	$2.5 \times 10^{16}$
Carrier gas flow ( $\text{mL min}^{-1}$ )	380	500
Carrier gas flow rate, $F_g$ (Torr L $\text{s}^{-1}$ )	5.12	6.69
Carrier gas flow velocity, <sup>b</sup> $v_g$ ( $\text{cm s}^{-1}$ )	860	705
Ion flow velocity, <sup>c</sup> $v_i$ ( $\text{cm s}^{-1}$ )	1290	1058
Reaction time, <sup>d</sup> $t_r$ (ms)	27.5	33.5
Mean kinetic energy between reactants, <sup>e</sup> $KE_{cm}$ (eV)	0.05	0.04
H <sub>2</sub> O concentration range injected in the flow tube, <sup>f</sup> (molecule $\text{cm}^{-3}$ )	$(0.01-943) \times 10^{12}$	$(0.02-1160) \times 10^{12}$
FM concentration range injected in the flow tube, <sup>g</sup> (molecule $\text{cm}^{-3}$ )	$(0.68-13.6) \times 10^8$	$(0.83-16.6) \times 10^8$
GL concentration range injected in the flow tube, <sup>g</sup> (molecule $\text{cm}^{-3}$ )	$(0.68-16.9) \times 10^8$	$(0.83-20.0) \times 10^8$

288 <sup>a</sup>: Distance between sample flow injection point and the end of the flow tube; <sup>b</sup>: calculated from the expression  $v_g =$   
289  $\frac{4F_g T_g}{P_g \pi D^2 273}$  where  $F_g$  is the carrier gas flow rate,  $T_g$  the temperature of the carrier gas,  $P_g$  the pressure in flow tube, and  
290  $D$  the flow tube internal diameter; (Španěl and Smith, 1996) <sup>c</sup>: calculated as  $v_i = 1.5 \times v_g$ ; (Smith and Adams, 1988)  
291 <sup>d</sup>: estimated from the expression  $t_r = \frac{L+\varepsilon}{v_i}$  where  $\varepsilon = 1.5$  and corresponds to the distance for a full mixing of neutral  
292 molecules with the carrier gas in the flow tube; <sup>e</sup>: calculated using the recommended expressions by Hansel et al.  
293 (1997).  $KE_{cm} = \frac{m+M}{M} (KE_{ion} - 1.5k_B T) + 1.5k_B T$  where  $m$  and  $M$  are the masses of the carrier gas and the neutral  
294 reactant, respectively,  $k_B$  is the Boltzmann constant and  $KE_{ion}$  is the kinetic energy of ions obtained by the expression  
295  $KE_{ion} = 1.5k_B T + 0.5mv_i^2 + 0.5M_{ion}v_i^2$ , where  $M_{ion}$  is the mass of reactant ion; <sup>f</sup>: estimated using the following  
296 expression  $[H_2O] = \frac{F_{H_2O}}{F_{total}} \times N$ , where  $F_{H_2O}$  is the sample flow of pure water in the sample flow calculated as the  
297 product of RH with the total sample flow rate ( $35 \text{ mL min}^{-1}$ ),  $F_{total}$  the total flow rate inside the flow tube, and  $N$  the  
298 number density; <sup>g</sup>: calculated in a similar way with water concentrations,  $[VOC] = \frac{F_{VOC}}{F_{total}} \times N$  where  $F_{VOC}$  is the sample  
299 flow of pure VOC in the sample flow calculated as the product of VOC mixing ratio in the total sample flow ( $35 \text{ mL}$   
300  $\text{min}^{-1}$ ).

302 We observed that operating the instrument under SC or CC modes has a negligible impact on the  
303 concentration of the  $\text{NO}^+$  and  $\text{O}_2^+$  primary ions. However, the distribution of  $\text{H}_3\text{O}^+$  and  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$  clusters  
304 is influenced. The hydronium water cluster can be formed from (R1):

306 The rate coefficient of (R1) is  $k_1(298 \pm 2K) = (6.55 \pm 0.75) \times 10^{-28} \text{ cm}^6 \text{ s}^{-1}$ . It is an average value  
307 retrieved from three literature studies (Bierbaum et al., 1976; Bolden and Twiddy, 1972; Španěl and Smith,  
308 2001). The errors quoted correspond to the standard deviation of the measurements.

309  
310 Reaction 1 is an association reaction, and therefore the rate coefficient depends on the thermal stabilization  
311 of the adduct leading to the formation of  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$ , favored at low temperatures and high pressures.  
312 Consequently, both temperature and pressure modifications, applied to establish CC, enhance the formation  
313 of  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$  clusters. In addition, reaction time also plays a role. Under CC,  $t_r$  is increased by a factor of  
314 1.22 compared to SC, and thus an increase in the concentration of  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$  is expected. In order to  
315 establish a criterion for the humidity adjustments during the calibration experiments and the different  
316 operation modes of the instrument, the ratio of the signals for the  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$  cluster at the  $m/z$  37 ( $I_{37}$ ) and  
317  $\text{H}_3\text{O}^+$  at the  $m/z$  19 ( $I_{19}$ ) is considered. Note that similar approaches have been applied in literature. (Inomata  
318 et al., 2008; Stönner et al., 2017) In Fig. S1 are presented these relative ratios of  $I_{37}/I_{19}$  versus the RH in the  
319 gas flow for the two different operation modes of the SIFT-MS. It should be noted that, as displayed in Fig.  
320 S1 when ambient water vapor concentration is close to zero level, i.e. close to dry conditions, the  $I_{37}/I_{19}$   
321 ratio approaches zero pointing that the water coming from the discharge ion source entering the flow tube  
322 is negligible compared to water vapor from the sampled dry air. This is in contrast with what has been noted  
323 in PTR-MS studies (Inomata et al., 2008; Stönner et al., 2017).

324  
325 In theory, it is possible to estimate the water concentration inside the flow tube to better predict the changes  
326 on the abundances of  $\text{H}_3\text{O}^+$  and  $\text{H}_3\text{O}^+\cdot\text{H}_2\text{O}$  ions. Lacko et al. (2020), applied the following expression to  
327 estimate the water concentration:

$$328 \quad [\text{H}_2\text{O}] = \frac{H}{t_r k_1} \quad \text{Eq. (2)}$$

329

$$330 \quad \text{where } H = \ln \frac{[\text{H}_3\text{O}^+] + [\text{H}_2\text{O}\cdot\text{H}_3\text{O}^+] + [(\text{H}_2\text{O})_2\cdot\text{H}_3\text{O}^+]}{[\text{H}_3\text{O}^+]} \quad \text{Eq. (3)}$$

331 However, in the literature,  $k_1$  has solely been determined at room temperature, thus extrapolation cannot be  
332 directly performed to SC or CC. Alternatively we can use the mixing ratios of water in the sample flow to  
333 estimate the concentration of water molecules introduced in the flow tube (Table 1). The background  $[\text{H}_2\text{O}]$   
334 has been estimated in the range of  $10^{10} \text{ molecule cm}^{-3}$  (based on  $\text{H}_2\text{O}$  residual levels in the zero-air flow,  
335  $<2\text{ppm}$  corresponding to  $\text{RH} < 0.01\%$ ), while the increase in RH resulted in water concentrations introduced  
336 in the flow tube in the order of  $10^{14} \text{ molecule cm}^{-3}$ , corresponding to around 5 % of the total number density.  
337 A similar approach was applied to estimate the concentrations of FM and GL inside the flow tube. Using  
338 mixing ratios of 50 up to 1200 ppb in the sample flow, the concentrations of the title VOCs were in the  
339 range of  $10^8 \text{ molecule cm}^{-3}$ , and thus several order of magnitude lower than  $[\text{H}_2\text{O}]$ .

## 340 **3.2 Formaldehyde Determination using SIFT-MS**

341

### 342 **3.2.1 Experimental Calibration of Formaldehyde under SC and CC**

343 Figure 3 displays typical calibration curves of FM operating SIFT-MS under standard and custom  
 344 conditions. The slope of the linear fit of experimental results corresponds to the calibration factor of the  
 345 compound of interest. In both cases, a linear response ( $R^2 > 0.997$ ) of the instrument is noticed on the entire  
 346 concentration range explored. However, at 70% of RH the experimental data points are more scattered  
 347 resulting in a lower precision fit. In Table 2 are summarized the calibration factors at each  $I_{37}/I_{19}$  ratio.  
 348 Under CC, the sensitivity of SIFT-MS towards FM is increased by a factor of ca. 2, compared to SC. In  
 349 addition, considering the experimental uncertainties, under SC, the SIFT-MS response is not influenced by  
 350 the level of RH used while under CC the sensitivity of the instrument is reduced by a factor of 2 from dry  
 351 ( $I_{37}/I_{19} < 0.01$ ) to 70% ( $I_{37}/I_{19} = 1$ ). Actually, a careful look at the data presented in Table 2 points that SIFT-  
 352 MS sensitivity is not impacted by water presence when the relative ratio of  $I_{37}/I_{19}$  is below ca. 0.55,  
 353 irrespectively of the SIFT-MS operation mode. Under CC, to express the relative humidity dependence of  
 354 the instrument sensitivity at the mass peak 31, the calibration factors were plotted as a function of the  $I_{37}/I_{19}$   
 355 ratio, using a weighted fit power function (Fig. S2). The weighted fitting considers the uncertainties denoted  
 356 for each calibration factor. The following expression describes the instrument sensitivity under SC for the  
 357 mass peak 31:

358  $C_F^{31}(\text{counts ppb}^{-1}) = 162 - 82.3 \left(\frac{I_{37}}{I_{19}}\right)^{2.41}$  Eq. (4)  
 359

360  
 361  
 362 **Figure 3.** Calibration curves of FM at the  $m/z$  31, derived from  $H_3O^+$  precursor ion under dry conditions.  
 363 The error bars on Y axis are 5 % (extreme value) and correspond to the  $2\sigma$  standard deviation of the  
 364 averaged value of the SIFT-MS signal for each measurement. The errors reported in X axis are 8 % and  
 365 correspond to the uncertainty given for the cross section value of FM (4%) and other systematic  
 366 uncertainties (in the flow of the mixture, sampling flow of the instrument, etc.) added in quadrature.

367 **Table 2.** Calibration factors and detection limits of FM at the  $m/z = 31$  as a function of relative humidity  
 368 for standard and custom operational conditions of the SIFT-MS. The calibration factor is derived from the  
 369 slope of a typical experiments shown in Fig. 3. The errors given in the calibration factors are the  $2\sigma$  precision  
 370 of the linear fit.

RH gas flow (%)	Standard Operational Conditions			Custom Operational Conditions		
	$I_{37}/I_{19}$	Calibration factor (counts ppb <sup>-1</sup> )	Detection limits (ppt)	$I_{37}/I_{19}$	Calibration factor (counts ppb <sup>-1</sup> )	Detection limits (ppt)
Dry	0.001	84.8±3.8	400	0.005	163±4	100
10	0.09	88.4±6.2		0.28	148±6	120
30	0.26	83.0±2.2		0.56	145±4	
50	0.41	82.7±1.0		0.79	115±5	145
70	0.54	70.0±12	500	1.0	82.5±14	200

371 Contrariwise, in literature it is reported that the sensitivity of a PTR-MS is massively reduced with RH. For  
372 instance, in the study of Stönner et al. (2017), the PTR-MS sensitivity was reduced by a factor of five or  
373 even greater when the relative ratio of H<sub>3</sub>O<sup>+</sup>·H<sub>2</sub>O to H<sub>3</sub>O<sup>+</sup> masses (measured as  $I_{39}/I_{21}$ ) varies from <0.1 to  
374 0.4.

### 375 3.2.2 Comparison of Formaldehyde Determination between SIFT-MS and PTR-MS

376 The contrasted behavior between the SIFT-MS and PTR-MS instruments are related to their distinct  
377 operational principles and chemical reactions. Therefore, before getting into the chemistry of proton transfer  
378 reactions for FM measurement, it is essential to discuss the major differences between the conditions inside  
379 the flow tube of the SIFT-MS used in the current study and inside the drift tube of the PTR-MS instruments  
380 deployed in literature for FM characterization (Inomata et al., 2008; Stönner et al., 2017; Vlasenko et al.,  
381 2010; Warneke et al., 2011).

382  
383 The pressure inside the flow tube of the voice 200 Ultra SIFT-MS instrument ranges between 0.6 to 0.9  
384 Torr (Table 1), which is by a factor of two lower than the pressure inside the drift tube in a PTR-MS. This  
385 pressure difference can impact the ion chemistry and mainly the formation of H<sub>3</sub>O<sup>+</sup>·H<sub>2</sub>O clusters. Besides  
386 pressure, the main difference between the two instruments relies in the mean relative kinetic energy of  
387 reactants ( $KE_{cm}$ ). In the flow tube of the SIFT-MS the  $KE_{cm}$  of analytes and precursor ions depend mainly  
388 on the temperature of the tube. Under the SC and CC the kinetic energy was calculated to be ca. 0.05 and  
389 0.04 eV respectively (Table 1). On the contrary the application of an electrical field inside the drift tube of  
390 a PTR-MS leads to significantly higher  $KE_{cm}$  values, reducing the sensitivity of the instrument. Typical  
391 values of  $KE_{cm}$  range between 0.10 to 0.23 eV in studies using PTR-MS for FM monitoring ( Table 3),  
392 (Inomata et al., 2008).

### 394 Ion Chemistry Involved in Formaldehyde Measurement with H<sub>3</sub>O<sup>+</sup> Precursor Ion

395 The proton transfer reaction in case of FM can occur according to the following reaction:

397 The rate coefficient of (R2a),  $k_{2a}$  is in the order of  $3 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$  at  $297 \pm 3 \text{ K}$  (Michel et al., 2005) (Table  
398 3), and slightly dependent on  $KE_{cm}$ .

399 However, due to the low exothermicity of (R2a) the back reaction is also possible:

401 Hansel et al. (1997) evidenced that (R2b) is strongly dependent on the  $KE_{\text{cm}}$  values of reactants. The highest  
 402 the  $KE_{\text{cm}}$  of protonated FM ( $\text{FM-H}^+$ ), the highest the probability for a successful collision. Thus, the rate  
 403 coefficient of deprotonization reaction  $k_{2b}$  increases. Table 3 summarizes the values of  $k_{2b}$  for different  $KE_{\text{cm}}$   
 404 used in PTR-MS studies and under SC or CC conditions of the SIFT-MS. Furthermore, (R2b) also depends  
 405 on the concentration of water molecules when evaluating the response of the SIFT-MS and PTR-MS  
 406 instruments as a function of RH. Therefore, the contribution of these two parameters, i.e.  $KE_{\text{cm}}$  of reactants  
 407 and water concentration inside the reaction tubes, may explain the contrasted behaviors between the two  
 408 instruments. In SIFT-MS, due to the low kinetic energy of reactants, the protonation of FM is strongly  
 409 favored. Indeed,  $k_{2a}/k_{2b}$  ratio is ca.1600 and ca.5300 respectively under SC and CC. It has to be noted that  
 410 an increase of water concentration due to RH variation in the analytes shows a negligible impact on the  
 411  $k_{2a}/k_{2b}$  ratio. It can also be suggested that the higher  $k_{2a}/k_{2b}$  ratio under CC could explain the amplification  
 412 by a factor of ca. 1.9 of FM sensitivity compared to SC. On the contrary, in the case of PTR-MS where  
 413 higher kinetic energies are achieved, the relative ratio of  $k_{2a}/k_{2b}$  remains below 160 and possibly goes down  
 414 to 26. Thus, a substantial increase of water concentration makes (R2b) more impactful and the sensitivity  
 415 of the instrument is strongly decreased.

416 **Table 3.** Rate coefficients of ion-molecule chemical reactions of FM under typical PTR-MS studies  
 417 retrieved from literature and the conditions where SIFT-MS is deployed in this work.

Values	PTR-MS <sup>a</sup>			SIFT-MS	
				Standard operational conditions	Custom operational conditions
$KE_{\text{cm}}$ (eV)	0.10	0.17	0.23	0.05	0.04
$k_{2a}$ ( $10^{-9} \text{ cm}^3 \text{ s}^{-1}$ )	1.6	1.4	1.3	3.2 <sup>b</sup>	3.2
$k_{2b}$ ( $10^{-11} \text{ cm}^3 \text{ s}^{-1}$ )	1.0	2.9	5.0	0.2 <sup>b</sup>	0.06 <sup>c</sup>
$k_{3a}$ ( $10^{-9} \text{ cm}^3 \text{ s}^{-1}$ )	-	-	-	2.65±0.35 <sup>d</sup>	-
$k_{3b}$ ( $10^{-10} \text{ cm}^3 \text{ s}^{-1}$ )	-	-	-	4.4±1.1	-
$k_4$ ( $10^{-11} \text{ cm}^3 \text{ s}^{-1}$ )	Negligible			1.2	>1.2
$k_{2a}/k_{2b}$	160	48	26	1600	5333
$k_4/k_{2b}$	Negligible			6	>20

418 <sup>a</sup>: data retrieved from the work of Inomata et al. (2008). Authors extracted the  $k_{2a}$  and  $k_{2b}$  values based on the work of  
419 Hansel et al. (1997); <sup>b</sup>: average value determined by Hansel et al. (1997) ; <sup>c</sup> calculated by Bohme et al. (1979); <sup>d</sup>:  
420 average literature value from the studies of Bohme et al. (1979) and Midey et al. (2000). The error corresponds to the  
421 standard deviation of the measurements.

422 Although solely the  $m/z = 31$  is used to monitor FM, in SIFT-MS other ion reactions can occur and form a  
423 protonated methyl hydroperoxide (PMH) complex with  $m/z = 49$  (Hansel et al., 1997). These ion reactions  
424 are not expected to occur in PTR-MS due to the high  $KE_{cm}$  values. These reactions are strongly dependent  
425 on water concentrations in the flow tube, and they are competitive to (R2a) and (R2b). However, their  
426 contribution to the ion chemistry inside the flow tube of the SIFT-MS is expected to be of minor importance,  
427 especially under SC. Indeed, under SC the calibration factor of FM is not impacted by increasing water  
428 concentration by almost 540 times (considering the  $I_{37}/I_{19}$  ratios calculated under dry and 70 % of RH).  
429 However, since their occurrence cannot be excluded and they could play a role for  $I_{37}/I_{19}$  ratios above 0.55,  
430 these reactions are discussed in the following of the manuscript.

431 The protonation of FM can occur through ligand switching from the hydronium water cluster,  $H_3O^+ \cdot H_2O$   
432 and to form PMH through the following reaction:

434 At room temperature, the rate coefficient of this reaction has been estimated to be  $(2.65 \pm 0.35) \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$   
435 <sup>1</sup> calculated from the average of literature values, (Bohme et al., 1979; Midey et al., 2000), and the error  
436 corresponds to the standard deviation of the measurements. The rate coefficient of the back reaction (R3b)  
437 was estimated to be around six times lower  $(4.4 \pm 1.1) \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$

439 Reaction 3 is expected to be highly sensitive on RH, i.e. the water concentrations in the flow tube. On one  
440 side, the increase in water concentration will increase the concentration of  $H_3O^+ \cdot H_2O$  enhancing (R3a), on  
441 the other side the excess of water compared to FM enhances (R3b). Therefore, the impact of (R3) in the ion  
442 chemistry occurring in the flow tube of SIFT-MS is linked with the relative ratio of  $I_{37}/I_{19}$ . However, as  
443 abovementioned, under SC the calibration factor at  $m/z$  31 remains constant within the experimental  
444 uncertainties and the RH range studied (0 -70 %), and thus (R3) seems to have insignificant impact on the  
445 sensitivity of the instrument. However, in case of CC where the  $I_{37}/I_{19}$  is greater than 0.55, the gradual  
446 reduction in FM sensitivity could be due to the competition between (R2a) and (R3a).

447 An alternative pathway of PMH formation is through (R4) in presence of a third body and water molecules:

449 Reaction 4 is an association reaction competitive with (R2b) and depends on the total pressure of the  
450 reaction system and the kinetic energy of reactants. In the presence of a third body, the  $FM-H^+$  and water  
451 molecules can lose part of their energy through collisions and further stabilize to form PMH increasing the  
452 rate coefficient  $k_4$ . Therefore, it is expected that the rate coefficient of this association reaction is enhanced  
453 with increasing pressure. Under a given pressure,  $k_4$  is reduced as  $KE_{cm}$  increases because the third body  
454 fails to stabilize reactants. Hansel et al. (1997) have studied the pressure dependence of the rate coefficient  
455  $k_4$  at 0.05 eV; i.e. with  $KE_{cm}$  values similar with SIFT-MS SC used in the present study. The rate coefficient

456 of the ternary association at room temperature proposed by these authors was  $k_4 = 5.7 \times 10^{-28} \text{ cm}^6 \text{ s}^{-1}$ . They  
457 concluded that for  $KE_{\text{cm}}$  greater than 0.06 eV  $k_4$  is negligible compared to  $k_{2b}$ . For that reason, this reaction  
458 is not taken into account in most of PTR-MS studies. Nevertheless, (R4) could contribute to SIFT-MS  
459 response.

460 Indeed, we estimated that under SC and CC of SIFT-MS, the binary rate coefficient of the association  
461 reaction at room temperature and the established pressures is greater than  $1.2 \cdot 10^{-11} \text{ cm}^3 \text{ s}^{-1}$  and thus higher  
462 than  $k_{2b}$  (Table 3). This value is calculated as the product of  $k_4$  with the number density inside the flow tube  
463 of SIFT-MS. However, it remains around 260 times lower than FM protonation. At this point it should be  
464 noted that the value of  $1.2 \cdot 10^{-11} \text{ cm}^3 \text{ s}^{-1}$  should be considered as an upper limit of the contribution of  $k_4$   
465 reaction, since under both SC and CC the flow tube was operated above room temperature, and thus lower  
466 rate coefficient for  $k_4$  is anticipated (ternary association reactions decrease with increasing temperature).  
467 The importance of (R4) is expected to be enhanced at high water concentrations. Hansel et al. (1997),  
468 reported that  $k_4$  is increasing from dry to low concentrations of water reaching a maximum value, and then  
469 decreases with the extra addition of water due to (R3b), which is around 37 times faster than (R4). Note  
470 that absolute values cannot be extrapolated from their data. To determine the role of (R4) it is essential to  
471 remind that it is competitive with (R1) for hydronium ion formation. Although  $k_1$  has not been determined  
472 for the temperatures of 323 and 393 K, considering that  $\text{H}_3\text{O}^+$  is in high excess compared to FM, (R1) is  
473 expected to be the dominant.

#### 474 **Wrap up on Formaldehyde Determination**

475 In the case of SIFT-MS, the ion chemistry of FM is mainly controlled by (R2a) and (R2b). The increased  
476 sensitivity observed under CC conditions is mainly linked to the higher  $k_{2a}/k_{2b}$  values achieved compared  
477 with SC. The low kinetic energy of reactants in SIFT-MS flow tube is the reason why the sensitivity of the  
478 instrument is not significantly impacted by RH. This behavior contrasts with PTR-MS. (R3) and (R4),  
479 involving PMH production and inducing a lower sensitivity at the mass peak 31, seem to be of minor  
480 importance or at least to be in equilibrium state for  $I_{37}/I_{19}$  below 0.55. Above that threshold, their occurrence  
481 could explain a lower sensitivity but this point needs further investigations to be experimentally validated.  
482 The detection limit of FM is  $450 \pm 50$  ppt under SC. The CC allow decreasing the detection limits of the  
483 SIFT MS instrument by a factor of ca. 4 for 0-50% RH (100 ppt) and by a factor of 2 under 70 % RH (200  
484 ppt) (Table 2). These detection limits, based on a signal to noise ratio  $S/N = 3.3$ , are comparable or lower  
485 than those reported in the PTR-MS studies that mentioned DL between 200-500 ppt with  $S/N = 2$ , (Inomata  
486 et al., 2008), and DL 100 ppt under dry and 300 ppt under humid using  $S/N = 1$ , (Warneke et al., 2011),  
487 and close to the most performant spectroscopic techniques noting DL around 80 ppt (Catoire et al., 2012;  
488 Winkowski and Stacewicz, 2020).

### 489 **3.3 Glyoxal Determination with SIFT-MS**

490  
491 This section is dedicated to the evaluation of the performances of the SIFT-MS instrument to determine GL  
492 in the ppb range as a function of RH. To that end, SIFT-MS is operated under both SC and CC, with a focus  
493 on the chemistry of  $\text{H}_3\text{O}^+$  and  $\text{NO}^+$  ions. Note that,  $\text{O}_2^+$  ion is not considered in the present study, due to  
494 significant fragmentation of molecular GL induced by this ions and a subsequent lower sensitivity, strongly  
495 impacted by RH.

496 **3.3.1. Experimental Calibration of Glyoxal as a Function of RH**

497 Figure 4 displays a typical calibration experiment of GL deploying SIFT-MS under SC and recording the  
 498 mass peak 59 ( $C_2H_3O_2^+$ ) with  $H_3O^+$  as precursor ion. A linear response ( $R^2 > 0.999$ ) of the instrument is  
 499 noticed on the entire concentration range explored. The data points presented in Fig. 4 are obtained from  
 500 two different GL syntheses and on three different days dispatched on three months. Table 4 summarizes  
 501 the calibration factors and corresponding uncertainties retrieved for the mass peaks used to record GL under  
 502 SC and CC.

503 **Figure 4.** Calibration curves of GL at the  $m/z$  59 derived from  $H_3O^+$  precursor ion under dry conditions.  
 504 The error bars on Y axis are 5% (extreme value) and correspond to the  $2\sigma$  standard deviation of the averaged  
 505 value of the SIFT-MS signal for each measurement. The errors in X axis are 8% and corresponds to the  
 506 uncertainty given for the cross section value of GL (4%) and other systematic uncertainties (in the flow of  
 507 the mixture, sampling flow of the instrument, etc.) added in quadrature. Circles corresponds to experiments  
 508 carried out on different days (13 March 2020 and 16 March 2020) from the same gas mixture. Squares  
 509 correspond to experiments carried out almost three months later (5 June 2020) with a new gas mixture and  
 510 synthesis of GL.  
 511

512 **Table 4.** Calibration factors and relative ratios determined for GL under SC and CC at the  $m/z$  59 ( $C_2H_3O_2^+$ )  
 513 and  $m/z$  88 ( $C_2H_2O_2 \cdot NO^+$ ) using the  $H_3O^+$  and  $NO^+$  precursor ions respectively. The errors quoted  
 514 correspond to the  $2\sigma$  precision of the fit to obtain the calibration factors.

Standard Conditions (SC)			Custom Conditions (CC)			
$I_{37}/I_{19}$	Calibration factors (counts ppb <sup>-1</sup> )		Relative ratios	Calibration factors (counts ppb <sup>-1</sup> )		Relative ratios
	m/z 59 ( $H_3O^+$ )	m/z 88 ( $NO^+$ )	$I_{59}/I_{88}$	m/z 59 ( $H_3O^+$ )	m/z 88 ( $NO^+$ )	$I_{59}/I_{88}$

0.001	71.9±2.4	0.41±0.02	175	0.005	161±1	3.20±0.06	50.3
0.06	36.2±3.6	0.45±0.03	81.0	-	n.d <sup>b</sup>	n.d	n.d
0.09	32.0±0.9	0.44±0.03	72.7	0.28	32.9±0.5	3.41±0.07	9.6
0.27	12.1±0.6	0.48±0.05	25.2	0.56	11.4±0.1	3.68±0.18	3.1
0.41	7.6±0.7	0.50±0.03	15.2	0.79	6.9±0.1	4.30±0.05	1.6
0.54	5.5±1.0	0.52±0.02	10.5	1	4.2±0.2	4.47±0.07	0.94

515 Considering the  $\text{H}_3\text{O}^+$  precursor ion and the mass peak 59, an increase of the sensitivity of the instrument  
516 by a factor of 2 is noticed under CC compared to SC (left panel of Fig. 5). Note that a similar enhancement  
517 is observed for FM (Figure 3 and Table 2). Nevertheless, the sensitivity is diminished with increasing RH  
518 under both SC and CC. To evaluate whether the impact of water to GL detection is similar under both  
519 operational conditions, we plotted the normalized sensitivity (calibration factor dry / calibration factor  
520 humid) versus  $I_{37}/I_{19}$  ratios, and results are also displayed in Fig. 5 (right panel). It seems that the impact  
521 of water to the sensitivity of the instrument at the mass peak 59 is similar for both SC and CC. The  
522 calibration factors were fitted versus the  $I_{37}/I_{19}$  ratios and the sensitivity of the instrument under SC and CC  
523 are given by the following expression:

$$524 \quad C_F^{59}(\text{counts ppb}^{-1}) = \frac{a}{b + \left(\frac{I_{37}}{I_{19}}\right)^c} \text{ Eq. (5)}$$

525 where  $a=2.99$ ,  $b=0.04$ ,  $c=1.20$  for SC and  $a=4.53$ ,  $b=0.03$ ,  $c=1.74$  for CC, respectively.

526 Under dry, the detection limits for GL at the mass peak 59 are determined as  $280 \pm 30$  ppt and  $120 \pm 12$  ppt  
527 for SC and CC respectively for 1-minute integration time (Table S1 and S2). Nevertheless, with the increase  
528 of relative humidity to 70% detection limits are increased up to  $6 \pm 1$  ppb.

529

530  
531  
532

533 **Figure 5.** Left panel: calibration factors of GL at  $m/z$  59 derived from  $\text{H}_3\text{O}^+$  precursor ion under SC (filled  
 534 symbols) and CC (open symbols) conditions. The errors quoted correspond to the  $2\sigma$  precision of the fit to  
 535 obtain the calibration factors. The lines are the fitting of calibration factors with the empirical expression:  
 536  $C_F^{59}(\text{counts ppb}^{-1}) = \frac{a}{b + \left(\frac{I_{37}}{I_{19}}\right)^c}$  where for SC  $a=2.99$ ,  $b=0.04$ ,  $c=1.20$  and CC  $a=4.53$ ,  $b=0.03$ ,  $c=1.74$ .

537 Right panel: GL normalized sensitivity at the mass peak 59 of SIFT-MS (in black) and PTR-MS (in red)  
 538 versus the  $I_{37}/I_{19}$  and  $I_{39}/I_{21}$  ratios. For SIFT-MS, the reduction to instrument sensitivity is similar for both  
 539 SC and CC conditions. For comparison purposes, the data presented in Fig. 5 of Stönner et al. (2017) study  
 540 were extracted and displayed in the graph. A steeper decrease to GL sensitivity is noticed with SIFT-MS at  
 541 low levels of humidity than PTR-MS.

542  
 543 The detection of GL was also achieved using the  $\text{NO}^+$  precursor ion at the mass peak 88. Table 4 displays  
 544 the calibration factors determined. Under SC we noticed a weaker response of the instrument using the  $\text{NO}^+$   
 545 precursor ion compared to  $\text{H}_3\text{O}^+$  ion. Remarkably, the introduction of water had no significant impact on  
 546 the sensitivity of the mass peak 88. In fact, at the highest RH corresponding to  $I_{37}/I_{19} = 0.54$ , the instrument  
 547 was 20% more sensitive than under dry. Operating the instrument under CC, increased by a factor of eight  
 548 the sensitivity at the mass peak 88. Again, the introduction of water improved the detection of GL at the  
 549 mass peak 88, by around 28% this time. Interestingly, as displayed in Table 4 at high water concentrations,  
 550 peak 88 is more sensitive than mass peak 59.

551  
 552 **3.3.2. Comparison of Glyoxal Determination between SIFT-MS and PTR-MS**  
 553 There are only a few studies in literature exploring the measurement of GL using PTR-MS. Thalman et al.  
 554 (2015) performed a thorough inter-comparison study of spectrometric and spectroscopic techniques for the  
 555 detection of GL in an atmospheric simulation chamber. In their experiments authors used concentrations of  
 556 GL up to 32 ppb, but they were unable to detect GL with their PTR-MS, attesting of the low sensitivity of  
 557 the instrument (Thalman et al., 2015). However, in the recent study of Stönner et al. (2017), GL was  
 558 detected at low concentrations deploying an Ionicon PTR-TOF-MS-8000 instrument. Interestingly these  
 559 authors observed a decreasing sensitivity of the PTR-MS instrument with increasing water concentration,  
 560 similarly to our study. As can be seen in Fig. 5 the decrease in GL sensitivity at the mass peak 59 is steeper  
 561 in our SIFT-MS compared with PTR-MS (data are also presented in Table S3). Stönner et al. (2017),  
 562 estimated the detection limits for GL at 250 ppt under dry and 700 ppt at the highest level of RH used.

563  
 564 **Ion Chemistry Involved in Glyoxal Measurement with  $\text{H}_3\text{O}^+$  Precursor Ion**  
 565 Considering the ion chemistry of  $\text{H}_3\text{O}^+$ , the protonation of GL can occur through the following reaction:

567 The rate coefficient of (R5a),  $k_{5a}$  is  $1.9 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$  and is competitive with hydronium formation (reaction  
 568 1). Due to the low proton affinity of GL the deprotonization reaction is expected to occur as reported by  
 569 (R5b):

571 The rate coefficient of (R5b) has not been determined in literature, it could depend on  $KE_{\text{cm}}$ , similarly to  
 572 (R2b). Considering this scenario, the increased sensitivity of the instrument under CC could be due to higher

573  $k_{5a}/k_{5b}$  relative ratios, similarly to what is noticed for FM. The decreasing sensitivity of the SIFT-MS with  
574 increasing water concentration could be also due to the competition between (R5a) and (R5b). In this case,  
575 (R5b) should be relatively fast even under dry conditions. Its impact would be enhanced with the addition  
576 of water to the reaction system, leading to initial reactants. Note that Stönner et al. (2017) made a similar  
577 hypothesis to explain the decreased sensitivity with water concentration of their PTR-MS.  
578 Another plausible explanation for the decreasing sensitivity of the SIFT-MS at the mass peak 59 with  
579 increasing RH could be reaction (R6) which act competitively with (R5a), due to the increase of water  
580 clustering in the flow tube of the SIFT-MS. Reaction (R6) leads to the formation of the mass peak with  $m/z$   
581 =77.

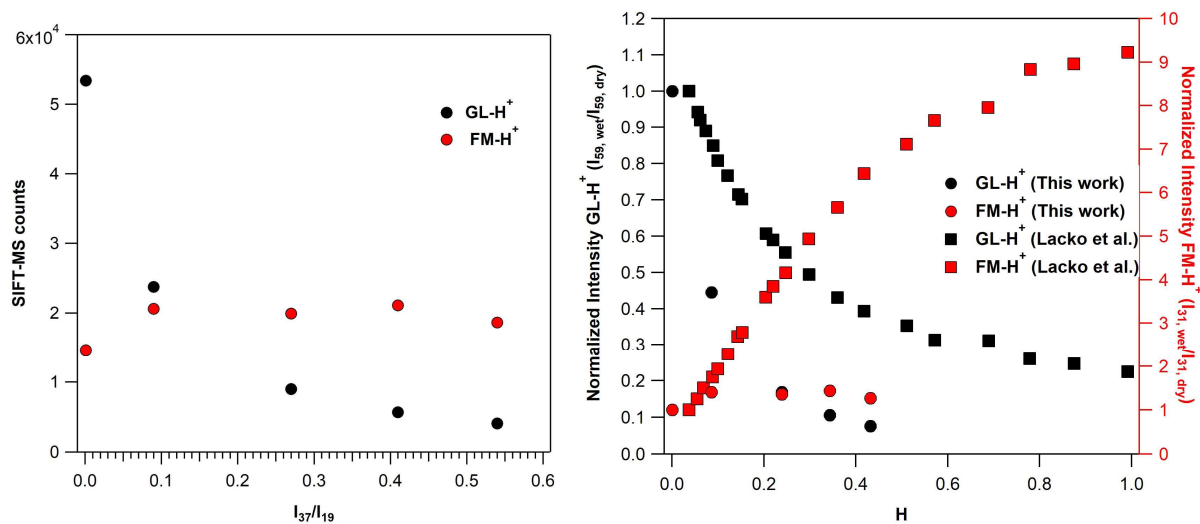

583 To evaluate the effect of water clustering the complete mass spectrum pattern of GL (concentration of 300  
584 ppb) was recorded for all RH levels under SC and CC. Typical normalized spectra under CC for dry and  
585 50% of RH are presented in Fig. S4. Note that CC operational conditions enhance the water clustering due  
586 to the lower temperature and higher pressure in the flow tube (reflected also in the  $I_{37}/I_{19}$  ratios). Under dry  
587 conditions, the main peak observed is the  $m/z=59$ . The intensity of the  $m/z=77$  corresponds solely to 1%  
588 of the peak 59. Interestingly a peak at  $m/z=31$  was observed corresponding to ca. 14% of the peak 59.  
589 Under 50% of RH the intensity of the mass peak 59 is diminished and the primary peak in the mass spectrum  
590 is the 31. However, the mass peak 77 is not impacted by RH and has a similar absolute intensity with dry.  
591 Therefore, our results clearly demonstrated that the decrease of the instrument sensitivity in the mass 59  
592 with increasing RH is not due to water clustering and thus reaction (R6) has a negligible contribution in the  
593 sensitivity of our SIFT-MS.

594 The observation of the mass peak 31 in the mass spectrum of GL could arise from the fragmentation of  
595 protonated GL ( $\text{C}_2\text{H}_3\text{O}_2^+$  or  $\text{GL-H}^+$ ) to protonated FM ( $\text{CH}_3\text{O}^+$  or  $\text{FM-H}^+$ , with  $m/z=31$ ) inside the flow  
596 tube. The latter has been observed in the drift tube of the PTR-MS used by Stönner et al (2017). Authors  
597 report a considerably larger signal on  $\text{FM-H}^+$  than  $\text{GL-H}^+$ . In a recent study, Lacko et al. (2020) studied the  
598 fragmentation of  $\text{GL-H}^+$  deploying a SIFT-MS. The authors evidenced the strong impact of water  
599 concentration on  $\text{GL-H}^+$  fragmentation leading to  $\text{FM-H}^+$ . Interestingly, they have not observed  $\text{FM-H}^+$   
600 under dry conditions. Thus, authors proposed that it should be formed only in the presence of water. Similar  
601 conclusions are reported by Michel et al. (2005). Finally, Lacko et al. (2020) combined their experimental  
602 observations with numerical modeling and proposed a sequence of reactions to explain the fragmentation  
603 of  $\text{GL-H}^+$  to  $\text{FM-H}^+$ . The discussion of these reaction pathways is beyond the scope of this study,  
604 nevertheless to feed the discussion of the manuscript we present them with the following simple expression  
605 reported by (R7):

607 In this study we have further explored the possible fragmentation of  $\text{GL-H}^+$  to  $\text{FM-H}^+$ . These experiments  
608 have been performed under both SC and CC. Note that our observations were found to be independent of  
609 GL concentration introduced. First we discuss our observations under SC and then under CC. The left panel  
610 of Fig. 6 displays the variation of the signals recorded for  $\text{FM-H}^+$  and  $\text{GL-H}^+$  with  $I_{37}/I_{19}$  ratios. For  
611 comparison purposes we present the normalized signals versus  $H$  factor as determined in the study of Lacko  
612 et al. (2020), i.e. Eq. (3), in the right panel of Fig. 6 (data are also given in Table S4).

613 **Fragmentation of GL-H<sup>+</sup> under SC and dry.** In contrast with the work of Lacko et al, we observe the  
 614 formation of FM-H<sup>+</sup> even under dry conditions, (Lacko et al., 2020).

615  
 616 **Figure 6.** Left panel: SIFT-MS counts at the mass peak 59 (in black) of GL-H<sup>+</sup> and mass peak 31 (in red)  
 617 of FM-H<sup>+</sup> recorded by the SIFT-MS under SC conditions using around 750 ppb of GL operating the  
 618 instrument under SC. Right panel: Normalized sensitivity at the mass peak 59 (in black) of GL-H<sup>+</sup> and  
 619 mass peak 31 (in red) of FM-H<sup>+</sup>, recorded with SIFT-MS under SC based on the results of the current study  
 620 (circles) and Lacko et al. (2020) (squares, data extracted from their Fig. 3) versus the H value Eq. (3).

621 The FM-H<sup>+</sup> signal recorded corresponds to 27 % of GL-H<sup>+</sup>. Therefore, it is possible that in our SIFT-MS,  
 622 FM-H<sup>+</sup> is formed through alternative pathways. We propose that under our experimental conditions, GL-  
 623 H<sup>+</sup> can either thermally decompose inside the flow tube (operated at 393 K under SC, Table 1) or  
 624 fragmentizes through collisions with ions inside the flow tube leading to FM-H<sup>+</sup> (R8). Both pathways are  
 625 expected to be enhanced at higher temperatures and higher  $KE_{cm}$ . Note that GL-H<sup>+</sup> thermal fragmentation  
 626 is expected to be significantly lower in the system of Lacko et al. (2020) where the flow tube temperature  
 627 was 300 K, as well as in the PTR-MS where the drift tube temperature was set to 333 K and higher pressure  
 628 (Stönnner et al., 2017).

630 We expect that both the thermal decomposition and collision fragmentation pathways are independent of  
 631 the water concentration inside the SIFT flow tube. At this point it should be noted that possible thermal  
 632 decomposition of molecular GL in the sample plate or inside the flow tube should be considered negligible.  
 633 In particular, the most probable thermal decomposition pathway of molecular GL is through the following  
 634 reaction (Saito et al., 1984):

636 The molecular FM could then react with H<sub>3</sub>O<sup>+</sup> through (R2a) and lead to the formation of FM-H<sup>+</sup>. However,  
 637 the energy barrier for the thermal decomposition of the lowest transition state to give products in (R9) is  
 638 around 230 kJ mol<sup>-1</sup> (Koch et al., 2001). Therefore, it is unlikely to occur at these temperatures and in our

639 system. To further validate this point, we have performed a series of experiments introducing GL inside the  
640 optical cell of the FTIR spectrometer operated at 393 K and recording sequential spectra of GL for several  
641 hours. No thermal decomposition was noticed as previously reported in literature (Feierabend et al., 2008).

642  
643 **Fragmentation of  $GL-H^+$  under SC and humid.** Increasing the water concentration from dry to 10 % of  
644 RH (corresponding to an increase by a factor of 90 to the  $I_{37}/I_{19}$  ratios, Table 4) the signal of  $GL-H^+$  is  
645 reduced by 56 %, while the formation of  $FM-H^+$  is enhanced by 40% (see also Fig. 6). This clearly shows  
646 that water plays a role in the formation of  $FM-H^+$  to the reduced sensitivity of GL and processes proposed  
647 by Lacko et al. (2020), (R7) are probably taking place. Further increase of water concentrations in the flow  
648 tube had no impact on the formation  $FM-H^+$  but GL sensitivity is still reduced. Essentially, using SIFT-MS  
649 under SC conditions, the formation of  $FM-H^+$  is less impacted by water concentrations than other literature  
650 studies. Indeed, as displayed in the right panel of Fig. 6 although the GL sensitivity loss is steeper in our  
651 study compared to Lacko et al. (2020), the corresponding formation of  $FM-H^+$  is substantially lower.  
652 To conclude under SC conditions, the fragmentation of  $GL-H^+$  to  $FM-H^+$  occurs in the flow tube of the  
653 SIFT-MS, but it is less impacted by water concentrations than PTR-MS. Alternatively, we propose that  $GL-$   
654  $H^+$  decomposes either thermally or through ion collisions leading to  $FM-H^+$ . Therefore, it seems that the  
655 abrupt loss of GL sensitivity with water concentrations is mainly due to the competition of (R5a) and (R5b).  
656 Especially under the temperature of 393 K, the deprotonization (R5b) is expected to be faster than room  
657 temperature and to play a more significant role than in the work of Lacko et al. (2020).

658  
659 **Fragmentation of  $GL-H^+$  under CC and dry.** Under custom conditions (CC) of the SIFT-MS, the formation  
660 of  $FM-H^+$  from the fragmentation of  $GL-H^+$ , is also observed. Nevertheless, the ratio of  $FM-H^+$  to  $GL-H^+$   
661 signals is significantly diminished. Indeed, under dry conditions the fragmentation is reduced from 27 % to  
662 ca. 14 % for SC and CC respectively. This observation supports our previous hypothesis:  $GL-H^+$  could  
663 decompose inside our SIFT-MS flow tube. Both the temperature decrease and pressure increase, changing  
664 from SC to CC, tend to suppress the decomposition of  $GL-H^+$ .

665  
666 **Fragmentation of  $GL-H^+$  under CC and humid.** A similar reduction of the fragmentation of  $GL-H^+$  was  
667 noticed in presence of water when comparing the signals recorded under SC and CC for  $I_{37}/I_{19}$  equal to  
668  $0.27\pm 0.01$  and  $0.55\pm 0.01$ . As displayed in Fig. S3 the decreased sensitivity of GL is similar under both SC  
669 and CC. Note that Fig. S3 should be viewed as a way to compare the impact of water concentrations on the  
670 fragmentation of  $GL-H^+$  and the appearance of  $FM-H^+$ . Essentially, the impact of water to the sensitivity of  
671 SIFT-MS to GL is independent on the operational conditions of the instrument. However, with the increase  
672 of water concentration inside the flow tube from dry to a value of 0.28 for  $I_{37}/I_{19}$  ratio (an increase by a  
673 factor of 56) the signal of  $FM-H^+$  increases by almost a factor of 3. Therefore, water plays a more important  
674 role to the presence of  $FM-H^+$  under CC and we anticipate that reactions proposed by Lacko et al. (2020)  
675 can dominate (R7). Further increase of water concentration in the flow tube reduced the signal of  $FM-H^+$ .  
676 Although this looks as a paradox and in contradiction with the abovementioned discussion, we suggest that  
677 this decrease is related to the competition between the (R7) and (R8), i.e. the deprotonization reaction of  
678  $FM-H^+$  (R2b). Nevertheless, a more thorough investigation is necessary to support this point.  
679 Therefore, we propose that the increased sensitivity of the instrument under CC is mainly due to higher  
680  $k_{5a}/k_{5b}$  ratios. The expected lower values of this  $k_{5a}/k_{5b}$  ratio could explain the lower sensitivity to detect GL  
681 in the presence of water. Nevertheless, the decreasing GL sensitivity with increasing RH could be also

682 attributed to fragmentation of  $\text{GL-H}^+$  to  $\text{FM-H}^+$ , both linked to thermal decomposition and reactions  
683 involving water molecules as discussed by Lacko et al. (2020).

#### 684 **Ion Chemistry Involved in Glyoxal Measurement using $\text{NO}^+$ Precursor Ion**

685 The detection of GL in the flow tube of the SIFT-MS proceeds through the following reaction:

687 The rate coefficient measured at room temperature for (R10) is  $8 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$ , (Michel et al., 2005) i.e.  
688 around 24 times below the protonation reaction of GL (R5a). The latter could explain the reduced sensitivity  
689 at the mass peak 88 compared to the mass 59 under dry conditions. Furthermore, (R10) is a three-body  
690 association reaction. In an association process, an intermediate species is formed before the formation of  
691 final products. The stability of this intermediate is both temperature and pressure dependent, and determines  
692 the overall rate coefficient of the reaction. The increased sensitivity to the detection of GL under custom  
693 conditions, is related with the temperature and pressure conditions existing in the flow tube. In particular  
694 the decrease of the flow tube temperature combined with a 20% increase in the total pressure (from 0.65 to  
695 0.85 Torr) resulted in a better stabilization of the adduct that leads to product formation for (R10), and thus  
696 improved sensitivity. Apparently under our experimental conditions the reaction of  $\text{NO}^+$  with GL is in the  
697 exponential part of a typical fall-off graph of an association reaction (Guimbaud et al., 2007).

698 The positive impact of water concentrations on the detection of GL at the mass peak 88, could be linked  
699 with the formation of  $\text{H}_2\text{O} \cdot \text{NO}^+$  hydrate cluster at the mass peak 48. Indeed, we have observed an increase  
700 to the abundance of the cluster with increasing RH. The following reaction could be proposed:

702 Although the rate coefficient of (R10) has not been measured in literature, it has been showed that the  
703 reactions of  $\text{H}_2\text{O} \cdot \text{NO}^+$  with several VOCs are just as fast as or even faster than those with  $\text{NO}^+$  ion (Michel  
704 et al., 2005). Mass scan spectra using the  $\text{NO}^+$  ion were also collected but besides the mass peak 88, no  
705 other peaks that could be attributed to GL were observed.

## 706 **4. Conclusions**

707 SIFT-MS appears to be a powerful and reliable analytical tool for the real-time quantification of FM in  
708 laboratory studies and outdoor/indoor field environments. Remarkably, under SC the sensitivity of the  
709 instrument is not impacted by RH with a corresponding detection limit of ca. 500 ppt. Operating the  
710 instrument under CC increased the sensitivity however, for  $I_{37}/I_{19}$  above 0.58 the sensitivity is reduced and  
711 a correction factor should be applied. We recommend the operation of SIFT-MS under SC for the  
712 measurement of ambient FM greater than 500 ppt. Furthermore, our strategy to operate the SIFT-MS  
713 instrument under different modes, allowed us to shed light on the ion chemistry occurring in the flow tube  
714 and to identify the key reactions and processes that define the sensitivity of the instrument towards FM. A  
715 thorough comparison of our observations with literature studies carried out with PTR-MS, evidences that  
716 the strong decay of PTR-MS sensitivity with increasing RH is related to the application of the electrical  
717 field in the DRIFT tube. It enhances the rate coefficient of deprotonization reaction of FM. Regarding GL,  
718 we have performed a detailed research on the ion chemistry related with  $\text{H}_3\text{O}^+$  and  $\text{NO}^+$  ions. Regarding

719  $\text{H}_3\text{O}^+$  we evidenced a sharp decrease of the instrument sensitivity with increasing RH, similar to previous  
720 PTR-MS and SIFT-MS studies, due to  $\text{GL-H}^+$  fragmentation. Nevertheless, based on our experimental  
721 observations we propose alternative pathways of  $\text{GL-H}^+$  fragmentation, such as  $\text{GL-H}^+$  decomposition,  
722 which seems to be of greater importance than it has been considered previously in literature. Based on the  
723 detection limits achieved with the  $\text{H}_3\text{O}^+$  ion, we suggest that SIFT-MS is not able to monitor GL in outdoor  
724 ambient air due to the strong impact of RH on SIFT-MS sensitivity. It should be clarified that as shown in  
725 Figure 5, the fitting of calibration factors with  $I_{37}/I_{19}$  ratio is feasible (see figure 5 caption) and thus the  
726 concentrations of glyoxal can be retrieved even under environments where the RH changes during the  
727 experiment by following the  $I_{37}/I_{19}$  ratio. Therefore, the major limitation is the instrument sensitivity and  
728 not the variation of the RH of the ambient environment. On the contrary, SIFT-MS can be deployed  
729 efficiently in laboratory scale studies (i.e. atmospheric simulation chambers, photochemical reactors) or  
730 indoor experimental rooms where GL concentrations are in the ppb range. In addition, we recommend that  
731 using the  $\text{H}_3\text{O}^+$  ion for the monitoring of GL concentrations should be performed with great caution due to  
732 the strong RH dependence and contribution on the signal of  $\text{FM-H}^+$ . Nevertheless, deploying  $\text{NO}^+$  precursor  
733 ion for the monitoring of GL seems to be ideal since the sensitivity of the instrument is slightly impacted  
734 by RH. The GL detection limits using  $\text{NO}^+$  are in the ppb range, however, we evidence that slight pressure  
735 increase in the flow tube of the instrument can result to a vigorous increase to instrument sensitivity.  
736 Certainly, our research on the  $\text{NO}^+$  chemistry opens new pathways for GL quantification and detection in  
737 ambient air deploying soft ionization techniques, such as PTR-MS with  $\text{NO}^+$  ion, which are generally  
738 operated at higher pressures than SIFT-MS. Ultimately, our observations indicate that there is potential for  
739 sensitivity improvement for the SIFT-MS, and that it should be considered as a promising tool for the real-  
740 time monitoring of VOCs with low proton transfer affinity.

## 741 **5. List of abbreviations**

742 CC: Custom operational conditions of the SIFT-MS  
743  $C_F^{31}$ : calibration factor of formaldehyde at the mass peak 31  
744  $C_F^{59}$ : calibration factor of glyoxal at the mass peak 59  
745  $D$ : Internal diameter of the flow tube  
746  $DL$ : Detection limit  
747 DNPH: Dinitrophenylhydrazine  
748 DOAS: Differential optical absorption spectroscopy  
749 EAR: Electron attachment reaction  
750  $\epsilon$ : Distance for a full mixing of neutral molecules with the carrier gas in the flow tube  
751  $F_g$ : Carrier gas flow rate,  
752  $F_{\text{H}_2\text{O}}$ : Sample flow of pure water in the sample flow  
753  $F_{\text{total}}$ : Total flow rate inside the flow tube  
754  $F_{\text{VOC}}$ : Sample flow of pure VOC (formaldehyde or glyoxal) in the sample flow  
755 FM: Formaldehyde  
756  $\text{FM-H}^+$ : Protonated formaldehyde  
757 FTIR spectroscopy: Fourier transform infrared spectroscopy  
758 GL: Glyoxal  
759  $\text{GL-H}^+$ : Protonated glyoxal  
760 HPLC: High-performance liquid chromatography

761 IBBCEAS: incoherent broadband cavity-enhanced absorption spectrometer  
762  $k_B$ : Boltzmann constant  
763  $KE_{cm}$ : Mean kinetic energy between reactants  
764  $KE_{ion}$ : Kinetic energy of ions  
765  $L$ : Length of the flow tube  
766  $m$  and  $M$ : Masses of the carrier gas and the neutral reactant, respectively  
767  $M_{ion}$ : Mass of reactant ion  
768 MFC: Mass flow controller  
769  $N$ : Molecular density in the flow tube  
770 SC: Standard operational conditions of the SIFT-MS  
771 SIFT-MS: Selected ion flow tube mass spectrometer  
772 SOA: Secondary aerosol formation  
773  $P_g$ : Pressure in flow tube  
774 PMH: Protonated methyl hydroperoxide  
775 PTR-MS: Proton transfer mass spectrometry  
776 RH: Relative humidity  
777 TDLAS: Tunable-diode laser absorption spectrometer  
778  $t_r$ : Reaction time inside the flow tube of the SIFT-MS  
779  $T_g$ : Flow tube temperature  
780  $v_g$ : Carrier gas velocity  
781  $v_i$ : Ions flow velocity  
782  $[H_2O]$ :  $H_2O$  concentration in the flow tube  
783  $[VOC]$ : VOC (i.e. formaldehyde or glyoxal) concentration in the flow tube  
784  
785
