Abstract. A total of 99 dual soundings with Meisei iMS-100 radiosonde and Vaisala RS92 radiosondes were carried out at Aerological Observatory of the Japan Meteorological Agency, known as Tateno (36.06 °N, 140.13 °E, 25.2 m; WMO station number 47646), from September 2017 to January 2020. Global Climate Observing System (GCOS) Reference Upper-Air Network (GRUAN) data products (GDP) from both sets of radiosonde data for 57 flights were subsequently created using a documented processing program along with the provision of optimal estimates for measurement uncertainty. Differences in radiosonde performance were then quantified using these GDPs. For daytime observations, the iMS-100 temperature is around 0.5 K lower than RS92-GDP in the stratosphere with significant differences in the upper troposphere and lower stratosphere with RS92-GDP in consideration of combined uncertainties. For nighttime observations, the difference is around -0.1 K and data are mostly in agreement. For relative humidity (RH), iMS-100 is around 1 – 2 %RH higher in the troposphere and 1 %RH smaller in the stratosphere than RS92, but both GDPs are in agreement for most of the profile. The mean pressure difference is ≤ 0.1 hPa, the wind speed difference is from 0.15 m s^{-1} to 0.01 m s^{-1} , the wind direction difference $\leq 5^\circ$, and the root mean square of vector difference (RMSVD) for wind is $\leq 0.72 \text{ m s}^{-1}$.

1 Introduction

The Aerological Observatory of the Japan Meteorological Agency (JMA), called as 'Tateno' (location: 36.06° N, 140.13° E, 25.2m above mean sea level), was established in 1920 and has played a leading role in the operation of all JMA radiosonde stations. The Tateno station was chosen as a candidate site for the Global Climate Observation System (GCOS) Reference Upper-Air Network (GRUAN; Seidel et al., 2009; Bodeker et al., 2016) in 2009, and was certificated as a GRUAN site in 2018. The Vaisala RS92-SGP radiosonde (referred to here as RS92; Dirksen et al., 2014) was used for routine observation at Tateno site from December 2009. While RS92-SGP provides the data with high time resolution, that is, high altitude resolution, and highly reliable data, the lighter radiosonde was required to ensure safety in landfall into populated area. In response of this request, the Meisei RS-11G radiosonde (Kizu et al., 2018; Kobayashi et al., 2019; Hoshino et al., 2021), whose weight is 85 g,

was released in 2012, and started to be used at Tateno in July 2013. Following the release of the Meisei iMS-100 radiosonde (Kizu et al., 2018; Hoshino et al., 2021), smaller ($55 \times 53 \times 131 \text{ mm}^3$) and lighter (40 g) model, in 2014, it has been used since September 2017. The temperature and humidity sensor of iMS-100 are basically identical with RS-11G, but relative humidity sensor of iMS-100 has a dedicated thermometer and GPS module is different between the two. RS-11G has also been used in operation at Syowa station (Antarctica) since March 2018, while iMS-100 has been used at Minamitorishima and other JMA stations since 2017, as well as at stations of other meteorological service providers and numerous research institutes and universities. Syowa and Minamitorishima are currently candidate GRUAN sites.

Figure 1 gives an overview of the GRUAN data stream. Raw data output from the ground system (“dc3cb” or “mwx” files for RS92 radiosonde data and “JFMT files” for iMS-100 radiosonde data) and meta-data files are submitted to GRUAN LC for archiving, and GRUAN LC issues a data processing ticket file including the data and meta-data file names, IDs for the measurement and the product, the output file name, and other elements for processing. The data processing center (PC; Lindenberg for RS92 and Tateno for iMS-100 radiosondes), collects raw data, meta-data and ticket files from GRUAN LC and performs processing to create GDP files in NetCDF format. The output GDP file are submitted to GRUAN LC. The GDP files are distributed at National Centers for Environmental Information (NCEI; <ftp://ftp.ncdc.noaa.gov/pub/data/gruan/processing/level2/>) after quality checking.

The evaluation of GDP for RS-11G (RS-11G-GDP.1; Kizu et al., 2019) using GDP for RS92 (RS92-GDP.2; Sommer et al., 2012) in dual flight discussed in Kobayashi et al. (2019); the RS-11G-GDP.1 temperature is around -0.4 K lower than RS92-GDP.2 in daytime measurement in stratosphere, while nighttime measurements generally agree well. The RS-11G-GDP.1 RH was 2 %RH smaller than the RS92-GDP.2 for 90 %RH – 100 %RH, and the RS-11G GDP was around 5 %RH larger than the RS92-GDP.2 at values lower than 50 %RH, so RH difference exceeds 2 %RH between 500 and 150 hPa in both daytime and nighttime data. The pressure difference was 0.5 hPa in the troposphere, and the geopotential height difference was around 10 – 20 m in the stratosphere.

Although the sensors of iMS-100 are almost identical with RS-11G, the data processing algorithms have some distinct updates for iMS-100-GDP, such as the correction of hysteresis effect of the RH sensor and the correction of geoid model used in GPS module.

In this paper, Sect. 2 describes the instrumentation used and GRUAN data products (including a brief description of data processing) for iMS-100 and RS92. Sect. 3 outlines dual soundings and Sect. 4 describes the comparison analysis method. The comparison results are given in Sect. 5 and Sect. 6 discusses outcomes from a dual flight of iMS-100 and a chilled-mirror hygrometer, Meisei SKYDEW (Sugidachi, 2019). Sect. 7 summarizes the findings. See Appendix A for a summary of related abbreviations.

2 Instrumentation

2.1 Sensor material and specifications

Table 1 shows the specifications of iMS-100 and RS92. More detailed specification for each model are described in Vaisala Oyj. (2013), Dirksen et al. (2014), Meisei Electric Co., Ltd. (2020) and Hoshino et al. (2021). The ground system for iMS-100 is Meisei MGPS2, ant that for RS92 was Vaisala DigiCORA III and was replaced to Vaisala MW41 in September 2019.

2.2 GRUAN data processing for iMS-100

Figure 2 gives an overview of GRUAN data processing for iMS-100. The ticket file (*.gpt) contains the raw data file name (*JFMT.DAT) and meta data file name (*.gmd), the individual identification number for observation in the GRUAN data archive, and the file name for processed data. GMDB is the abbreviation for the “GRUAN Meta DataBase”, which contains information on payload equipments (such as radiosondes, balloons, parachutes, unwinders, rigs). In pre-processing, the lag of data acquisition timing in the processor between temperature / humidity and GPS related data (time and positioning) are adjusted, relative humidity is re-calibrated with additional ground check data (at the 0 %RH and 100 %RH conditions, where available), geometric altitude is corrected with the finer geoid model (see Section 2.2.3), and initial data for ascending are extracted by identifying the start and end of ascent. Usually, the end of ascent is when the radiosonde reached its maximum altitude (thus, the start of descent or the end of radiosonde signals), but ascent data are truncated to ensure its reliability in the event of missing temperature values (i.e., gaps in observation), over a period of 180 seconds or more. Initial data are processed at each step as outlined below to produce the final data. Derived data related to humidity (such as partial water vapor pressure, frost point temperature, and precipitable water vapor) are also calculated. To support climate record quality, GDP data include their uncertainty at each measurement point. The processed data are stored in NetCDF format, and the GDP for iMS-100 radiosonde data is noted as “IMS-100-GDP”. The processing algorithm is documented in Hoshino et al. (2021) for detail, so outline and difference from RS-11G-GDP.1 (Kizu et al., 2018; Kobayashi et al., 2019) is described in this paper.

2.2.1 Temperature

An overview of temperature calculation is given in Fig. 3. T_0 , U_0 , P_{surf} and H_{fin} are uncorrected temperature values, uncorrected relative humidity values, surface pressure and corrected geopotential height (see Sect.2.2.3). The process for calculation of provisional pressure, heat spike filtering and calculation of amount of radiation heating is same as the process for RS-11G-GDP.1 (Kizu et al., 2018; Kobayashi et al., 2019). As the thermistor is not completely spherical, there is a small dependence on the angle to sunlight. Accordingly, the Kaiser filtering of this orientation effect are applied to derive the final temperature value, T_{fin} , in algorithm for IMS-100-GDP.

The uncertainty budget for temperature is shown in Table 2.

2.2.2 Relative humidity (RH)

An overview of RH calculation is given in Fig. 4. T_{hum} and L are temperature of humidity sensor and length of unwinder or string, respectively. For the time-lag correction, which corrects the effect of the time constant delay, the response time coefficients are constant for the RS-11G-GDP.1, but are dependent on whether the RH sensor is absorbing or desorbing water vapor molecules (i.e., whether RH is increasing or decreasing, respectively) for the IMS-100-GDP. The trend of RH change is estimated from the slope of the tangent of U_0 using the method proposed by Savitzky and Golay (1964) using the U_0 values within ± 5 seconds values. The response time, τ_{hum} , is calculated from obtained trend value together with the temperature of the RH sensor, T_{hum} . For the contamination correction to filter out spike-like variations in high frequency components, an infinite impulse response (IIR) filter process is newly added to IMS-100-GDP. For hysteresis errors (i.e., the “slow-regime” in Dupont et al., 2020), they are not corrected but only considered as an uncertainty component in the RS-11G-GDP.1. For the IMS-100-GDP, the slow part ratio and its response times for absorption and for desorption are assumed as 3%, 300 seconds and 12000 seconds, respectively. The RH of the slow part, U_{delay} , and the hysteresis corrected RH, U_3 are derived via iterative calculation with:

$$U_{delay}(t) = \frac{U_2(t) + (1 - \alpha)\tau_{hys}U_{delay}(t-1)}{(1 - \alpha)\tau_{hys} + 1} \quad (1)$$

$$U_3(t) = (1 + \tau_{hys})U_{delay}(t) - \tau_{hys}U_{delay}(t-1) \quad (2)$$

where α is the slow part ratio, τ_{hys} is the response time for the slow part and U_3 is the corrected RH.

The process of temperature-humidity-dependence (TUD) correction is same as RS-11G-GDP.1, but the coefficients are redetermined via additional chamber experiments and flight comparison results with Cryogenic Frostpoint Hygrometer (Vömel et al., 2007, 2016). The T_s/T_a correction is same as RS-11G-GDP.1.

U_{fin} is the final value of RH. The uncertainty budget for RH is shown in Table 3. If $U_{fin} + u(U)$ is less than 0 %RH, these are treated as missing values (NaN) in output.

2.2.3 Geopotential height

An overview of geopotential height calculation flow is given in Fig. 5. The raw geometric altitude, Z_0 , is calculated from ellipsoidal height derived with GPS signal and the internal geoid model of iMS-100, but the grid resolution of the internal geoid model with $10^\circ \times 10^\circ$ is too coarse and the interpolated geoid height may differ from the actual geoid height by 20 m or more in some regions (Northwest Pacific basin including the sea near Japan is the one of the region with large differences. see Fig. 6). Accordingly, geometric altitude is recalculated using the geoid model (Pavlis et al., 2012) with a finer grid ($5' \times 5'$) to derive Z_1 . The results of the verification using the GNSS simulator show that Z_0 was found to have a $\simeq 1$ s delay with respect to the assumed altitude. Z_1 is corrected for this delay to obtain Z_2 . Also this verification shows that there is a delay of several seconds in measurements just after launch. This delay is attributed to Kalman filtering in positioning by the GPS module and the difference becomes negligible several seconds after launch. Accordingly, the altitude in this “transition”

period is interpolated with the known release altitude and the observed altitude at the end of transition to obtain Z_3 , which is then applied with a moving average to determine the final geometric altitude, Z_{fin} . The geopotential height, H_{fin} is calculated using:

$$H_{fin} = \frac{g_\phi}{g_0} \frac{R \times Z_{fin}}{R + Z_{fin}} \quad (3)$$

where R is the radius of the earth (6378136.0 m), g_0 is standard gravity acceleration (9.80665 m s^{-2}), and g_ϕ is gravity acceleration at the observation latitude.

2.2.4 Pressure

The iMS-100 radiosonde is not equipped with a pressure sensor. Pressure is calculated from the geopotential height, H_{fin} , temperature, T_{fin} , and RH, U_{fin} , using the hydrostatic equation.

2.2.5 Wind

An overview of wind calculation flow is given in Fig. 7. While the initial (unsmoothed) wind speed and direction are derived from GPS Doppler shift for RS-11G-GDP.1, the initial wind speed w_{speed_0} and direction w_{dir_0} are derived as motion vectors from GPS positioning, thereby supporting longitude (λ) and latitude (ϕ) for IMS-100-GDP. The great-circular distance, d , and direction, θ , between the position at t_i (λ_i, ϕ_i) and t_{i+1} ($\lambda_{i+1}, \phi_{i+1}$) are given with spherical trigonometry by:

$$d = R \arccos(\sin \phi_i \sin \phi_{i+1} + \cos \lambda_i \cos \lambda_{i+1} \cos(\lambda_{i+1} - \lambda_i)) \quad (4)$$

$$\theta = 90 - \arctan\left(\frac{\cos \lambda_i \tan \lambda_{i+1} - \sin \phi_i \cos(\lambda_{i+1} - \lambda_i)}{\sin(\lambda_{i+1} - \lambda_i)}\right) \quad (5)$$

where R is the radius of the earth, and d and θ are rendered as w_{speed_0} and w_{dir_0} , respectively. Smoothing process is same as RS-11G-GDP.1. The wind vectors with a wind speed of w_{speed_0} and a wind direction of w_{dir_0} are decomposed to the zonal and meridional wind components, u_0 and v_0 . Each components are smoothed by a low-pass filter using Kaiser window with a cut-off frequency of $1/T_{pend}$ to derive the final wind components, u_{fin} and v_{fin} , respectively. The final wind components are synthesized to wind speed, $w_{speed_{fin}}$, and direction, $w_{dir_{fin}}$.

2.3 GRUAN data processing for RS92

As data processing for RS92-GDP version 2 has detailed by Dirksen et al. (2014), only a brief description is provided here.

Raw temperature data are corrected for solar radiation and heat spike errors. Solar radiation errors relate to overall direct and scattered solar irradiance, ambient pressure, and ventilation, and are estimated at the GRUAN Lead Centre from a radiative transfer model that takes into account the solar elevation angle at the time of monitoring. Vaisala radiation error correction data are also available in table form. GRUAN data processing for RS92 involves application of the average of the two, as it remains unclear which the correction model is more appropriate. Heat spike errors are removed via a low-pass digital filter with a cut-off frequency of 0.1 Hz.

RS92 RH sensors have a temperature-dependent dry bias. GRUAN data processing corrects for this based on multiplication with an empirical correction factor before other forms of the correction are applied. Raw RH data are corrected for radiation dry bias, sensor time lag, and temperature-dependence errors. Radiation dry bias is caused by solar heating on the RH sensors, and the same approach as for the temperature sensor is used to estimate the amount of the correction required. The RH sensor response slows at low temperatures, and time lag becomes significant below -40°C . This is corrected based on the relationship between a time constant and temperature using a low-pass filter in the GRUAN data product for RS92 (Dirksen et al., 2014).

The RS92 used at Tateno has a pressure sensor and a GPS receiver, both of which can be used to calculate geopotential height. Pressure measurement data are used to derive geopotential height in the lower part of the profile where the signal-to-noise performance of the pressure sensor is sufficiently good, and measurements from the GPS sensor are used in the upper part of the profile. The altitude of the switch is typically between 9 and 17 km (Sommer et al., 2016). The pressure sensor is recalibrated against the reference value from a station barometer during the ground check, and calculation is performed to determine the correction factor for application to the entire pressure profile during sounding (Dirksen et al., 2014). U and V data are retrieved from the Doppler shift in the GPS carrier signal, and noise is removed using a low-pass digital filter. The smoothed data are converted into wind speed and direction values (Dirksen et al., 2014). Uncertainties of each parameters for RS92 are described in Dirksen et al. (2014).

While the authors used version 2 of the RS92 GDP, version 3 is supposed to be available in the near future (Sommer et al., 2016) and it would be useful to redo the analysis with it.

3 Method used for dual sounding

Dual soundings with iMS-100 and RS92 for intercomparison have been conducted from September 2017 to January 2020 at 00 UTC (09 LT; daytime) or 12 UTC (21 LT; nighttime) once a week, except for wind conditions in which a payload may fall to populated areas around metropolitan Tokyo (in general, from July to mid-September with relatively weak westerly winds in the upper troposphere due to northward displacement of the subtropical jet stream and the stratospheric easterly winds). There were 99 flights during this period (52 daytime, 47 nighttime).

Payload configuration for dual sounding is shown in Figure 8. A 1200 g balloon was used for all dual sounding. The iMS-100 and RS92 radiosondes were hung on both ends of a 0.9 – 1 m plastic cardboard or bamboo rod, and this rig was covered with aluminum tape to reduce the effects of radiation based on the proposal of Rohden et al. (2016).

4 Method for comparison

GDPs data both for iMS-100 and RS92 are collected at 1 s intervals. Temporally simultaneous measurements were compared using the statistical approach adopted by Kobayashi et al. (2019) to evaluate differences in the data products.

170 4.1 Screening with quality assessment

Prior to statistical comparison, irregular or inappropriate data for comparison should be excluded. RS92-GDP, processed by the GRUAN LC, has been checked with a quality assessment algorithm by the GRUAN LC. As the algorithm for IMS-100-GDP in this study is designed with reference to that for RS92-GDP, the algorithm for RS92-GDP is described before that for IMS-100-GDP.

175 For RS92, the first quality screening is based on differences between radiosonde and references sensor in the ground check. The thresholds are 1.5 hPa for pressure, 1.0 K for temperature and 1.5 %RH for RH (Sommer, 2013). Data with larger difference are not used. The second screening is based on the uncertainty amounts (Sommer, 2013). The thresholds for uncertainty, $u_{\text{spec}}^{\text{RS92}}$, are calculated as:

$$u_{\text{limit}}^{\text{RS92}}(T) = 0.5 \quad (6)$$

180

$$u_{\text{limit}}^{\text{RS92}}(U) = 0.025U + 2.5 \quad (7)$$

$$u_{\text{limit}}^{\text{RS92}}(P) = 0.0004P + 0.6. \quad (8)$$

When uncertainties for 95 % or more of data in the entire profile are within u_{limit} , the profile is approved and otherwise labeled
 185 as “Checked”.

For RH, however, the criterion in Eq.7 is too strict, because it is lower than actual typical values especially for 50 %RH – 70 %RH. Thus, the original formula as per Eq.9 is used here.

$$u_{\text{limit}}^{\text{RS92}}(U) = -0.000578U^2 + 0.0925U + 1.457 \quad (9)$$

However, the lower limit of $u_{\text{limit}}^{\text{RS92}}(U)$ is set to 2.5 %RH.

190 For iMS-100, the first screening is performed at ground check under room conditions in preparation. The thresholds of differences from reference sensors for temperature and RH are ± 0.5 °C and 7 %RH, respectively. Sensors values exceeding these criteria are not used for observation.

The second screening checks contamination or changes in the RH sensor specifications associated with icing. In some soundings with iMS-100, abnormal RH profiles such as the one shown in Figure 9 (for 12UTC on 22 September, 2017) are
 195 sometimes observed. In this case, RH does not decrease in the stratosphere, probably due to contamination and changes in the RH sensor specifications related to icing or freezing during passage through supercooled droplet clouds. As checking to determine whether the radiosonde has passed through such clouds is impractical from the RH profile, ice saturated regions (pink shaded layer in Fig. 9(b)) are considered. However, as not all data associated with ice-saturated clouds passage are contaminated, the length of the ice-supersaturated region (ISSR) and the RH and water vapor mixing ratio at the top of the

upper troposphere and lower stratosphere (UTLS) are used for screening in this study. ISSR determination is based on saturated water vapor for liquid water and ice calculated using Hyland and Wexler equation (Hyland and Wexler, 1983). The observed RH is the ratio of water vapor pressure to e_{s_liq} , and is limited to $U_{s_ice} = e_{sat_ice}/e_{sat_liq}$ for the ice phase. Accordingly, ISSR is the layer in which $U > U_{sat_ice}$. In this study, two adjacent ISSRs with intervals of ≤ 60 seconds or where the minimum of $U - U_{sat_ice}$ is more than -10 %RH (i.e., with no dry layer in the interval) are merged and treated as a single ISSR.

For screening of ice-contaminated profiles, the probability of icing, Pr_{ice} , is derived via logistic regression using 452 training routine observations with a single payload taken from April to November 2018. Pr_{ice} is calculated with:

$$Pr_{ice} = \frac{1}{1 + \exp(-22.38 + 7.18 \times 10^{-3} T_{ISSR_max} + 0.517 U_{ST1} + 0.977 U_{ST2} + 0.105 W_{ST1} + 0.427 W_{ST2})} \quad (10)$$

where ST1 and ST2 are data points at 2000 m and 4000 m above the tropopause in geopotential height, U [%RH] is RH, W [ppmv] is the water vapor volume mixing ratio, and T_{ISSR_max} is the pass-through period of maximum ISSR. In this study, profiles with $Pr_{ice} > 0.5$ are considered as potentially ice-contaminated data and excluded in the RH analysis below.

The third screening is based on uncertainties for temperature, RH and pressure as with RS92. The thresholds for these values are derived from Eqs.11 – 13, respectively. Coefficients are determined empirically.

$$u_{limit}^{iMS}(T) = 0.7 \quad (11)$$

$$u_{limit}^{iMS}(U) = -8.246 \times 10^{-6} U^3 + 2.046 \times 10^{-3} U^2 - 5.114 \times 10^{-2} U + 3.018 \quad (12)$$

$$u_{limit}^{iMS}(P) = 1.609 \times 10^{-9} P^3 - 4.589 \times 10^{-6} P^2 + 4.120 \times 10^{-3} P + 3.810 \times 10^{-2}. \quad (13)$$

The ratio criterion is set to 90 %. It should be noted that this quality assessment and screening are only for this study only, and are not authorized as standard for GDPs. The standard method for quality assessment of GDPs is currently under discussion by the quality task force in the GRUAN community.

Dual sounding data for 57 flights (27 daytime and 30 nighttime; Table 4) are used for comparison. The major factors associated with data screening is illustrated in Fig. 10 for each season and daytime/nighttime. Seasonal profiles for temperature, RH, and wind speed are shown in Figs. 11 – 13, with seasonal classification (MA, MJJ, ASON and DJF) described in Sect. 4.4.

4.2 Timestamp adjustment

Radiosonde observation have timestamps from the relevant sounding system (for iMS-100, this is based on received GPS clock data). As there may be minor discrepancies in balloon-launch time stamps, these data are time-adjusted using the temperature profile. In this study, shift registration in functional data (Ramsay and Silverman, 2005) is used for adjustment using the temperature data from between 5 and 20 minutes of the launch time of RS92. Temperature data for each radiosonde, $T_i(t)$, in

this period are converted to functional data, $x_i(t)$. Shift values, δ_i , are calculated to minimize the least squares of $x_i(t + \delta_i)$,

230 i.e.,

$$\text{REGSEE} = \sum_i \int [x_i(t + \delta_i) - \hat{\mu}(t)]^2 ds, \quad (14)$$

where $\hat{\mu}(t)$ is the mean function of $x_i(t)$. For calculation of δ_i , the scikit-fda package (Carreño, 2020) for python is used and actual adjustment values (seconds to shift) are derived with

$$\delta t = \delta t_{\text{RS92}} - \delta t_{\text{iMS}}. \quad (15)$$

235 When $\delta t > 0$, timestamps for iMS-100 are shifted backward by $|\delta t|$, and vice versa.

4.3 Data pretreatment

Profiles with $> 90\%$ of abnormal data points as whole profile are excluded via screening as described in Section 4.1, while abnormal data are also seen at individual points in overall normal profiles (e.g, superadiabatic lapse rates). Such data points should be excluded from statistical comparison. In this study, superadiabatic lapse rate layers and abnormal wind data immediately
 240 before balloon burst are pre-treated for masking.

4.4 Statistical comparison

After timestamp adjustment, per-second differences between iMS-100 and RS92 measurements were calculated and differences were allocated to the 13 pressure layers based on RS92 pressure data (P_i^{RS92} , where i indicates the time step) based on Kobayashi et al. (2012, 2019). The bins for the 13 layers are listed in Table 5.

245 $A_{i,j}^{\text{iMS}}$ and $A_{i,j}^{\text{RS92}}$ are values at the time step i for iMS-100 and RS92 in the j th dual sounding data set ($j = 1, \dots, M$; M in the number of data sets), respectively. The differences between the two radiosonde types, $\Delta A_{i,j} = A_{i,j}^{\text{iMS}} - A_{i,j}^{\text{RS92}}$, are averaged for each pressure layer with:

$$\overline{\Delta A_{k,j}} = \frac{\sum_{i=i_{b,j}}^{i_{t,j}} \Delta A_{i,j}}{N_{k,j}} \quad (16)$$

250 where k is the layer number ($k = 1, \dots, 13$), $N_{k,j}$ is the number of data points in the layer k , $i_{b,j}$ and $i_{t,j}$ are the bottom and top time step at the j th data set, respectively. The ensemble mean of the difference in each pressure layer is calculated as

$$\langle \Delta A_k \rangle = \frac{\sum \overline{\Delta A_{k,j}}}{M}. \quad (17)$$

The standard deviation of the ensemble mean difference for individual pressure layers is

$$\sigma(A_k) = \sqrt{\frac{\sum_{j=1}^M (\overline{\Delta A_{k,j}} - \langle \Delta A_k \rangle)^2}{M}} \quad (18)$$

255 Comparison of wind data is performed with the indices of the wind speed bias, $BIAS$, and the root mean square error the vector difference, $RMSVD$ (CGMS, 2003) for each pressure layer at each dual sounding. $BIAS$, MVD and $RMSVD$ are

calculated as

$$BIAS_{k,j} = \sum \frac{1}{N} (V_{i,j}^{iMS} - V_{i,j}^{RS92}) \quad (19)$$

$$VD_{i,j} = \sqrt{(u_{i,j}^{iMS} - u_{i,j}^{RS92})^2 + (v_{i,j}^{iMS} - v_{i,j}^{RS92})^2} \quad (20)$$

260

$$MVD_{k,j} = \frac{1}{N_{k,j}} \sum VD_{i,j} \quad (21)$$

$$SD_{k,j} = \sqrt{\frac{1}{N_{k,j}} \sum (VD_{i,j} - MVD_{k,j})^2} \quad (22)$$

$$265 \quad RMSVD_{k,j} = \sqrt{MVD_{k,j}^2 + SD_{k,j}^2}, \quad (23)$$

where V , u , and v is the wind speed, zonal wind speed and meridional wind speed, respectively. The mean difference of wind direction (Szantai et al., 2007), $\overline{\Delta DIR}$, is also used.

$$\overline{\Delta DIR}_{k,j} = \frac{180}{N\pi} \sum \arccos\left(\frac{\mathbf{V}_{i,j}^{iMS} \cdot \mathbf{V}_{i,j}^{RS92}}{V_{i,j}^{iMS} V_{i,j}^{RS92}}\right) \quad (24)$$

where \mathbf{V} is the wind vector. The ensemble mean of these parameters is then calculated as for Eq.17.

270 Statistics for each pressure layer are calculated for daytime, nighttime, and individual seasons. Due to the safety consideration described in Section 3, few dual soundings are performed in July and August, and the weather conditions for August flights are categorized as for autumn rather than summer. Thus, in this study, the flights from August to November are categorized as those for autumn (here, ASON), and previous studies for seasonal comparison campaigns of radiosondes at Tateno (Kobayashi, 2015; Kobayashi and Hoshino, 2018), the “summer” covered the period from May to June, flights in March and
 275 April are categorized with spring (here, MA), those from May to July are categorized with summer (MJJ), and those from December to February are categorized with winter (DJF).

4.5 Method for verification of consistency with uncertainties

Uncertainty estimation for RS92 and iMS-100 GDPs are described in Dirksen et al. (2014) and Hoshino et al. (2021), respectively. The statistical consistency check considering uncertainties is performed based on Immler et al. (2010) and Sect. 5 in
 280 Kobayashi et al. (2019).

5 Results

5.1 Temperature

Figure 14 shows the ensemble mean (lines) and standard deviation (error bar) of temperature differences, for (a) daytime and nighttime for all season, (b) seasonal daytime, and (c) seasonal nighttime. In the stratosphere, IMS-100-GDP value are around -0.5 K lower than RS92-GDP for the daytime. For the nighttime, differences are around -0.1 K below the 10 hPa level. Seasonal differences are small.

Figure 15 shows the percentage of consistency rank in each layer for (a) daytime and (b) nighttime. The percentages of significantly different or inconsistent data exceed 50 % in L07 (100 – 70 hPa), 30 % in L08 (70 – 50 hPa) and L09 (50 – 30 hPa) for daytime observation (Fig 15(a)). However, 80 % of data are in agreement for nighttime comparison (Fig 15(b)). Fig. 16 shows the distribution of temperature at L09 (50 – 30 hPa), L07 (100 – 70 hPa), L05 (200 – 150 hPa) and L03 (500 – 300 hPa). Fig. 16 (a1), (a2) and (a3) show differences in L09, L07 and L05 in general are normally distributed with a sufficient sample size. Accordingly, daytime temperature differences in the stratosphere and the upper troposphere are associated with systematic effects. These differences (especially between 100 and 30 hPa) are attributed to difference in the solar radiation correction models. However, some samples show significant differences ($> \pm 0.5\text{K}$) even in the troposphere or for nighttime soundings (not shown), which are associated either with issues during flights or calibration problems.

Kobayashi et al. (2019) found that the RS-11G-GDP.1 temperature data are about -0.4 K lower than RS92-GDP.2 data for daytime observations in the stratosphere. This means that the IMS-100-GDP temperatures show larger differences from RS92-GDP.2 than RS-11G-GDP.1 temperatures do. On the other hand, the ratio of data that are evaluated as “consistent” or “in agreement” with RS92-GDP.2 temperatures is greater for IMS-100-GDP than RS-11G-GDP.1. This is probably due to the newly included correction for the sensor orientation effects in IMS-100-GDP. Further investigation is needed using intercomparison results between RS-11G and iMS-100 radiosondes.

The GDPs for Vaisala RS41 radiosonde (Rohden et al., 2021) and for Meteomodem M10 radiosonde (Dupont et al., 2020) and an upgraded of GDP for RS92 are currently under development. Also, the WMO 2022 Upper-Air Instrument Intercomparison Campaign (CIMO Task Team on Upper-air Intercomparison, 2020) is being planned in 2022. These upcoming GDPs and the results from the WMO intercomparison campaign are expected to be useful for further evaluation of IMS-100-GDP.

5.2 Relative humidity

Figure 17 shows the ensemble mean (lines) and standard deviation (error bars) of RH differences, for (a) daytime and nighttime for all seasons, (b) seasonal daytime and (c) seasonal nighttime. This shows that iMS-100 RH is around 1 – 2 %RH larger than RS92 RH around the tropopause and -1 %RH smaller in the stratosphere. Unlike temperature, differences between daytime and nighttime soundings are small but seasonal variations are large in the upper troposphere and the lower stratosphere. Figure 18 shows the ensemble mean of RH differences for six RH ranks. In the lower troposphere (below 500 hPa level), differences are around 1 %RH and exhibit limited correspondence with RH values. In the middle and upper troposphere (500 – 100 hPa), the difference increases with altitude for 10 – 90 %RH. For data with $\text{RH} \leq 10\%$, the difference is within $\pm 1\%$ RH for

all layers; iMS-100 RH is wetter in the troposphere and drier in the stratosphere. For data with $RH > 90\%$, the dataset is
 315 limited above 300 hPa and drier than RS92 figures for the middle troposphere (500 – 300 hPa).

Kobayashi et al. (2019) found that RS-11G-GDP.1 RH data shows about 2 %RH dry tendencies for conditions with $RH > 90\%$ and about 1 %RH wet tendencies for conditions with $RH \leq 10\%$. These different behaviors between of RS-11G-GDP.1 and IMS-100-GDP with respect to RS92-GDP.2 in very dry and very wet conditions make the ΔU profiles different in the lower troposphere (below 700 hPa) and in the stratosphere (above 50 hPa) (See Fig.17 in this study and Fig. 11 of
 320 Kobayashi et al., 2019). In particular, the 1 %RH wet bias of RS-11G-GDP.1 with respect to RS92-GDP.2 and the dry bias of IMS-100-GDP in the stratosphere are a notable differences. The major reason of these differences would be the including of hysteresis correction in the IMS-100-GDP. The ratio of data that are evaluated as “consistent” or “in agreement” with RS92-GDP.2 RH data in the troposphere is greater for RS-11G-GDP.1. This is also due to the inclusion of hysteresis correction in the IMS-100-GDP, because the RH profiles in the troposphere often show rapid changes as shown in Fig.12. Further investigation
 325 on the differences between RS-11G and iMS-100 results by making intercomparison flights is a future task.

Figure 19 shows the percentage of consistency rank in each layer for (a) daytime and (b) nighttime. In the troposphere and lower stratosphere (L1 – L7, below 70 hPa level), around 10 – 20 % of data are significantly different or inconsistent. The RH profiles for individual flights (Fig. 12) show that RH often shows rapid changes. For the flight at 12 UTC (21 LT) on 19 April, 2019 (Fig. 20), iMS-100 shows a slow tendency in relation to the rapid decrease in RH (e.g., at about 330 hPa), compared to
 330 RS92. This difference in response to rapid changes is considered a reason for the inconsistency of 1-second RH values between the two radiosondes. In the stratosphere (L8 – L13, above the 70 hPa level), RH data from iMS-100 and RS92 seem to be almost in agreement.

5.3 Pressure

Figure 21 shows the ensemble mean (lines) and standard deviation (error bars) of pressure differences for (a) daytime and
 335 nighttime for all season, (b) seasonal daytime, and (c) seasonal nighttime. The absolute value of ensemble mean difference is less than 0.4 hPa, but there are cases with large differences in the lower troposphere (below 700 hPa level). This may be attributable to the effect of pressure differences between RS92 pressure sensor and the barometer used for surface observation. The pressure of IMS-100, with no pressure sensor, is derived from recursive calculation via the hydrostatic equation, so that the surface pressure is equal to that observed using ground-based barometer. Meanwhile, RS92 involves independent pressure
 340 sensor usage, meaning that near-surface pressure may differ between GDPs. A histogram of RS92 GDP surface pressure error for ground-based barometer content (Fig. 22) shows that the difference is not normally distributed around zero. RS92 pressure tends to be slightly higher than ground-based barometer content with a difference median of 0.33 hPa, which is greater than barometer uncertainty (0.06 hPa). The effect of this difference decreases with height, but is more noticeable near the ground.

For RS-11G-GDP.1, the pressure is about -0.5 hPa lower for daytime observation in middle of troposphere, but the difference
 345 between IMS-100-GDP and RS92-GDP.2 is little in those layer statistically. At this time, the reason of this difference of pressure is not clear.

5.4 Geopotential height

Figure 23 shows the ensemble mean (lines) and standard deviation (error bars) of geopotential height differences, for (a) daytime and nighttime for all seasons, (b) seasonal daytime, and (c) seasonal nighttime. The difference in geopotential height is around 2 – 3 m in the lower and middle troposphere, but becomes larger with altitude above 100 hPa level and become about 10 m at 20 hPa. This tendency is attributed to difference in geoid height as referenced by IMS-100-GDP and RS92-GDP. As described in Section 2.2.3, the grid size of the original geoid model used for the iMS-100 GPS module is $10^\circ \times 10^\circ$, which is replaced with a $5' \times 5'$ model for geometric height calculation in GDP processing. The grid size difference causes significant discrepancy in geoid and geometric height especially for the northwest Pacific basin around Japan. Figures 24(a) and (b) show geoid height for IMS-100-GDP and original iMS-100, respectively, 24(c) shows differences in geoid height and typical radiosonde track for each season (green for MA, red for MJJ, orange for ASON and blue for DJF), and 24(d) shows geoid correction values for typical seasonal tracks. The difference increases with height for all seasons. The grid size of the geoid model for RS92-GDP is unknown but as geometric height values are used without modification, geoid model differences may have caused geopotential height differences.

The geopotential height difference between IMS-100-GDP and RS92-GDP.2 seems to have no noticeable different with that between RS-11G-GDP.1 and RS92-GDP.2, although the RS-11G-GDP.1 is not corrected geoid model. This implies that the geoid model used in RS-11G has enough resolution for GDP.

5.5 Wind

Figure 25 compares wind for (a) wind speed bias, (b) RMSVD and (c) wind direction difference for all seasons. The difference is small enough with BIAS from -0.15 to $+0.01 \text{ m s}^{-1}$, RMSVD is less than 0.72 m s^{-1} except for L13 (above 10 hPa), and $\overline{\Delta DIR}$ is less than 5° .

6 Comparison with a frost-point hygrometer

Due to the technical limitations of the RH sensors mounted on operational radiosondes in low temperature and dry conditions, GRUAN requires comparisons of RH data with values from reference instruments. At Tateno, the comparison flights with radiosondes and cryogenic frostpoint hygrometer (CFH; Vömel et al., 2007, 2016) have been conducted twice a year since 2015. However, since the R-23 (HFC-23) liquid cryogen material used to cool the mirror of CFH was regulated under the Montreal Protocol, a new frost-point hygrometer, Meisei SKYDEW (Sugidachi, 2019) was adopted in 2020 for cooling the mirror with a Peltier element instead. Figure 26 shows results from the comparison conducted at 06 UTC (15 LT) on 21 October 2020. Although the difference in RH are significant (with ΔU exceeding the extended uncertainty ($k = 2$)) in the limited part around the tropopause (17041.6 m, 92.2 hPa and -73.4°C), Fig. 26(c) shows that the RH of IMS-100-GDP and SKYDEW are generally in agreement for the entire profile and consistent for most of the troposphere.

7 Summary

To characterize GDPs for iMS-100 and RS92, data from dual soundings conducted at Tateno from September 2017 to January 2020 are analyzed in this study. The iMS-100 temperature is around 0.5 K lower than RS92-GDP for daytime observation in the stratosphere and over 50 % of data from between 100 and 70 hPa and over 30 % from between 70 hPa and 30 hPa shows significant differences from RS92-GDP. For nighttime observation, the difference is around -0.1 K with over 80 % of data showing in agreement both in the troposphere and the stratosphere. The difference for daytime measurements in the stratosphere is attributed to the correction procedures for solar radiation heating and differences in sensor characteristics.

The iMS-100 RH is around 1 – 2 %RH higher in the troposphere and 1 %RH lower in the stratosphere than RS92, but both GDPs are generally in agreement in the troposphere and stratosphere. The difference may be larger in places where rapid RH change occurs. A comparison flight with the SKYDEW, frost-point hygrometer, shows that iMS-100 RH agrees well with SKYDEW both in the troposphere and stratosphere.

While there are some cases with significant differences are observed in the lower troposphere (≥ 700 hPa), the mean pressure difference is less than 0.4 hPa. The difference in geopotential height is around 2 – 3 m in the lower and middle troposphere, but increases with altitude above 100 hPa level, from 10 m at 20 hPa. This relationship between height and related differences may stem from differences in the geoid model used for the two GDPs. In wind comparison, BIAS is between -0.15 and +0.01 m s^{-1} , RMSVD is lower than 0.72 m s^{-1} except for above 10 hPa, and $\overline{\Delta DIR}$ is smaller than 5 °, showing good GDP correspondence.

The modified data processing described in Sect. 2.2.1 – 2.2.2 will be implemented to processing for RS-11G to create new version of RS-11G-GDP, which will be evaluated with intercomparison campaigns written in Kobayashi et al. (2019) (RS-11G and RS92) and Kobayashi and Hoshino (2018) (iMS-100 and RS-11G). Further direct comparison between RS-11G-GDP and IMS-100-GDP will be discussed in the future study.

This study involved evaluation of the characteristics of IMS-100-GDP values with RS92-GDP as a reference, as the latter is certified as a GRUAN data product. GRUAN certification for iMS-100 is underway, and ongoing analysis of GDP data is considered important for the provision of high-quality products to the climate research/monitoring community. Since February 2020, regular dual soundings of iMS-100 and Vaisala RS41 (the successor to RS92), have been ongoing. RS41-GDP is under development (Rohden et al., 2021) and the comparison results will be published when sufficient IMS-100-GDP and RS41-GDP data available. In addition, IMS-100-GDP, RS41-GDP and M10-GDP (Dupont et al., 2020) are also candidates of the reference data in the WMO 2022 Upper-Air Instrument Intercomparison Campaign (CIMO Task Team on Upper-air Intercomparison, 2020) which will be conducted in 2022. These data will support further evaluation and improvement of IMS-100-GDP.

Data availability. The GRUAN data products for RS92-GDP.2 are available from <https://doi.org/10.5676/GRUAN/RS92-GDP.2> (Sommer et al., 2012). Further data are available upon request.

Author contributions. SH, TS, KS, and EK developed the iMS-100 GRUAN data product, with SH and EK performing data analysis and creating the figures. All authors provided ideas and contributed to interpretation of the results. The first draft of the paper was written by SH, with all authors contributing to improvement of the paper.

Acknowledgements. The authors are grateful to the Aerological Observatory, the Observation Division of JMA's Atmosphere and Ocean
 430 Department, and Meisei Electric for their support and helpful advice. Thanks are also due to GRUAN Lead Centre staff for their support.

(c) As per (b), but for nighttime data

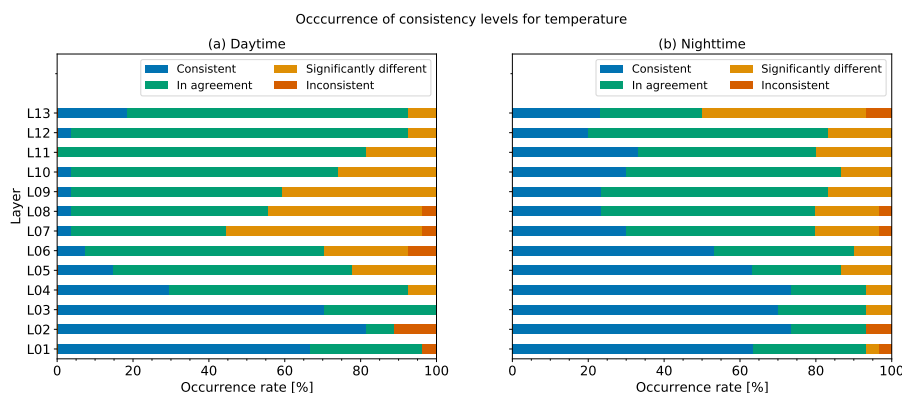

Figure 15. Temperature consistency rank for individual pressure layers

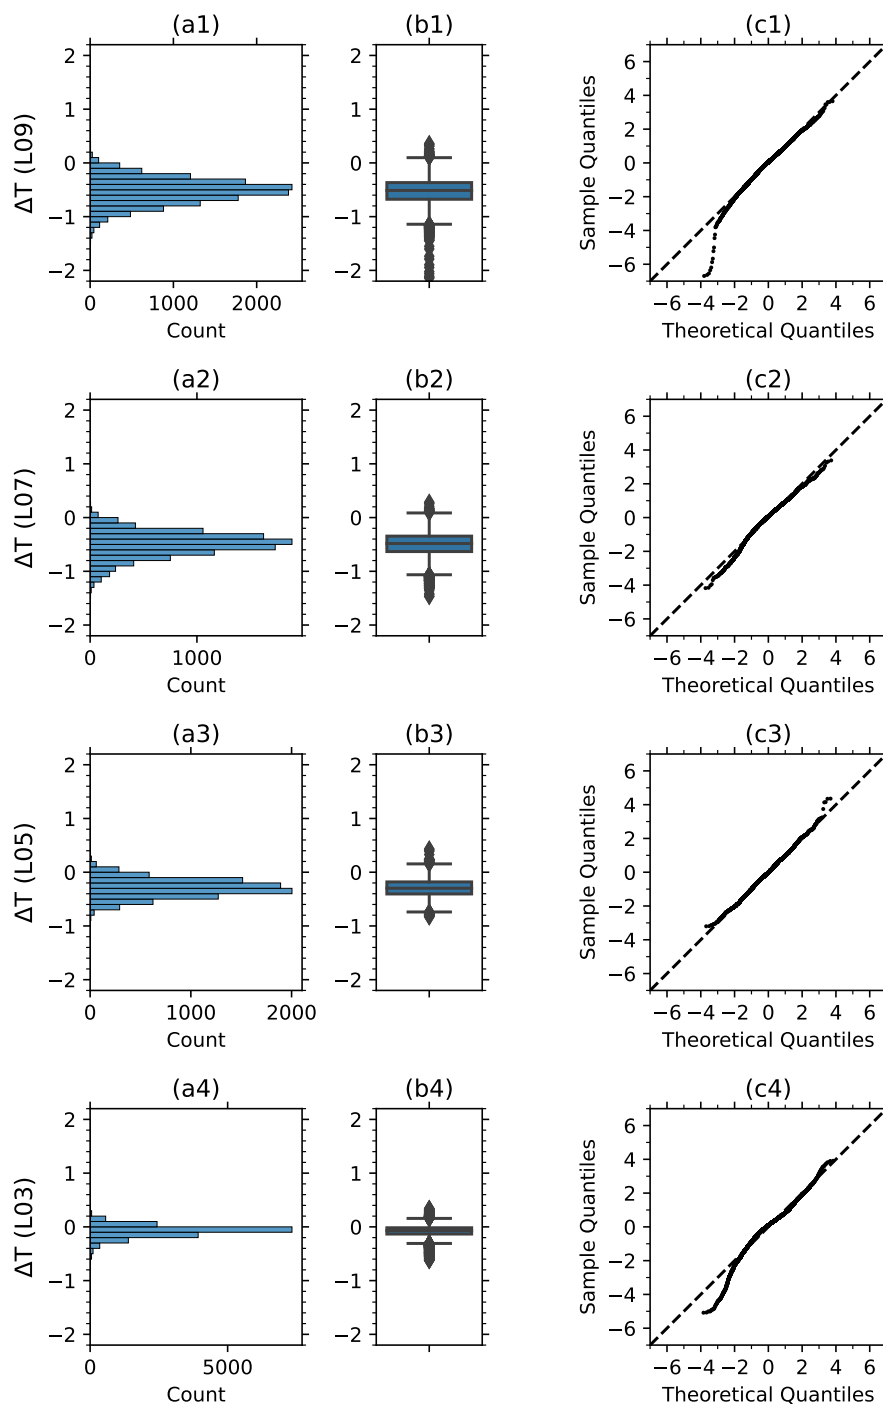

Figure 16. Distribution of temperature differences for daytime observations. aX: histogram; bX: boxplots; and cX: quantile-quantile plots. X indicates layer for (1) L09 (50 – 30 hPa), (2) L07 (100 – 70 hPa), (3) L05 (200 – 150 hPa), and (4) L03 (500 – 300 hPa)

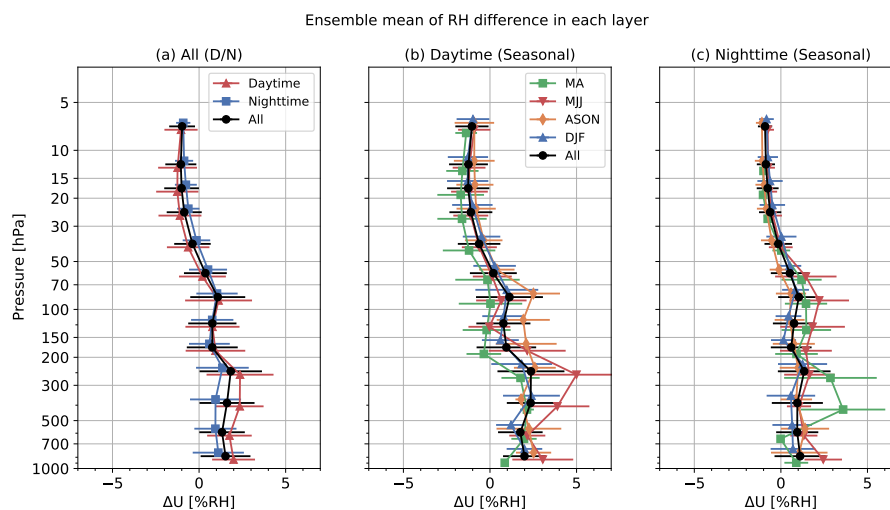

Figure 17. As per Fig. 14, but for RH

Figure 18. Mean RH difference for six RH ranks

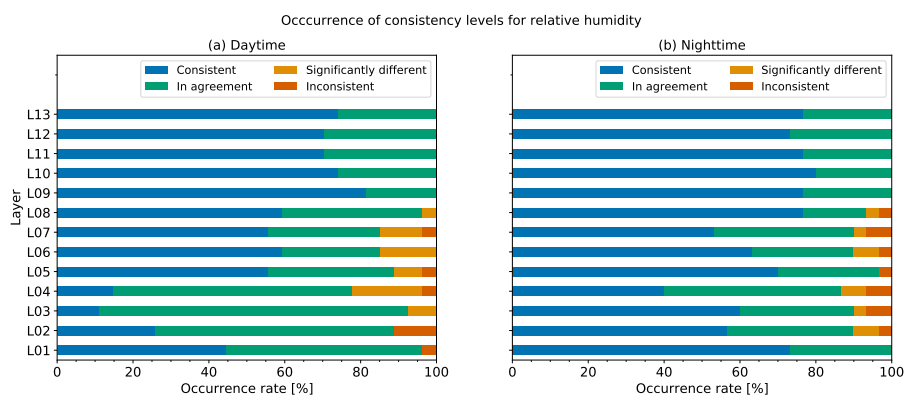

Figure 19. As per Fig.15, but for RH

Figure 20. Comparison between 500 and 150 hPa levels (L3 to L5) at 12 UTC (21 LT) on 19 April 2019: (a) temperature, (b) RH, (c) RH difference

Figure 21. As per Fig. 14, but for pressure

Figure 22. Histogram for the surface pressure difference (RS92 minus barometer values)

Figure 23. As per Fig. 14, but for geopotential height

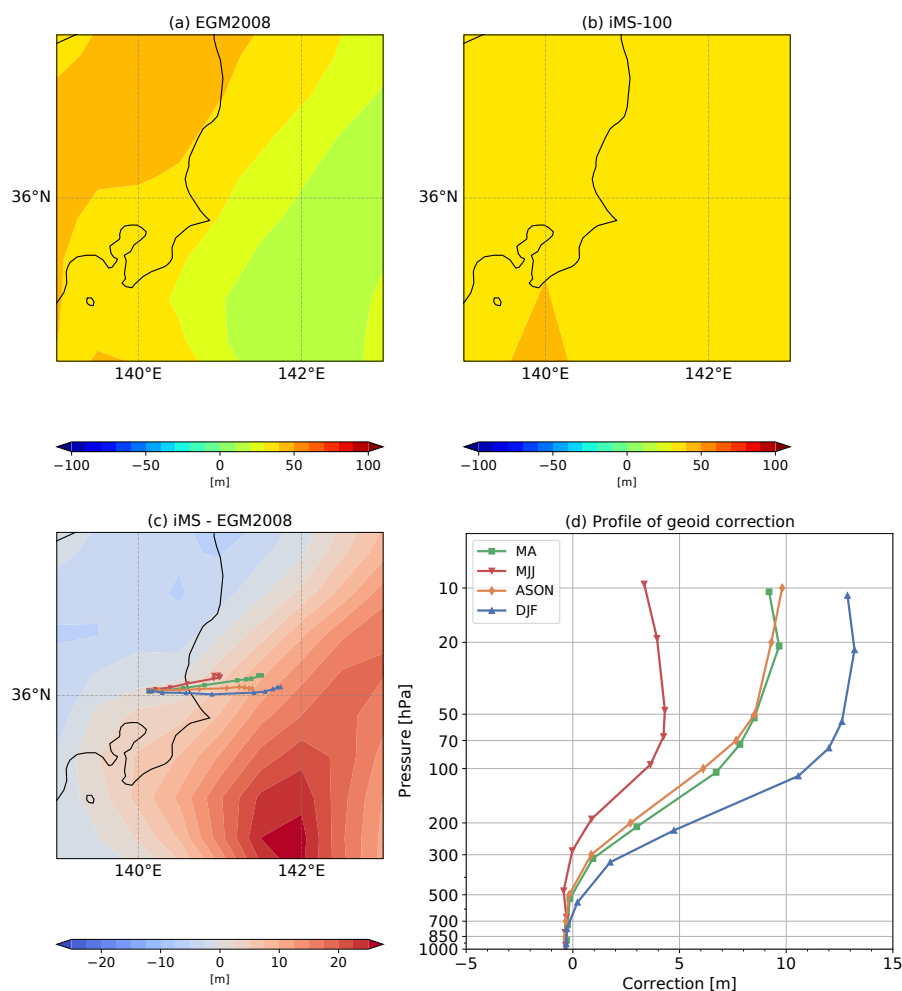

Figure 24. (a) Geoid height for IMS-100-GDP, (b) iMS-100 original, (c) difference of geoid height and seasonal typical tracks, (d) correction values along typical tracks

Figure 25. Seasonal wind difference parameters with coloring as per Fig. 14(b): (a) BIAS, (b) RMSVD (c) $\overline{\Delta DIR}$.

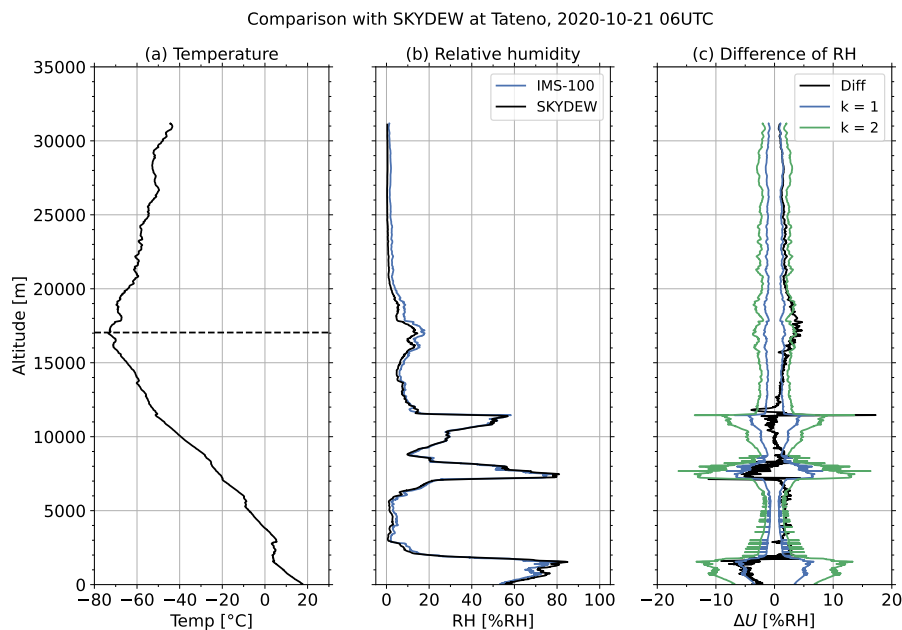

Figure 26. Comparison of RH profiles between IMS-100-GDP and SKYDEW at 06 UTC (15 LT) on 21 October 2020. (a) Air temperature from iMS-100. The dashed line shows the tropopause height (17041.6 m). (b) RH from both. The blue and black lines show IMS-100-GDP and SKYDEW, respectively. SKYDEW RH is calculated from SKYDEW frost/dew-point temperature and iMS-100 air temperature. (c) RH difference in iMS-100 from SKYDEW (black) and RH uncertainty for IMS-100-GDP (blue/green for $k = 1$ and 2 , respectively).

Table 1. Specifications of radiosondes (Vaisala Oyj., 2013; Meisei Electric Co., Ltd., 2020; Dirksen et al., 2014; Hoshino et al., 2021)

Radiosonde	iMS-100	RS92
Temperature		
Sensor type	Thermistor	Capacitive wire
Range	-90 °C to +60 °C	-90 °C to +60 °C
Resolution	0.1 °C	0.1 °C
Humidity		
Sensor type	electrostatic capacitance humidity sensor	thin-film capacitor, headed twin sensor
Range	0 %RH to 100 %RH	0 %RH to 100 %RH
Resolution	0.1 %RH	1 %RH
Saturation vapor pressure formulation	Hyland and Wexler equation (Hyland and Wexler, 1983)	
Pressure / geopotential height		
Sensor type	Calculated from GPS altitude	Silicon pressure sensor and calculated from GPS altitude
Pressure range	1050 hPa to 3 hPa	1080 hPa to 3 hPa
Pressure resolution	0.1 hPa	0.1 hPa
Calculation	Pressure is calculated from the GPS geopotential height using the hypsometric equation	In the lower part of the profile: the pressure sensor is used, and the geopotential height is derived from pressure using the hypsometric equation In the upper part of the profile: use the GPS sensor
Wind		
Sensor / calculation	Motion vector from GPS positioning (with SBAS) ^[1]	GPS wind finding (with GBAS)
Dimension (DWH)	53 mm × 55 mm × 131 mm	75 mm × 80 mm × 220 mm
Weight (with batteries)	40 g ^[2]	290 g
Ground system	MGPS2 (version 3 or higher)	DigiCORA III (version 3.6.4) MW41

[1] Wind also can be derived from Doppler shift of GPS signal, like RS-11G. [2] Weight for biodegradable materia model, while 38 g for EPS model.

Table 2. Sources contributing to iMS-100 temperature measurement uncertainty.

Source	Value	(Un)correlated
Thermistor calibration, u_{Tcal1}	$0.3/\sqrt{3}$	correlated
Variation in temperature in calibration chamber, u_{Tcal2}	$0.13/\sqrt{3}$	correlated
Spike correction, u_{spike}	$\sigma(\Delta T_{spike})$	uncorrelated
Moving average, u_{ma}		uncorrelated
Albedo for radiation correction, $u_{albedo}(T)$	$ \Delta T_{albedo=90\%} - \Delta T_{albedo=10\%} /(2\sqrt{3})$	correlated
Ventilation for radiation correction, $u_{vent}(T)$	$ \Delta T(\overline{asc}) - \Delta T(vent_{pt}) /\sqrt{3}$ $\Delta T(vent_{pt}) = \sqrt{asc_{raw}^2 + \sigma_{wind}^2}$	correlated
Sensor orientation, $u_{orien}(T)$		uncorrelated
Correlated uncertainty, $u_{cor}(T)$	$\sqrt{u_{Tcal1}^2 + u_{Tcal2}^2 + u_{albedo}(T)^2 + u_{vent}(T)^2}$	
Uncorrelated uncertainty, $u_{ucor}(T)$	$\sqrt{u_{spike}^2 + u_{ma}^2 + u_{orien}^2}$	
Total uncertainty, $u(T)$	$\sqrt{u_{cor}^2(T) + u_{ucor}^2(T)}$	

Table 3. Sources contributing to iMS-100 relative humidity measurement uncertainty.

Source	Value
Sensor calibration, u_{Ucalib}	$2/\sqrt{3}$
Time-lag correction, $u_{TL}(U)$	$\frac{ U(\tau + u_\tau) - U(\tau - u_\tau) }{2\sqrt{3}}$ $u_\tau = 0.25\tau$
Low-pass filtering in contamination correction, u_{LPPF}	
IIR filtering for high-pass component in contamination correction, u_{IIR}	
Hysteresis correction, $u_{hys}(U)$	$u_{\tau_hys} = \frac{ U(\tau_{hys} + u_{\tau_{hys}}) - U(\tau_{hys} - u_{\tau_{hys}}) }{2\sqrt{3}}$ $u_{\alpha_hys} = \frac{ U(\alpha_{hys} + u_{\alpha_{hys}}) - U(\alpha_{hys} - u_{\alpha_{hys}}) }{2\sqrt{3}}$ $u_{hys}(U) = \sqrt{u_{\tau_hys}^2(U) + u_{\alpha_hys}^2(U)}$
TUD correction, $u_{TUD}(U)$	Propagated from $u_{hys}(U)$
Ts/Ta correction, $u_{TsTa}(U)$	Propagated from $u_{TUD}(U)$
Correlated uncertainty, $u_{cor}(U)$	$\sqrt{u_{Ucalib}^2 + u_{TsTa}^2(U)}$
Total uncertainty, $u(U)$	$\sqrt{u_{cor}^2(U) + u_{LPPF}^2(U) + u_{IIR}^2(U)}$

495 **Table 4.** List of dual sounding events with iMS-100 and RS92 used for comparison. Weather code is according to WMO code table 4677.
