16 **Abstract**

17 To enable chemical speciation, monitoring networks collect particulate matter (PM) on different
18 filter media, each subjected to one or more analytical techniques to quantify PM composition
19 present in the atmosphere. In this work, we propose an alternate approach that uses one filter
20 type (teflon or polytetrafluoroethylene, PTFE, commonly used for aerosol sampling) and one
21 analytical method, Fourier Transform Infrared (FT-IR) spectroscopy to measure almost all of the
22 major constituents in the aerosol. In the proposed method, measurements using the typical
23 multi-filter, multi-analytical techniques are retained at a limited number of sites and used as
24 calibration standards. At all remaining sites, only sampling on PTFE and analysis by FT-IR is
25 performed. This method takes advantage of the sensitivity of the mid-IR domain to various
26 organic and inorganic functional groups and offers a fast and inexpensive way of exploring sample
27 composition. As a proof of concept, multiple years of samples collected within the Interagency
28 Monitoring of PROtected Visual Environment network (IMPROVE) are explored with the aim of
29 retaining high quality predictions for a broad range of atmospheric compounds including total
30 mass, organic (OC), elemental (EC) and total (TC) carbon, sulfate, nitrate and crustal elements.

31 Findings suggest that models based on only 21 sites, covering spatial and seasonal trends in
32 atmospheric composition, are stable over a three year period within the IMPROVE network with
33 acceptable prediction accuracy ($R^2 > 0.9$, median bias less than 3%) for most constituents. The
34 major limitation is measuring nitrate as it is known to volatilize off of PTFE filters. Incorporating
35 additional sites at low cost, partially replacing existing, more time and cost intensive techniques
36 or using the FT-IR data for quality control, are among the potential benefits of one-filter, one-
37 method approach.

38 1 Introduction

39 In the United States, filter-based chemical speciation of ambient aerosols has been in operation
40 for decades to quantify trends, assess transport and atmospheric transformation, identify
41 sources of air pollution, evaluate impacts of pollution regulations, assess impacts on visibility,
42 radiative forcing, human and ecosystem health and evaluate atmospheric and climatological
43 models. The two federally funded speciation networks, the Interagency Monitoring of PROtected
44 Visual Environments (IMPROVE) and the Chemical Speciation Network (CSN) collect 24-hour filter
45 samples using three filter media: polytetrafluoroethylene for analysis by gravimetry, hybrid
46 integrating plate and sphere (HIPS), and x-ray fluorescence (XRF), quartz for thermal optical
47 reflectance (TOR) and nylon for ion chromatography. Over the decades of operation, the
48 analytical methods have evolved with efforts to maintain consistency in trends while also
49 adopting improved methodology and retiring obsolete equipment. Impacts of many of these
50 changes have been addressed in the literature (Hyslop et al., 2015, 2012; White et al., 2016;
51 Zhang et al., 2021; Chow et al., 2007a, 2015) and in data advisories posted on the IMPROVE
52 website (<http://vista.cira.colostate.edu/Improve/data-advisories/>).

53 In this paper, we explore the use of Fourier transform-infrared spectroscopy (FT-IR) to reproduce
54 most of the existing speciation data based on the optical activity of the components in the mid-
55 IR. The number and bands of organic compounds are numerous, but generally group frequencies
56 can be found above 1500 cm^{-1} and compound-specific spectral patterns (“fingerprint region”)
57 below this frequency; down to approximately 700 cm^{-1} (for example, Weakley et al., 2016; Mayo
58 et al., 2004). Graphitic carbon displays peaks near 1600 cm^{-1} due to lattice defects (Tuinstra and
59 Koenig, 1970; Friedel and Carlson, 1971), displacement vibrations near 868 cm^{-1} (Nemanich et
60 al., 1977), and a broad, sloping absorbance between 4000 and 1500 cm^{-1} due to the tail of the
61 electronic transition more strongly observed in the UV (Parks et al., 2021). Inorganic substances
62 containing polyatomic ions such as sulfate, nitrate, and ammonium have strong vibrational
63 modes above 600 cm^{-1} (Mayo, 2004). Crystalline and amorphous geological minerals in the form
64 of oxides (which include hydroxides and oxyhydroxides) have distinct internal vibrational modes
65 influenced by the electronegativity of the metal to which the oxygen is bonded (Busca and Resini,
66 2006; Chukanov and Chervonnyi, 2016; Margenot et al., 2017).

67 FT-IR spectra with partial least squares (PLS) calibrations have been shown to reproduce OC and
68 EC concentrations using organic and graphitic carbon absorption bands, respectively, at a limited
69 number of sites in the IMPROVE network (Dillner and Takahama, 2015a, b; Reggente et al., 2016),
70 CSN (Weakley et al., 2016, 2018a) and FRM (Weakley et al., 2018b). Takahama et al. (2019)
71 reviews these findings and the overall framework to be used for the two phases of such statistical
72 calibrations: model building (sample selection, spectral preparation, model generation, model
73 selection, model evaluation, and model understanding) and operation (error anticipation and
74 model updating). Inorganic ions and geological mineral absorption bands have been used for

75 chemical speciation of these substances using FT-IR in prior studies (e.g., Cunningham et al.,
76 1974; McClenny et al., 1985; Pollard et al., 1990; Bogard et al., 1982; Foster and Walker, 1984).

77 Organic absorption bands are useful for measuring OC but also provide spectral information
78 needed to add detailed knowledge of composition not currently measured in air quality
79 monitoring networks – such as organic matter (OM) and organic functional group composition –
80 which is the subject of other work (Reggente et al., 2019; Boris et al., 2019, 2021; Burki et al.,
81 2020). Such calibrations, also combined with factor analytic approaches, can provide source
82 characterization on par with more costly mass spectrometric techniques (Boris et al., 2021;
83 Yazdani et al., 2021a; Hawkins et al., 2010; Takahama et al., 2011; Liu et al., 2012; Corrigan et al.,
84 2013).

85 Although FT-IR shows promise for measuring many constituents in aerosol, it is not without its
86 challenges. One limitation is that not all PM constituents can be measured, or measured with
87 high sensitivity, from the FT-IR spectrum. For instance, NaCl and MgCl₂ do not have IR-active
88 substituents. While a multitude of spectral signatures associated with mineral dust arise from
89 their constituent bonds – e.g., the metal-oxygen bonds in oxides (the oxide form is explicitly
90 assumed in estimating dust mass concentrations from elemental composition for the IMPROVE
91 network), some must be predicted from correlation with other constituents (e.g., some forms of
92 iron) if IR-activity is lacking. Other substances are IR-active but have weak responses, such as
93 graphitic carbon (Niyogi et al., 2006; Parks et al., 2021). The absorption and scattering by the
94 PTFE filter also pose challenges for quantitative analysis. The PTFE-based material changes over
95 time due to change in manufacturer or manufacturing process, and is difficult to fully characterize
96 a priori or treat with simple blank subtraction techniques. PTFE absorption limits full access to
97 the range of spectroscopic information in the mid-IR, for instance in the region of carbon-oxygen
98 bonds that can lead to less than full recovery of OM mass. Additionally, scattering leads to
99 broadly-varying slope in the group frequency region. This scattering artifact is minimized by
100 baselining (Kuzmiakova et al., 2016) and using many standards that have a range of scattering
101 and absorption observed in the network (Debus et al., 2019), yet these techniques can still lead
102 to errors in quantification. Weakley et al., (2018b) demonstrated that calibrations built using one
103 brand of filter can be accurately extended to another brand of PTFE filter with numerically
104 marginal but statistically significant increase in method error (e.g., +2% error for $\alpha=0.05$).
105 However, these studies are insufficient to generalize findings to all types of sampling filters.

106 The goal of this work is to assess the capability of using FT-IR to measure the aerosol chemical
107 composition at all IMPROVE sites. FT-IR quickly and non-destructively collects information-rich
108 spectra from routinely collected PTFE filter samples. Ambient samples from strategically-
109 selected IMPROVE sites are used for calibration and reasonably mimic the composition, matrix
110 effects and substrates of the unknowns, all of which theoretically lead to accurate estimations of
111 concentrations. Using all samples from selected sites reduces maintenance, shipping, processing

112 and coordinating required to maintain intermittent quartz and nylon filter sampling at every site.
113 Sites are selected using data from 2015 and are used for calibrating samples from 2015-2017.
114 Samples from all other (non-calibration) IMPROVE sites are predicted and compared to routine
115 IMPROVE data to assess the quality of prediction. Aerosol components to be measured include
116 TC, OC, EC, inorganic ions, soil elements, particulate mass, and light absorption.

117 2 Methods

118 2.1 Network data

119 IMPROVE samples collected every third day at all North American sites (Section S1) from January
120 2015 through December 2017 are included in this study. Fine particulate matter (aerodynamic
121 diameter less than 2.5 micrometers) is deposited on 25 mm diameter filters
122 polytetrafluoroethylene (PTFE, Teflo, Pall Gelman) and quartz filters by sampling air at a nominal
123 flowrate of 22.8 liters per minute from midnight to midnight local time. Parallel 37 mm nylon
124 filters are collected at the same flow flowrate. PTFE filters are analyzed by multiple instruments
125 and archived for future analysis. Nylon filters and a portion of each quartz filter undergoes
126 destructive analysis and a remaining part of the quartz filters are retained for archive.

127 Over the period covered in this study, two different TOR instruments were employed to measure
128 OC, EC and TC. Quartz filters sampled prior to 2016 were analyzed on a DRI Model 2001 thermal
129 optical carbon analyzers (Chow et al., 1993) while filters collected beginning in January of 2016
130 were analyzed on a DRI Model 2015 multi-wavelength thermal optical carbon instrument (Magee
131 Scientific – Berkley, USA)(Chow et al., 2015). Both instruments use the IMPROVE_A protocol
132 (Chow et al., 2007b), which outlines the temperature step, gaseous environment in the
133 instrument and that reflectance is used to define the split point between OC and EC. To correct
134 for gas phase adsorption onto the quartz filter, the monthly median field blank OC concentration
135 is subtracted from each OC measurement during that sample month. Carbon concentrations are
136 reported in $\mu\text{g}/\text{m}^3$.

137 An in-house Hybrid Integrating Plate and Sphere (HIPS) system evaluates light absorption from
138 the PTFE filters in the IMPROVE network (White et al., 2016). In this work, the measured
139 absorption coefficient (F_{abs}) is converted into a TOR EC equivalent concentration assuming a
140 F_{abs} / EC ratio of $10 \text{ m}^2\text{g}^{-1}$ (Malm et al., 1994). The resulting value, referred to as HIPS Black
141 Carbon (HIPS BC), is used as part of a quality control procedure to evaluate potential outliers in
142 TOR EC measurements.

143 Data from gravimetry and X-ray fluorescence (XRF) analysis obtained from PTFE filters and ion
144 chromatography from the nylon filters are also used in this study. Additional information on
145 routine IMPROVE methods can be found on the IMPROVE website
146 (<http://vista.cira.colostate.edu/Improve/>). IMPROVE data are available online at
147 (<http://views.cira.colostate.edu/fed>).

148 2.2 Outlier removal

149 Data were screened for outliers to eliminate their influence on the results. Out of the ~61,500
150 total number of samples in the three-year period, fewer than 800 were excluded from the
151 analysis due sampling issues or missing TOR, XRF or IC data. In addition, 65 samples collected at
152 the Wheeler Peak Wilderness (New Mexico) site between November 2015 and April 2016 were
153 excluded due to an EC contamination caused by a diesel-powered ski lift.

154 Potential outliers in TOR measurements were investigated by regressing TOR EC against HIPS BC
155 concentrations. Samples with differences exceeding a predefined threshold value ($0.68 \mu\text{g}/\text{m}^3$)
156 were flagged as potential outliers (section S2). The status of these samples was confirmed by
157 building separate TOR EC and HIPS BC calibrations. The poor agreement between TOR EC and FT-
158 IR EC concentrations contrasts with the nearly 1:1 relationship HIPS BC and FT-IR BC predicted
159 values indicating that TOR EC concentrations were likely compromised (Section S2). For the
160 period considered in this study, 112 samples with faulty TOR EC values were identified and
161 excluded from further analysis. The number of valid sample spectra retained in this study is
162 61,462.

163 2.3 Fourier-transform infrared (FT-IR) analyses

164 Since 2015, all PTFE in the IMPROVE network have been analyzed by infrared spectroscopy for
165 research and evaluation purposes. FT-IR measurement occurs after gravimetric analysis and prior
166 to XRF and HIPS to prevent possible loss of volatile species under the mild vacuum in XRF. Three
167 FT-IR spectrometers including one Tensor 27 and two Tensor 2 instruments (Bruker Optics,
168 Billerica, MA) equipped with a pre-aligned mid-IR source and a liquid nitrogen-cooled wide-band
169 mercury cadmium telluride (MCT) detector were used for spectra acquisition in the range $4000 -$
170 420 cm^{-1} by averaging 512 scans at a nominal resolution of 4 cm^{-1} . The single beam signal
171 associated with each PTFE filter was converted to an absorbance spectrum using the most recent
172 zero reference signal, updated hourly.

173 Previously, it was determined that calibration transfer between multiple FT-IR instruments is not
174 required as long as their spectral response is carefully matched by controlling a set of key
175 environmental and instrumental parameters (Debus et al., 2019). Briefly, each mercury cadmium
176 telluride (MCT) detector is connected to an automatic liquid nitrogen micro dosing system
177 (NORHOF, Ede, Netherlands) designed to improve signal stability and maintain a high signal to
178 noise ratio. The repeatability and reproducibility of the filter position relative to the IR beam is
179 controlled via a house-built sample chamber ($4.0 \times 5.1 \times 4.5 \text{ cm}$) mounted inside the instrument
180 sample compartment. Details regarding the chamber design have been published elsewhere
181 (Debus et al., 2019). Finally, the contribution of water vapor and carbon dioxide to the signal was
182 minimized by continuously purging both the sample chamber and the optical bench with a VCD
183 Series CO_2 adsorber / dryer system (PureGas LLC, Broomfield, CO). For each sample, the
184 acquisition procedure involves a 4 minutes purge period followed by a spectrum collection lasting

185 about 1 minute. An in-house macro interfaced to the OPUS software (Bruker Optics, Billerica,
186 MA) controls each step. PTFE filters were measured in transmission mode without sample
187 preparation. No interpolated data (from zero-filling) are included in the final raw spectra.
188 Collected spectra are subjected to weekly quality control procedures detailed in (Debus et al.,
189 2019). Duplicate and replicate measurements were also performed to evaluate instrument
190 stability and found to be within +/- 10%.

191 2.4 Multivariate Calibration Model - Partial Least Squares (PLS) Regression

192 While the presence of certain category of atmospheric compounds can be identified qualitatively
193 from an FT-IR spectrum, an accurate quantification of their concentration requires calibration.
194 PLS is a commonly used algorithm to relate a multi-wavenumber measurement to any particular
195 sample properties such as concentration (Wold et al., 2001). In brief, PLS maximizes the co-
196 variance between a set of response variables (species measurements) and a reference
197 measurement (FT-IR spectra) from which equivalent predicted values are desired. In so doing,
198 the optimal combination of response variables best describing the reference measurement is
199 identified and the selected features are used to build a multivariate calibration. With all least-
200 squares calibration methodologies, concentration-dependent biases in residuals that are
201 determined by the quality of fit (R^2) and dynamic range of the data are expected due to the nature
202 of least-squares estimation (Besalú et al., 2006; Draper and Smith, 1998, pp. 63-64,173,638). For
203 further discussion of these biases, see Section S1.

204 The applicability of PLS to quantify carbonaceous aerosol species (Reggente et al., 2016; Weakley
205 et al., 2016, 2018a) or functional groups (Boris et al., 2019; Ruthenburg et al., 2014) collected on
206 PTFE filters in various monitoring networks and field campaigns has been successfully
207 demonstrated. A complete review of the implementation of PLSR calibration in the framework
208 of atmospheric particulate matter characterization has been recently published (Takahama et al.,
209 2019).

210 To evaluate model performance, FT-IR predicted concentrations were regressed against their
211 reference measurement to quantify residuals and a series of metrics. Reported figures of merit
212 include the coefficient of determination (R^2), bias, error and the method detection limit (MDL).
213 Residuals are defined as the difference between predicted and reference concentrations, bias
214 corresponds to the median residual while error is the median absolute residual. To facilitate inter-
215 model comparison, relative performance metrics were calculated by normalizing the values by
216 their reference value. FT-IR PLSR calibration MDL was estimated from field blank predicted
217 concentrations as the 95th percentile minus the median residuals, as is done for other species in
218 the IMPROVE network [http://vista.cira.colostate.edu/improve/wp-](http://vista.cira.colostate.edu/improve/wp-content/uploads/2021/07/IMPROVE-SOP-351_Data-Processing-and-Validation_2021_final.pdf)
219 [content/uploads/2021/07/IMPROVE-SOP-351_Data-Processing-and-Validation_2021_final.pdf](http://vista.cira.colostate.edu/improve/wp-content/uploads/2021/07/IMPROVE-SOP-351_Data-Processing-and-Validation_2021_final.pdf).
220 Performance is reported for all samples together regardless if the samples were included in the
221 calibration. This enables comparison between models with different samples used for calibration.

222 For further insight into model prediction accuracy, the distribution in FT-IR residuals is
223 qualitatively compared with residuals from collocated measurements. Collocated quartz filters
224 are collected at the Everglades (FL), Hercules-Glades (MO), Medicine Lake (MT) and Phoenix (AZ)
225 sites. Similarly, collocated Teflon filters are sampled at Mesa Verde (CO), Proctor Maple Research
226 Facility (VT), Saint Marks National Wildlife Refuge (FL), Yosemite (CA) and Phoenix (AZ) sites while
227 collocated nylon filters are featured at the Phoenix (AZ), Frostburg Reservoir (MD), Mammoth
228 Cave (KY) and San Gabriel (CA) sites.

229 Data handling and analysis was performed in Matlab R2018a (The MatWorks, Inc, Natick, MA,
230 United States) using the statistics and signal processing toolboxes. PLS was computed via the
231 libPLS Matlab package (v1.9) (Li et al., 2018).

232 2.5 FT-IR Calibrations for Predicting PM Composition

233 This section presents the design of calibrations for quantifying the concentration of major
234 atmospheric species by taking advantage of the composition-based information embedded
235 within an FT-IR spectrum. In practice, spectra are calibrated against reference measurements
236 from TOR, XRF, IC, HIPS and gravimetric analysis with the aim of predicting concentrations of
237 atmospheric constituents using only spectra of PTFE filters as input.

238 A multilevel model (Snijders and Bosker, 2011; Takahama et al., 2019) is proposed in which
239 dedicated calibration models for subgroups of samples are constructed, and applied according
240 to a predetermined selection criterion for each sample. This model considers two subgroups: i)
241 samples determined to be dominated by biomass burning, which are calibrated with similar
242 samples, and ii) the remaining samples, which are calibrated with samples from a limited number
243 of sites.

244 To establish baseline performance metrics for comparison, a “Global model” in which a single
245 calibration (for each species) is constructed from all samples considered together is described in
246 Section S1 (Supplement).

247 The first step in the development of the Multilevel model consists of screening for biomass
248 burning samples. These samples are removed from consideration during the site selection
249 process. A simple detection method combining estimates of key functional group spectral peak
250 areas and spectral dissimilarity metrics were used to segregate biomass burning samples from all
251 other samples. Next, a Gaussian Mixture Model (GMM) was applied to the spectra of all non-
252 biomass burning samples. The GMM exploits the specificity of the infrared signal for organic and
253 inorganic species. The GMM was implemented with the aim of clustering the non-biomass
254 burning FT-IR spectra into groups sharing similar spectral features (Section 2.5.2). Those groups
255 were later used as part of the methodology for selecting sites with representative atmospheric
256 composition. Spectra from the year 2015 were used as a benchmark to validate the biomass
257 burning detection strategy, build the GMM and establish the list of representative sites where

258 multi-filter collection/multi-analyses should be retained (section 2.5.2). The identified biomass
259 burning samples are used to build a calibration for biomass burning samples (Section 2.5.1).

260 2.5.1 Biomass burning model

261 FT-IR spectra were used to estimate functional group areas and calculate spectral dissimilarities
262 metrics to segregate biomass burning samples from all other samples. Although this paper
263 focuses on using FT-IR to measure the major aerosol components in routine speciated aerosol
264 monitoring networks, FT-IR is more frequently used to measure organic functional groups (e.g.
265 (Russell et al., 2011; Ruthenburg et al., 2014; Boris et al., 2019). Specific regions in the IR spectra
266 correspond to specific functional groups. Peak areas, calculated from baseline corrected spectra
267 (see Section S3 for baseline procedure), for carbonyl, OH and CH were used rather than functional
268 group calibrations for simplicity. Because the relative functional group peak area tends to
269 increase significantly as the cumulative peak area decreases, typically for low mass deposition
270 samples, an estimate of spectral dissimilarities, the squared Mahalanobis distance (D_i^2), for each
271 site is also considered to minimize false detection. The Mahalanobis distance (Mahalanobis,
272 1936; Cios et al., 1998) is a measure of the spectral dissimilarity between a given spectrum at a
273 site and the mean spectrum at the site. Taking advantage of D_i^2 and relative functional group
274 areas, a set of criteria were established from observations at known wildfire sites during wildfire
275 season (O'Dell et al., 2019). First, samples collected under heavy smoke conditions whose spectra
276 fulfill $C-H \geq 2\%$, $C=O \geq 15\%$ and $D_i^2 \geq 3 \overline{D^2}$ were detected (Section S3). This group of spectra
277 tend to have large D_i^2 values and, consequently, the $3 \overline{D^2}$ threshold often excludes samples with
278 low to moderate biomass burning contributions. For a more inclusive detection, spectra from the
279 first group were removed from consideration, the D_i^2 values are updated for each sample and
280 the plots were regenerated. The cut-off value for the relative carbonyl functional group area was
281 lowered to 8 % while other parameters were not changed. Spectra identified by the first and
282 second rounds are considered biomass burning samples. This procedure is performed for each
283 site and for each year of sample collection (Section S.3)

284 Recent work has shown that smoke samples may be identified using techniques such as cluster
285 analysis and labeling (Burki et al., 2020) similar to the GMM used here and through detection of
286 molecular markers – levoglucosan and lignin – or peak profiles in FT-IR spectra (Yazdani et al.,
287 2021a, b). For the large data set in this work (~20,000 samples in 2015), cluster analysis
288 resulted in multiple clusters that could be associated with smoke-impacted samples likely due
289 to the variations in fuel, oxidation conditions, and contributions from other sources. Therefore,
290 for this work we selected a single group of smoke-impacted samples based on specific organic
291 features known to be present in FT-IR spectra. While the criteria for smoke-impact labeling can
292 be defined differently according to each intended purpose, the method presented here is
293 demonstrated to sufficiently partition the samples for building accurate submodels to predict
294 concentrations of PM constituents.

295 While ions and crustal species are not necessary correlated with wildfire emissions, the Biomass
296 Burning sub-model accounts for interferences that are necessary to track in order to maintain
297 high prediction accuracy for samples collected on smoky days.

298 2.5.2 Limited Sites Model

299 To assess major PM_{2.5} composition regimes in the network and to identify representative sites to
300 use as calibration standards in the Limited Sites model, screening of all FT-IR spectra (except
301 samples identified as biomass burning samples) across all locations and seasons was performed
302 by building a Gaussian Mixture Model (GMM) (Bilmes, J. A., 1998; Hastie, T et al., 2009). The basic
303 idea behind GMM is to group FT-IR spectra into clusters of similar spectral shape using a
304 probabilistic approach describing the likelihood that any given spectrum belongs to a particular
305 class. To minimize the concentration dependence and emphasize composition, raw spectra were
306 transformed to second derivative spectra using a 2nd order, 21 point, Savitzky-Golay filter
307 (Savitzky and Golay, 1964), differenced with filter blank spectra and divided by their respective
308 Euclidean norm (Bro and Smilde, 2003). Additional details about the GMM pre-processing and
309 implementation as well as cluster interpretation are provided in Section S4.

310 After classification, a single site per cluster was selected to represent the atmospheric
311 composition captured in that cluster. For any given cluster, the retained location was defined as
312 the site with the largest number of classified spectra with the highest probabilities of belonging
313 to that cluster. To prevent misleading site selection and enhance spatial coverage, the following
314 set of decision rules were used: *i)* if the same site is representative of two clusters, it is ascribed
315 to the cluster with the largest number of classified spectra from that site, *ii)* if none of the
316 retained sites accounts for a given spatial region or known source type in the network, an
317 additional site with the highest number of classified spectra is selected from a nearby cluster,
318 and *iii)* only sites under continuous operation between 2015 and 2017 are eligible for selection.
319 Criteria *ii)* was invoked once to add a site in the Midwest to improve spatial coverage in that
320 region and to capture prescribed fire emissions in Kansas. All non-biomass burning samples from
321 selected sites were used as FT-IR calibration standards for all species and all non-biomass burning
322 samples are predicted with these models. Once established, the selected sites are not re-
323 evaluated but instead were used in all subsequent years as would occur in practice.

324 2.5.3 Application of Multilevel Model

325 The Multilevel model is the combined FT-IR predicted concentrations from the Limited sites and
326 Biomass burning models. Multilevel modeling will be discussed in the context of carbonaceous
327 aerosols before extending the modeling to other atmospheric constituents with detectable
328 infrared signatures. In addition to OC and EC, species evaluated for FT-IR prediction include PM_{2.5}
329 mass, soil elements (silicon, aluminum, calcium, titanium, iron), anions (sulfate, nitrate) and HIPS
330 BC. As mentioned previously, NaCl is not IR active and so there is no direct measure of seasalt
331 from FT-IR. Next, the years 2016 and 2017 will be examined to assess the long-term stability of

332 the proposed Multilevel strategy by screening for smoke samples and re-calibrating each year
333 using the sites selected using 2015 data.

334 3 Results and discussion

335 In the following sections, the quality of FT-IR based calibrations for quantifying aerosol
336 composition across continental US and their long-term applicability to large speciation
337 monitoring networks will be assessed. Section 3.1 describes the selected calibration samples for
338 the Biomass Burning and Limited Sites models. In Section 3.2, Biomass Burning and Limited
339 model performance will be briefly reviewed before exploring the Multilevel FT-IR predictions for
340 all samples. Initially focused on carbonaceous species on PTFE samples collected in 2015, FT-IR
341 predictions will be extended to other atmospheric constituents and years.

342 3.1 Multilevel modeling – Calibration sample selection

343 3.1.1 Biomass burning sample selection

344 Using the methods described above, 492 samples impacted by biomass burning emissions were
345 identified in 2015 (2.5 % of the network), 288 samples in 2016 (1.5 %), and 817 samples in 2017
346 (3.7 %). The mean OC concentration of the biomass burning samples range was 5.6 – 8.3 $\mu\text{g}/\text{m}^3$
347 with maximum concentrations extending from 44 to 97 $\mu\text{g}/\text{m}^3$ over the three year period.
348 Similarly, per year, the mean EC concentration varies between 0.6 – 0.9 $\mu\text{g}/\text{m}^3$ with maximums
349 up to 2.9 – 3.9 $\mu\text{g}/\text{m}^3$. Mean OC/EC ratios are larger than 7, in agreement with past literature
350 (Schichtel et al., 2008; Sorooshian et al., 2011). Analysis of the detected samples shows reliable
351 spatial and seasonal distributions, consistent with biomass burning emissions predominantly in
352 summer and fall across the Pacific North West and Northwestern US (Section S3). Two-thirds of
353 the identified samples were selected (Section S5) as calibration standards for the calibration and
354 resulting model was applied to the remaining third of the smoke impacted samples.

355 3.1.2 Limited Sites model – clusters and retained sites

356 Figure 1 shows the spatial distribution and annual average composition (from routine IMPROVE
357 data) of the 21 sites selected for the Limited sites model calibratoin. From a spatial standpoint,
358 retained sites appear reasonably scattered across the network including Hawaii and the Virgin
359 Islands. Clusters are represented by a distribution of urban and rural sites. One urban cluster is
360 represented by Fresno and contains mostly urban samples from Fresno and Phoenix. All other
361 clusters contain mostly rural and pristine sites. However, two other urban sites were retained,
362 Phoenix and Birmingham. The Phoenix cluster contains samples from the southwest in the
363 spring. The Birmingham site along with the Tallgrass site represent a non-western cluster in the
364 spring and summer.

■ Rural sites (n = 18)
 ▲ Urban sites (n = 3)

Bondville (IL)

Dolly Sods (WV)

Birmingham (AL)

Chassahowitzka (FL)

Virgin Islands (VI)

Hawaii Volcanoes (HI) Point Reyes (CA)

Fresno (CA)

Dome Land (CA)

Great Basin (NV)

Meadview (AZ)

Phoenix (AZ)

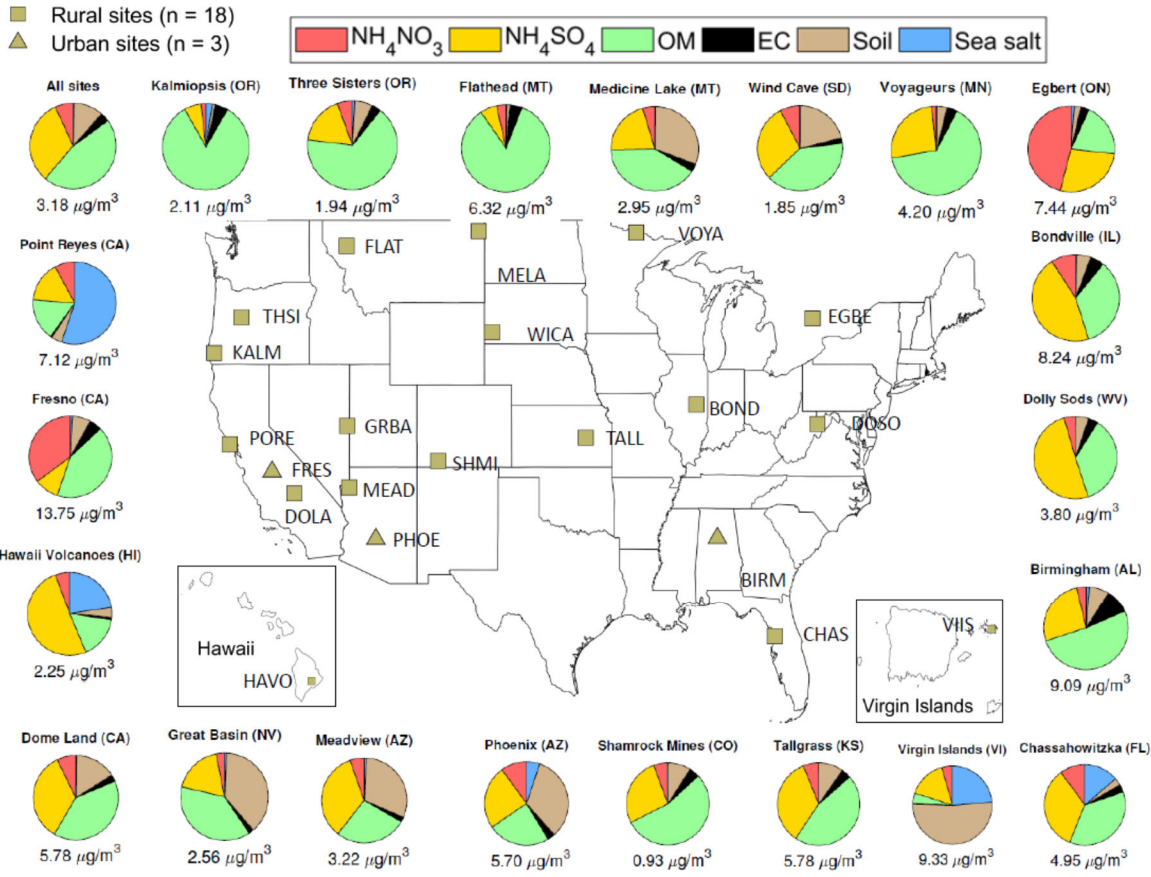

Shamrock Mines (CO)

Tallgrass (KS)

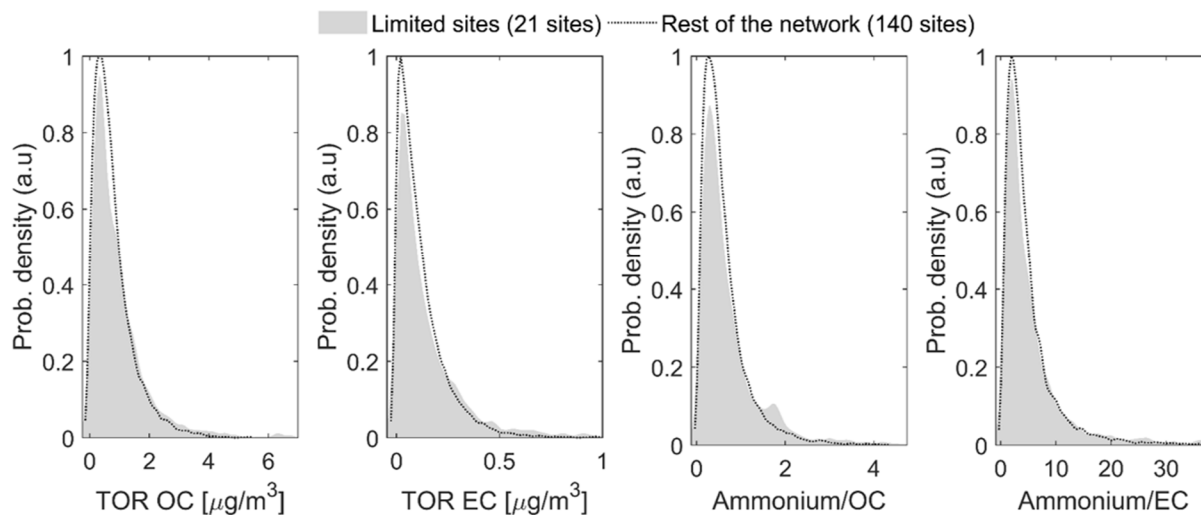

367

368 **Figure 1:** Spatial distribution, median PM_{2.5} concentration and composition of the 21
 369 representative sites. The composition is obtained from routine IMPROVE (non-FT-IR)
 370 measurements and the IMPROVE reconstructed fine mass equation
 371 (<http://vista.cira.colostate.edu/Improve/reconstructed-fine-mass/>) to calculate soil and seasalt.
 372 Sites are identified by the four letter site code which is the first four letters of a single word site
 373 name (Fresno = FRES) or the first two letters of the first and second word for two word site names
 374 (Dome Land = DOLA). ~~The composition is obtained from IMPROVE measurements and the~~
 375 ~~IMPROVE reconstructed fine mass equation.~~ The top left pie chart representing the median PM_{2.5}
 376 composition across all sites and samples is given for comparison.

377 The clusters are also seasonally distributed (Section S6): five clusters are dominated by fall -
 378 winter samples, ten clusters containing summer samples (along with varying number of spring
 379 and fall samples), two clusters are predominately spring and one is spring - fall. Three clusters
 380 have little seasonality.

381 Because FT-IR spectra are clustered based on composition, the first step in assessing the
 382 representativeness of the 21 sites is to compare the concentration ranges. For this purpose,
 383 distributions in TOR OC and EC concentrations excluding biomass burning samples are compared
 384 for the 21 sites used for calibration and the 140 remaining sites. In Fig. 2, the two probability
 385 density functions are very similar for both OC and EC despite large differences in sample
 386 populations (2572 and 16,543, respectively). In addition to matching the range of carbonaceous
 387 concentrations observed in the rest of the network, the presence of species interfering with
 388 organic functional groups should also be accounted for by the calibration. Because ammonium
 389 absorptions overlap with carbonaceous absorptions, situations where ammonium to OC and
 390 ammonium to EC ratios are different between calibration samples and samples to be predicted
 391 were associated with additional sources of bias and error (Dillner and Takahama, 2015a, b).
 392 Although not measured in IMPROVE, ammonium concentration is approximated from nitrate and
 393 sulfate assuming both species are fully neutralized. The corresponding probability distribution in
 394 Fig. 2 confirms the equivalence between the ranges of ammonium/OC and ammonium/EC
 395 concentrations spanned by the Limited sites samples and the overall network. In section S6, Fig.
 396 S6-3 shows reasonable agreement between the selected sites and the rest of the network for
 397 PM_{2.5} mass, ions, elements and HIPS BC. Together, these results suggest the list of 21 sites is a
 398 suitable representation of network variations in OC and EC and their relative proportion to
 399 ammonium, and for all other predicted constituents.

400
 401 **Figure 2:** Comparison of probability density function for OC, EC and ammonium concentrations
 402 in 2015 between the 21 sites retained for Limited calibration and the rest of the network.

403 The spatial and seasonal as well as the urban and rural diversity supports the compositional
 404 diversity of the selected sites as shown in Fig. 1. The three urban sites have distinct
 405 characteristics. At the Fresno, CA site, the composition is dominated by nitrate (35 %) and organic

406 matter (42 %) with an autumn – winter pattern consistent with agriculture and residential wood
407 burning activities (Ngo et al., 2010) as well as with the formation of secondary aerosols during
408 stagnation events and a low inversion layer (Watson and Chow, 2002). Phoenix, AZ site features
409 a strong soil component (33%) associated with spring dust storms and windblown dust and equal
410 proportions of ammonium sulfate (25 %) and OM (24 %) occurring mostly in spring and summer.
411 The ammonium sulfate and organic matter has been attributed to regional power production and
412 traffic (Brown et al. 2007). In contrast, Birmingham samples show little seasonal trend with
413 elevated OM (52 %) and EC (10 %) fractions originating from various combustion processes
414 including vehicle exhaust, biomass burning and biogenic secondary organic aerosols (Blanchard
415 et al. 2016). The other dominant species at this site is ammonium sulfate (26 %), characteristic of
416 coal burning and industrial activities in the East (Watson et al. 2015).

417 Among rural sites, four noticeable patterns in PM_{2.5} composition are distinguishable. The first
418 corresponds to OM fractions accounting for more than two-thirds of the filter mass. High OM
419 samples are encountered at four locations in Northwestern US, namely the Kalmiopsis (OR),
420 Three Sisters (OR), Flathead (MT) and Voyageurs (MT) sites. Samples from Voyageurs (MN) and
421 Flathead (MT) sites are from Summer-Fall and present elevated median PM_{2.5} concentrations
422 (4.20 µg/m³ and 6.32 µg/m³, respectively) and very large percentage of OM consistent with
423 biomass burning emissions. Kalmiopsis (OR) and Three Sisters (OR) samples have a lower and
424 nearly identical median PM_{2.5} concentration (≈ 2 µg/m³) but differ in their monthly distribution
425 with the former displaying more winter samples than any other season whereas the later shows
426 little seasonality.

427 The second type of sites have high OM and sulfate concentrations. Both Shamrock Mines (CO)
428 and Tallgrass Prairie (KS) sites have larger OM than sulfate content. However, the Colorado site
429 has more autumn – winter samples, represents samples in the Rockies and Alaska and an overall
430 small median PM_{2.5} concentration (< 1 µg/m³). The Kansas site has a majority of spring samples,
431 representing non-western samples and has a significantly larger PM_{2.5} concentration (≈ 6 µg/m³)
432 that is attributed to prescribed burning near the Tallgrass site (Whitehill et al. 2019). Other sites
433 have higher median sulfate concentrations (~50%) than OM concentrations (~40%) such as Dolly
434 Sods (WV) and Bondville (IL). The monthly sample distribution indicates seasonal influences:
435 Bondville (IL) samples are mostly from the summer and the concentrations are relatively high
436 while the Dolly Sods (WV) site samples are mostly not in the summer with lower concentrations.
437 Because the spectra were normalized to minimize influence of concentration, these two clusters
438 likely have different organic composition even though the relative amount of OM is the same.
439 Finally, situations where sulfate and OM are present in equal proportions (≈ 36 %) are reported
440 at the Dome Land (CA) and Chassahowitzka (FL) pristine sites mainly featuring spring – summer
441 and winter samples, respectively.

442 A third group of noteworthy PM_{2.5} compositions at rural sites contain a large fraction of (> 20 %
443 of the total mass). The Virgin Islands (VI) site presents the highest soil fraction across the network
444 52 % of the total PM_{2.5} mass, mostly originating from long-range Sahara soil dust transport
445 (Holmes and Miller 2004). In addition to sulfate and OM, elevated soil contributions are observed
446 for the Wind Cave (SD), Meadview (AZ), Medicine Lake (MT), and Great Basin (NV) sites with soil
447 content between 20 and 40%. Although the seasonality is somewhat different between these
448 sites, they all have many samples from the spring suggesting the dust is due at least in part to
449 spring dust storms and may also contain resuspended road dust and more localized dust sources.

450 A fourth and final distinct category of PM_{2.5} composition includes a collection of sites with unique
451 local atmospheric pollution sources, specific to those locations. The Hawaii Volcanoes (HI) site
452 where sulfur emitted as part as the volcanic activity, contains 51% sulfate along with sea salt (23
453 %). Another location with unique composition is the Point Reyes (CA) site where the sea salt
454 contribution reaches 55% of the median filter mass for the clustered samples, larger than any
455 other marine site in the network. Finally, the Egbert (ON) Canadian site, representing the upper
456 Midwest in winter is dominated by nitrate (46 %), sulfate (27 %) and OM (20 %).

457 As described above, the 21 sites retained for the Limited sites sub-calibration present seasonal,
458 regional and compositional features consistent with known or expected trends in PM_{2.5} across
459 the network. The median PM_{2.5} mass at those locations covers a broad range of concentrations
460 ranging from 0.93 µg/m³ to 13.75 µg/m³ and includes both urban and rural sites. Capturing the
461 large variability in PM_{2.5} composition and concentration is essential to ensure the proposed site
462 list is a representative subset of the parent network. However, it should be mentioned that the
463 proposed site list is not unique but is one of the many feasible solutions since sites whose samples
464 clustered together in the GMM are likely inter-exchangeable.

465 3.2 Evaluation of Biomass Burning Model

466 Prior to describing the overall results from the Multilevel model, the Biomass Burning model is
467 evaluated to determine if the biomass burning model improves predictions for those samples.
468 To evaluate the quality of the biomass burning model, the predictions are compared to a global
469 model (section S1) which contains a few samples from all 160 sites which are mostly non-smoke
470 samples but does contain a few smoke samples. Visual inspection of Fig. 3 suggests the
471 equivalence of the biomass burning models to the global model at the lower end of the
472 concentration range. However, improvement in prediction accuracy can be claimed at high
473 concentrations for the Biomass Burning model. The gain in model performance is subtle for OC
474 and TC; however, for EC, predictions benefit from having a dedicated calibration for samples
475 impacted by wildfire emissions, with an increase in R² from 0.747 to 0.902 (Section S7).

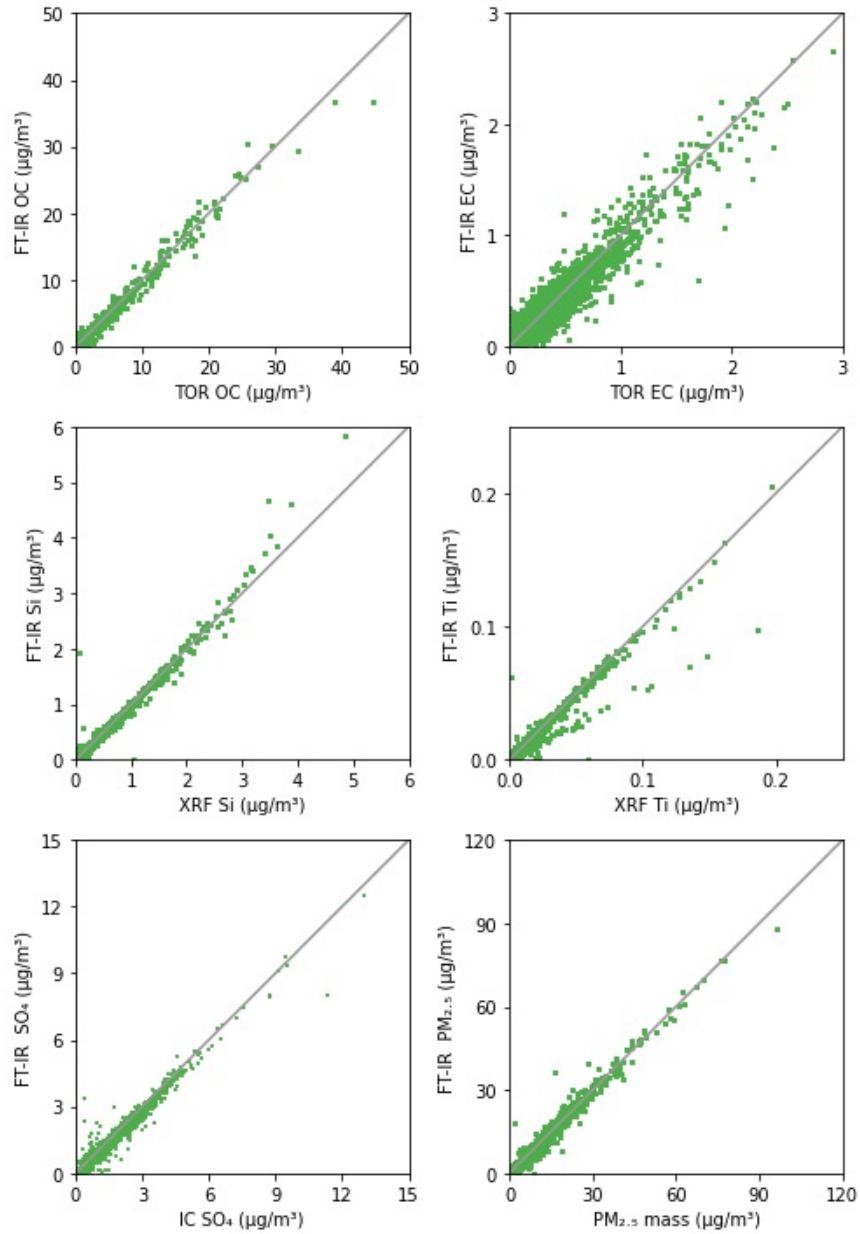

476
 477 **Figure 3:** Inter-model OC (left), EC (middle), TC (right) comparison between global (section S1)
 478 and Biomass Burning predicted concentrations for the 492 samples classified as biomass burning
 479 in 2015. EC prediction, in particular, benefit from having a dedicated Biomass Burning calibration
 480 model.

481 Therefore, we retain the biomass burning model as part of the multilevel model and present
 482 the results for the Multilevel model below.

483 3.3 Multilevel modeling – Performance evaluation

484 3.3.1 Carbonaceous aerosol predictions

485 Figure 4 shows the correspondence between FT-IR Multilevel concentrations for OC and EC and
 486 TOR measurements for 2015 (plot for TC can be found in Section S9) and Table 1 lists the
 487 prediction metrics for all 3 carbonaceous components. The visual agreement between FT-IR
 488 and the reference measurements of OC and EC is high but EC shows higher scatter than the
 489 other measurements. Table 1 indicates that FT-IR OC and TC has higher prediction quality than
 490 EC but both perform satisfactorily. FT-IR OC and TC error is on par with TOR precisions (Table 1)
 491 indicating that on average FT-IR does not add significant additional error to the measurement.
 492 FT-IR EC predictions, however, have higher error than TOR precision. With respect to reference
 493 (TOR) measurements, concentration-dependent biases in residuals that are determined by the
 494 quality of fit (R^2) and dynamic range of the data are expected due to the nature of least-squares
 495 estimation (Besalú et al., 2006; Draper and Smith, 1998). For bias defined as FT-IR predictions
 496 minus the reference (TOR) measurement, least-squares estimator causes an apparent linear
 497 bias which is positive at the low end of the concentration range and negative at the high end of
 498 the concentration range- (see Section S8 for further discussion). The satisfactory agreement
 499 between FT-IR and TOR concentrations as well as the equivalence agreements using the global
 500 model (Section S1) support the validity of the proposed Multilevel modeling in the context of
 501 carbonaceous aerosols prediction from PTFE filters in large speciation networks.

502

503 **Figure 4:** Comparison of predicted FT-IR OC, EC, Si, Ti, SO_4 and mass concentrations using the
 504 Multilevel model against their reference measurements. Each subplot contains all 19,608
 505 samples collected in the year 2015.

506

507 **Table 1:** Summary of Multilevel model performance for IR-active atmospheric constituents for
 508 19,608 spectra analyzed by FT-IR in the year 2015.

Species	R ²	Bias [µg/m ³]	Bias (%)	Error [µg/m ³]	Error (%)	Reference Data Error ¹ (%)	MDL [µg/m ³]	< MDL (%)
<i>OC</i>	0.983	0.01	1.6	0.08	12	10	0.06	0.9
<i>EC</i>	0.912	0	1.7	0.02	30	15	0.04	20.7
<i>TC</i>	0.984	0.01	1.2	0.08	12	11	0.07	1.3
<i>BC</i>	0.92	0	-0.3	0.03	23	---	0.04	19.3
<i>Si</i>	0.983	0	2.2	0.01	11	13	0.01	9.7
<i>Al</i>	0.985	0	2.2	0	12	10	0	4.7
<i>Ca</i>	0.979	0	1.1	0	13	9	0	6.9
<i>Ti</i>	0.941	0	2.7	0	21	16	0	14.9
<i>Fe</i>	0.95	0	1.1	0	25	8	0.01	19
<i>SO₄</i>	0.983	0	0.1	0.03	6	2	0.03	0.9
<i>NO₃</i>	0.927	0.02	15.3	0.07	54	8	0.07	21.8
<i>PM_{2.5} Mass</i>	0.985	0.03	1	0.18	6	6	0.25	1.1

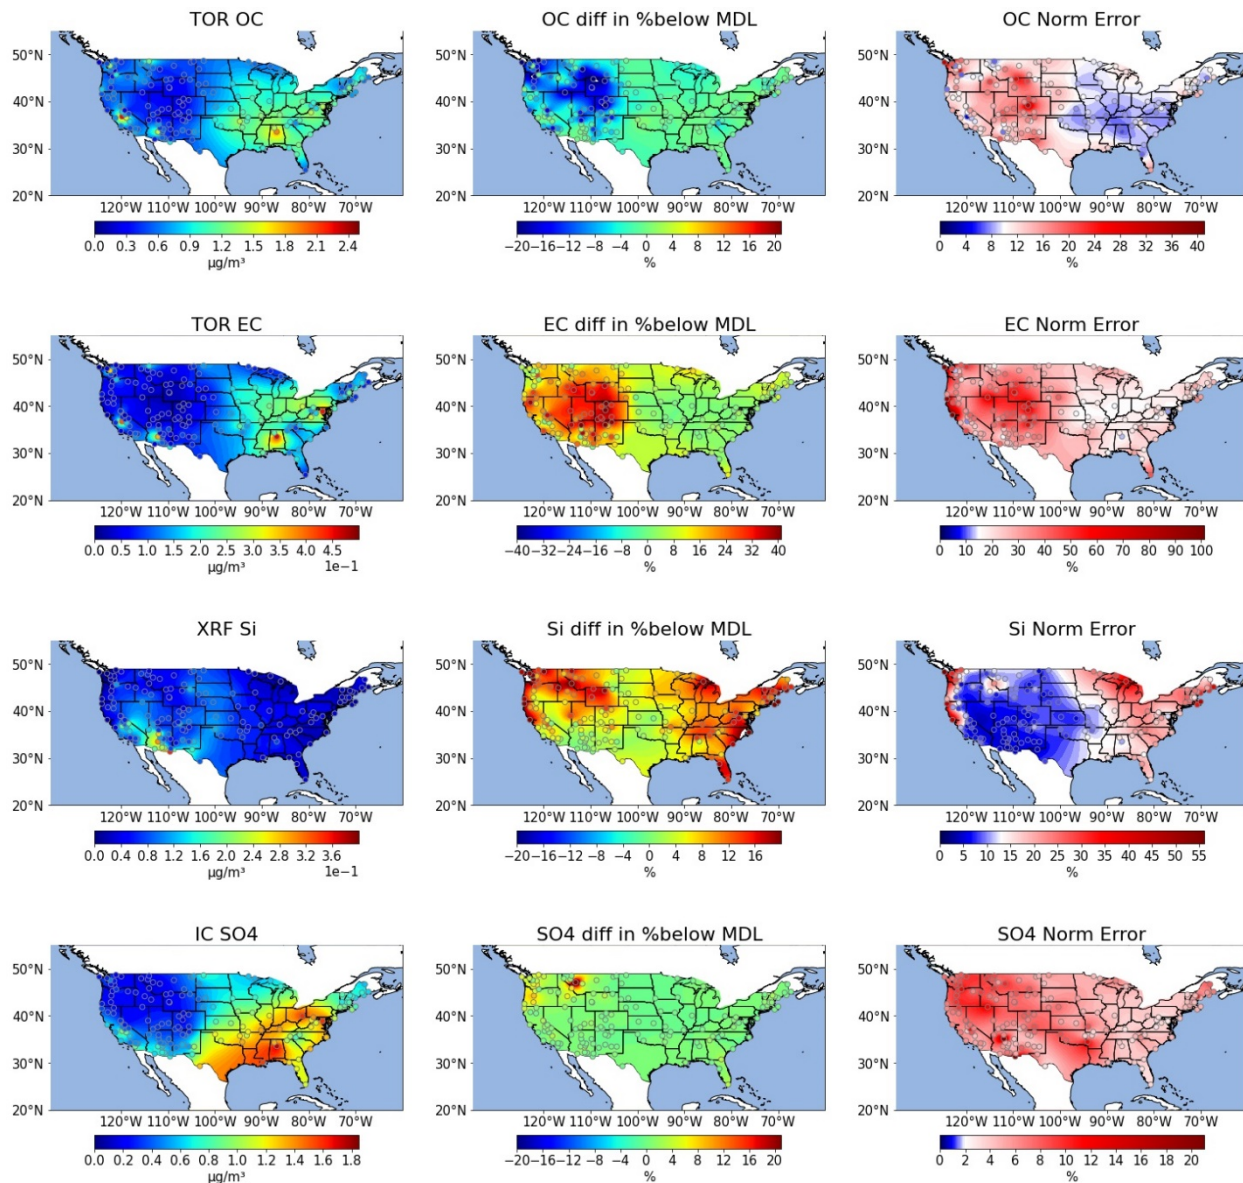

509 ¹Median relative error for TOR, XRF, IC and gravimetric analysis. OC, EC and TC median relative error estimated
 510 from collocated sampling as measurement error/uncertainty is not reported by IMPROVE for this components.
 511 For all other components, the normalized error was calculated as the uncertainty divided by the concentration
 512 prior to selecting the median. BC is not reported by IMPROVE so measurement error is not estimated.

513 In addition to OC, EC and TC, light absorption which is predominantly due to black carbon, is also
 514 a measure of one fraction of the carbonaceous aerosol. FT-IR calibrations are found to be
 515 adequate for replicating HIPS BC measurements (Section S9). As expected, the corresponding
 516 model is similar in performance to ~~its~~ EC with R² and relative error of 0.920 and 23.3 %,
 517 respectively (Table 1). FT-IR BC residuals have a broader interquartile range than in the HIPS BC
 518 collocated data (Section S9). We attribute this effect to a difference in signal to noise ratio and
 519 sensitivity to chemical interferents between the two analytical techniques. While HIPS exploits
 520 the strong absorption properties of refractory carbon in the visible domain, the weak absorptivity
 521 of EC in the mid-infrared domain (Niyogi et al., 2006) and the presence of overlapping species
 522 makes the quantification less accurate.

523 Further exploration of the regional and site by site quality of data is made via contiguous United
 524 States (CONUS) maps of annual median reference method concentrations (left), difference in %
 525 below MDL between FTIR and reference method (middle) and relative error (right) are shown in
 526 Figure 5 for OC and EC. TC is very similar to OC and BC is very similar to EC.

527 Maps for all constituents with annual median FTIR and reference method concentrations, as well
528 as annual median prediction metrics are shown in Section S10.

529

530

531 Figure 5. Annual median reference method concentrations (left), difference in % below MDL
 532 (middle) and normalized relative error (right) per site for OC, EC, silicon, and sulfate for CONUS
 533 for 2015. For the MDL plot, sites in green and blue indicate that the FTIR has the same or fewer
 534 samples below MDL than the reference method. Sites in yellow and red have more samples
 535 below MDL for FTIR than for the reference method. For the relative error maps, the median
 536 relative error of the reference method estimated using methods described in Table 1 is
 537 white. For sites in blue, FTIR has lower relative error than the reference method and sites in
 538 red are higher.

539 Annual median maps of FT-IR OC and TOR OC as well as maps of FT-IR EC and TOR EC
540 (Supplemental material S10) are nearly identical.- As shown in Figure 5, annual median OC and
541 EC concentrations are highest at the four urban IMPROVE sites of Seattle, WA, Fresno, CA,
542 Phoenix, AZ and Birmingham, AL than the rural sites and are higher in the east than in the west.
543 For OC, the relative error is lower than the TOR relative error in the east (where concentrations
544 are higher) and higher than TOR relative error in the west. OC has an equal or lower number of
545 samples below MDL than TOR at all sites. For EC, FTIR relative error is higher than TOR relative
546 error at almost all sites. The percentage of samples of EC that are below MDL for FTIR is similar
547 to are slightly higher than TOR in the eastern US where EC concentrations are higher and are
548 significantly higher than TOR in the western US where concentrations are lower. These
549 patterns indicate that FTIR does not add error to OC measurements when concentrations are
550 above 0.75 $\mu\text{g}/\text{m}^3$ but does add some error at lower OC concentrations and for EC
551 measurements.

552 3.3.2 Elemental oxide predictions

553
554 Taking advantage of known mineral absorbance bands in the mid-infrared range (Hahn et al.,
555 2018; Madejová and Komadel, 2001; Senthil Kumar and Rajkumar, 2013) (Section S9), Multilevel
556 calibrations for soil elements were evaluated for the five crustal elements commonly used to
557 estimate soil: silicon, aluminum, calcium, titanium, and iron (Table 1 and Fig. 4 for Si and Ti). All
558 models present a satisfactory agreement between XRF and FT-IR predicted concentrations ($R^2 >$
559 0.94). The quality of prediction of the elemental oxides falls into two groups. The first group
560 includes silicon, aluminum and calcium and is characterized by moderate relative errors (11 – 13
561 %), similar in magnitude to the FT-IR OC model (12 %) and have similar errors to XRF
562 measurements. This indicates that like OC and TC, on-average FT-IR does not add additional
563 uncertainty. The second group includes titanium and iron which have larger relative errors (20.9
564 – 24.8 %), analogous to HIPS BC and EC models (23.3 – 30 %). Comparing residuals to collocated
565 XRF measurements (Section S9) shows that the FT-IR based models have a larger interquartile
566 range. For Fe, XRF uncertainty is quite low and FT-IR adds additional uncertainty to the
567 measurement. XRF Ti measurements have higher error than the other elements but there is an
568 incremental increase in error due to FT-IR. In addition, cross plots of titanium concentrations
569 show a bifurcation (Fig. 4). While most samples fall near their expected titanium concentration,
570 samples collected at the Sycamore Canyon (AZ) site present a systematic negative bias, consistent
571 across years, tentatively attributed to a site-specific soil composition not accounted for by the
572 Limited calibration. Takahama et al. (2019) demonstrated several methods to identify the
573 possible occurrence of anomalous predictions in OC and EC based on comparison of new sample
574 spectra to calibration spectra based on projected PLS scores and regression residual vectors.

575 These samples with systematic negative bias in titanium predictions can presumably be identified
576 using such an approach, provided that compositional differences are detected in the IR spectrum.
577 Although distinct IR fingerprints exist, FT-IR calibrations for quantifying mineral contents should
578 be interpreted with care as specific elements may be indirectly quantified through their
579 correlation with another element even in the absence of clear IR signature (Hahn et al., 2018).
580 For instance, the variable importance in projection (VIP) scores for the Si, Al, and Ti calibrations
581 suggests use of similar spectral variables, with small differences, for prediction of these species
582 (Section S9). However, the 21 GMM sites coverage still meet the necessary requirements for
583 providing a reliable insight into soil composition in the IMPROVE network.

584 Figure 5 shows the distribution of concentrations of XRF Si across CONUS. The highest annual
585 median concentrations are in the southwest. Similar patterns are found for Al, Ca, Ti and Fe
586 except that high Fe concentrations are also observed at the urban sites, particularly Fresno, CA
587 and Birmingham, AL (Figures S10-6 through S10-9). For Si, FTIR normalized error is lower than
588 XRF in the west where concentrations are higher. For Ca, Ti and Al, FT-IR normalized error is
589 lower only in the southwest. For Fe, FT-IR is above XRF normalized error. The percentage of
590 samples below MDL are similar to XRF (0-10% different) in the southwest and central US and
591 modestly higher (15-20%) in the northwest and eastern US for Si. For Fe, the spatial pattern is
592 similar but the FTIR % below MDL is up to 50 % higher than XRF. However, for Al, Ca, and Ti, FTIR
593 percent below MDL is approximately the same or lower than XRF at all sites.

594 3.3.3 Inorganic ions

595 The two most abundant inorganic anions quantified in the network: nitrate and sulfate can also
596 be measured by FT-IR (absorption bands used for prediction are discussed in Section S9). FT-IR
597 sulfate concentrations display a satisfactory agreement with the reference IR measurements
598 (Fig. 4). Model performance metrics include R^2 above 0.98 and relative error of 6 %. The relative
599 error is the same as for FT-IR $PM_{2.5}$ and lower than OC, TC, and Si (Table 1). However, IC
600 measurements have even lower error than FT-IR sulfate. Compared to sulfate, FT-IR nitrate
601 concentrations (Section S9) are characterized by a moderate drop in the overall model
602 performance ($R^2 = 0.927$) while relative bias and error exceed 15 % and 50 %, respectively and
603 the error far exceeds reference IC nitrate measurement error. A direct comparison against
604 differential nitrate concentrations at collocated sites highlights the broad uncertainty in
605 determining nitrate content from PTFE filters (Section S9, Figure S9-3). Unlike nylon filters for
606 which nitrate is trapped on the surface, nitrate is known to evaporate from PTFE filters and
607 the extent of volatilization is dependent on temperature and relative humidity during and after
608 sampling. This causes a discrepancy between the mass of nitrate deposited onto the nylon filter
609 and the mass of nitrate on the PTFE filter (Eldred and Ashbaugh, 2004), making therefore FT-IR
610 calibrations with the nitrate measurements by IC from nylon filters as the reference method
611 error-prone should be used with caution. Although there are physical limitations to measuring

612 ambient nitrate on PTFE filters, a measure of nitrate on PTFE filters which corresponds to its
613 contribution to the gravimetric mass is useful for mass closure and data validation. FT-IR has
614 been shown to be useful for measuring and evaluating nitrate under controlled laboratory
615 conditions (ex. Wu et al., 2007). For network samples, FT-IR based nitrate concentrations,
616 measured in this way, should be considered with caution. A possible alternative is to develop a
617 set of nitrate could be measured using laboratory calibration standards and this effort will be
618 addressed in future work of ammonium nitrate for FT-IR calibration. The nitrate mass on the
619 PTFE would be useful for mass closure exercises on the PTFE filter but would not adequately
620 assess particulate nitrate in the atmosphere.

621 The annual median sulfate concentration by IC is shown in Figure 5. Annual median
622 concentrations are highest in the southeast and eastern US with a gradient in concentrations
623 observed across the midwest. The median relative error for sulfate by IC is only 2% and all FTIR
624 sulfate has higher relative error. There are however, spatial differences. In the eastern US
625 sulfate relative error is less than 15% but in the west, it is considerably higher, peaking in
626 Wyoming where concentrations are very low. The % below MDL is very similar for FTIR and IC
627 across the continent. Due to volatility of nitrate, the nitrate metrics for FTIR are poor compared
628 to sulfate (Figure S10-11).

629 3.3.4 PM_{2.5} mass predictions

630 Since the major aerosol species are shown to be reasonably well measured by FT-IR, it was
631 anticipated that PM_{2.5} mass calibration would perform well. The PM_{2.5} model presents reliable
632 filter mass predictions ($R^2 = 0.985$) characterized by relative bias and error that are 1/3 to 1/2 of
633 those for OC and on par with gravimetric error (Table 1). The cross plot of gravimetric mass and
634 FT-IR predictions (Fig. 4) and maps of predictions metrics (Figure S10-12) shows that PM_{2.5} mass
635 can be accurately predicted across a broad concentration range indicating that FT-IR spectra of
636 PTFE filters do not contain interferences or other limitations that make PM mass predictions error
637 prone.

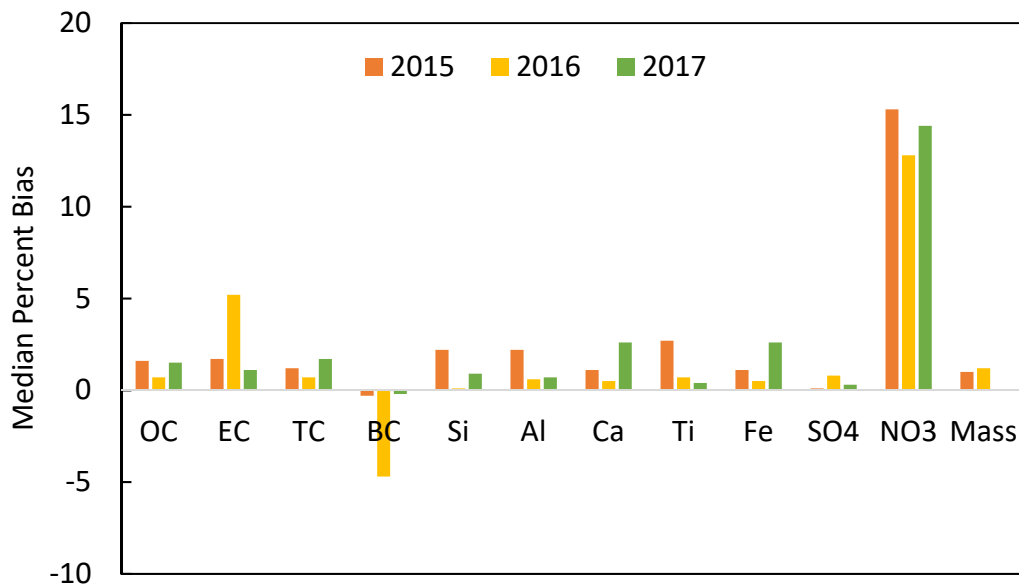

638 3.4 Long term stability

639 Finally, Multilevel calibrations are extended to 2016 and 2017 to evaluate the inter-year
640 consistency and determine if the assumptions behind Limited Sites and Biomass Burning models
641 remain valid over time. For each sampling year, new calibrations were developed following the
642 framework established for 2015. Models were recalibrated with data from the 21 sites and
643 biomass burning samples were detected by the functional group screening procedure. Fig. 65
644 shows the median relative bias (top) and error (bottom) for the three years of data (cross plots
645 and prediction metrics shown for all predicted species for 2016 and 2017 in Section S1140).

646 These results indicate that the modeling methodology provided reasonably consistent results
647 across all three years.

648 Normalized bias for most species is below 3% and normalized error is consistent for all species
649 across all three years. The relative bias for EC and BC are similar to other species in 2015 and
650 2017 but in 2016 they are larger in magnitude than the other two years and different in sign.
651 2016 is the first year of TOR data from the multiwavelength TOR instruments (Chow et al., 2015)
652 so higher bias could be potentially be related to the new instruments. However, the HIPS
653 instrument was overhauled beginning in 2017 which provides no explanation for high bias in 2016
654 (http://vista.cira.colostate.edu/improve/Data/QA_QC/Advisory/da0041/da0041_HIPSmodifications.pdf).
655 Further, the EC and BC calibrations are independent of each other except for using
656 the same filters for calibrations (as all species do) so the fact that the median bias is roughly equal
657 but opposite in sign is not due to codependence of the models.

658 In future work, calibrations models will be updated more frequently than annually with the most
659 recent year of ambient samples which may smooth biases and errors due to changes to
660 atmospheric condition and instrument drift.

661

662

663 Figure 65. (top) Median Percent Bias and (bottom) Median Percent Error for each constituent
 664 measured for each year.

665

666 4 Conclusion

667 In this paper, we investigate the feasibility of an FT-IR method that uses ambient samples as
 668 calibration standards for use by a large monitoring network. In this method, all sites in the

669 network collect PTFE filters for FT-IR analysis. A few select sites, used for calibration, would retain
670 all sampling and analyses of current IMPROVE sites to enable re-calibration of the FTIR method
671 on a routine basis. Re-calibration is especially important as atmospheric changes occur and as
672 conditions in the network evolve over time, for example new reference instruments, new or
673 significantly modified FT-IR instruments, changes to sampling protocol or possibly change in filter
674 material. The validity of such a design was evaluated with all PTFE filters collecting PM_{2.5} aerosols
675 at 161 IMPROVE sites in 2015 and then tested for all filters in 2016 and 2017.

676 A multi-level modeling algorithm was used whereby smoke impacted samples are identified and
677 predicted by one model and the rest of the samples are predicted by another model developed
678 from 21 selected IMPROVE sites. The data from the two models are combined to evaluate
679 performance of the FT-IR method. The selection of sites was performed such that if one of the
680 21 sites ceases to operate, another site, selected from the same compositional cluster can be
681 used for calibration.

682 The cross-plots and prediction metrics indicate that the Multilevel model is equivalent to
683 conventional calibrations built from samples from every available site. Reliable performance in
684 predicted concentrations were reported for a broad range of atmospheric constituents with
685 detectable infrared signatures such as OC, EC, TC, sulfate, soil elements (Si, Al, Ca, Ti, Fe), light
686 absorption, and PM_{2.5} mass. Due to volatilization off the PTFE filter, nitrate measurements were
687 found to be unsatisfactory. The calibration method was developed using data from 2015, and the
688 same methodology was applied to 2016 and 2017. The model performance metrics in all three
689 years were similar. Results across ~61,500 FT-IR spectra highlight the suitability of the Multilevel
690 calibration design to quantify multiple atmospheric PM_{2.5} species in large monitoring networks.

691 This work presents an alternative, lower cost, filter analysis method to measure speciated aerosol
692 in a routine monitoring network. This could be a valuable addition to routine speciated aerosol
693 monitoring networks, such as IMPROVE, by incorporating monitoring sites that collect samples
694 on only a PTFE filter for subsequent analysis. This would provide the opportunity to have a subset
695 of less expensive monitoring site, which could be used for scoping studies to understand the
696 aerosol composition in unmonitored locations. It could also serve as a network cost savings
697 method by having a subset of network sites collect aerosol samples on only a Teflon filter.
698 However, the inability to measure particulate nitrate is a significant deficiency for using this
699 method to replace existing monitoring sites. The FTIR derived aerosol concentrations are also a
700 semi-independent measurement from the routine speciated aerosol measurements. Therefore,
701 routine FTIR measurements would provide valuable QA/QC information for any speciated
702 monitoring network. In addition, FTIR derived concentrations could be used to substitute for
703 missing concentrations in the case where the Teflon sample is valid, but filter samples or analyses
704 on the nylon or quartz fiber filters are not.

705 For IMPROVE's urban counterpart, the CSN network, after evaluation of the quality of predictions
706 in CSN, this framework could be used to accomplish goals similar to those of IMPROVE.
707 Additionally, this method could be used to predict samples collected in the Federal Reference
708 Method (FRM) network which is a PM mass only network. In additionFinally, this method, with
709 appropriate ambient standards, could be applied at other regional or international monitoring
710 networks or sites to provide low-cost comprehensive composition data. As shown in our previous
711 work, additional data, including an estimate of organic matter and its functional group
712 composition, can also be obtained from FT-IR spectra of PTFE filters, further increasing the utility
713 of infrared spectroscopy of aerosol samples.

716 Data is available at <https://doi.org/10.25338/B8TP8V>.

717 6 Author contribution

718 BD developed the software, performed the formal analysis and visualization for much of the
719 manuscript and wrote the original draft of the manuscript, ATW developed software, performed
720 formal analysis and visualization of the GMM work, ST participated in conceptualization,
721 methodology software, visualization and reviewing and editing the manuscript. KMG developed
722 parts of the biomass burning identification methodology. [AAF performed the final visualizations
723 for parts of the paper and was responsible for additional visualizations made to the paper based
724 on reviewer comments.](#) BS, SC and ASW, provided input throughout the project and reviewed
725 and edited the manuscript, AMD conceptualized of and acquired funding for this project,
726 developed methodology, performed project administration and supervision and reviewed,
727 edited and finalized the manuscript.

728 7 Competing interests

729 The authors declare that they have no conflict of interest.

730 8 Acknowledgments

731 The authors acknowledge funding from the National Park Service in cooperation with the
732 Environmental Protection Agency (P18AC01222). Thanks to Anahita Amiri Farahani for assisting
733 with figures. We are particularly grateful to Kelsey Seibert for overseeing daily FT-IR operations
734 at the University of California Davis and to the numerous undergraduate students who
735 performed spectra collection from 2015 to 2017.
