16 **Abstract**

17 To enable chemical speciation, monitoring networks collect particulate matter (PM) on different  
18 filter media, each subjected to one or more analytical techniques to quantify PM composition  
19 present in the atmosphere. In this work, we propose an alternate approach that uses one filter  
20 type (teflon or polytetrafluoroethylene, PTFE, commonly used for aerosol sampling) and one  
21 analytical method, Fourier Transform Infrared (FT-IR) spectroscopy to measure almost all of the  
22 major constituents in the aerosol. In the proposed method, measurements using the typical  
23 multi-filter, multi-analytical techniques are retained at a limited number of sites and used as  
24 calibration standards. At all remaining sites, only sampling on PTFE and analysis by FT-IR is  
25 performed. This method takes advantage of the sensitivity of the mid-IR domain to various  
26 organic and inorganic functional groups and offers a fast and inexpensive way of exploring sample  
27 composition. As a proof of concept, multiple years of samples collected within the Interagency  
28 Monitoring of PROtected Visual Environment network (IMPROVE) are explored with the aim of  
29 retaining high quality predictions for a broad range of atmospheric compounds including total  
30 mass, organic (OC), elemental (EC) and total (TC) carbon, sulfate, nitrate and crustal elements.

31 Findings suggest that models based on only 21 sites, covering spatial and seasonal trends in  
32 atmospheric composition, are stable over a three year period within the IMPROVE network with  
33 acceptable prediction accuracy ( $R^2 > 0.9$ , median bias less than 3%) for most constituents. The  
34 major limitation is measuring nitrate as it is known to volatilize off of PTFE filters. Incorporating  
35 additional sites at low cost, partially replacing existing, more time and cost intensive techniques  
36 or using the FT-IR data for quality control, are among the potential benefits of one-filter, one-  
37 method approach.

## 38 1 Introduction

39 In the United States, filter-based chemical speciation of ambient aerosols has been in operation  
40 for decades to quantify trends, assess transport and atmospheric transformation, identify  
41 sources of air pollution, evaluate impacts of pollution regulations, assess impacts on visibility,  
42 radiative forcing, human and ecosystem health and evaluate atmospheric and climatological  
43 models. The two federally funded speciation networks, the Interagency Monitoring of PROtected  
44 Visual Environments (IMPROVE) and the Chemical Speciation Network (CSN) collect 24-hour filter  
45 samples using three filter media: polytetrafluoroethylene for analysis by gravimetry, hybrid  
46 integrating plate and sphere (HIPS), and x-ray fluorescence (XRF), quartz for thermal optical  
47 reflectance (TOR) and nylon for ion chromatography. Over the decades of operation, the  
48 analytical methods have evolved with efforts to maintain consistency in trends while also  
49 adopting improved methodology and retiring obsolete equipment. Impacts of many of these  
50 changes have been addressed in the literature (Hyslop et al., 2015, 2012; White et al., 2016;  
51 Zhang et al., 2021; Chow et al., 2007a, 2015) and in data advisories posted on the IMPROVE  
52 website (<http://vista.cira.colostate.edu/Improve/data-advisories/>).

53 In this paper, we explore the use of Fourier transform-infrared spectroscopy (FT-IR) to reproduce  
54 most of the existing speciation data based on the optical activity of the components in the mid-  
55 IR. The number and bands of organic compounds are numerous, but generally group frequencies  
56 can be found above  $1500\text{ cm}^{-1}$  and compound-specific spectral patterns (“fingerprint region”)  
57 below this frequency; down to approximately  $700\text{ cm}^{-1}$  (for example, Weakley et al., 2016; Mayo  
58 et al., 2004). Graphitic carbon displays peaks near  $1600\text{ cm}^{-1}$  due to lattice defects (Tuinstra and  
59 Koenig, 1970; Friedel and Carlson, 1971), displacement vibrations near  $868\text{ cm}^{-1}$  (Nemanich et  
60 al., 1977), and a broad, sloping absorbance between  $4000$  and  $1500\text{ cm}^{-1}$  due to the tail of the  
61 electronic transition more strongly observed in the UV (Parks et al., 2021). Inorganic substances  
62 containing polyatomic ions such as sulfate, nitrate, and ammonium have strong vibrational  
63 modes above  $600\text{ cm}^{-1}$  (Mayo, 2004). Crystalline and amorphous geological minerals in the form  
64 of oxides (which include hydroxides and oxyhydroxides) have distinct internal vibrational modes  
65 influenced by the electronegativity of the metal to which the oxygen is bonded (Busca and Resini,  
66 2006; Chukanov and Chervonnyi, 2016; Margenot et al., 2017).

67 FT-IR spectra with partial least squares (PLS) calibrations have been shown to reproduce OC and  
68 EC concentrations using organic and graphitic carbon absorption bands, respectively, at a limited  
69 number of sites in the IMPROVE network (Dillner and Takahama, 2015a, b; Reggente et al., 2016),  
70 CSN (Weakley et al., 2016, 2018a) and FRM (Weakley et al., 2018b). Takahama et al. (2019)  
71 reviews these findings and the overall framework to be used for the two phases of such statistical  
72 calibrations: model building (sample selection, spectral preparation, model generation, model  
73 selection, model evaluation, and model understanding) and operation (error anticipation and  
74 model updating). Inorganic ions and geological mineral absorption bands have been used for

75 chemical speciation of these substances using FT-IR in prior studies (e.g., Cunningham et al.,  
76 1974; McClenny et al., 1985; Pollard et al., 1990; Bogard et al., 1982; Foster and Walker, 1984).

77 Organic absorption bands are useful for measuring OC but also provide spectral information  
78 needed to add detailed knowledge of composition not currently measured in air quality  
79 monitoring networks – such as organic matter (OM) and organic functional group composition –  
80 which is the subject of other work (Reggente et al., 2019; Boris et al., 2019, 2021; Burki et al.,  
81 2020). Such calibrations, also combined with factor analytic approaches, can provide source  
82 characterization on par with more costly mass spectrometric techniques (Boris et al., 2021;  
83 Yazdani et al., 2021a; Hawkins et al., 2010; Takahama et al., 2011; Liu et al., 2012; Corrigan et al.,  
84 2013).

85 Although FT-IR shows promise for measuring many constituents in aerosol, it is not without its  
86 challenges. One limitation is that not all PM constituents can be measured, or measured with  
87 high sensitivity, from the FT-IR spectrum. For instance, NaCl and MgCl<sub>2</sub> do not have IR-active  
88 substituents. While a multitude of spectral signatures associated with mineral dust arise from  
89 their constituent bonds – e.g., the metal-oxygen bonds in oxides (the oxide form is explicitly  
90 assumed in estimating dust mass concentrations from elemental composition for the IMPROVE  
91 network), some must be predicted from correlation with other constituents (e.g., some forms of  
92 iron) if IR-activity is lacking. Other substances are IR-active but have weak responses, such as  
93 graphitic carbon (Niyogi et al., 2006; Parks et al., 2021). The absorption and scattering by the  
94 PTFE filter also pose challenges for quantitative analysis. The PTFE-based material changes over  
95 time due to change in manufacturer or manufacturing process, and is difficult to fully characterize  
96 a priori or treat with simple blank subtraction techniques. PTFE absorption limits full access to  
97 the range of spectroscopic information in the mid-IR, for instance in the region of carbon-oxygen  
98 bonds that can lead to less than full recovery of OM mass. Additionally, scattering leads to  
99 broadly-varying slope in the group frequency region. This scattering artifact is minimized by  
100 baselining (Kuzmiakova et al., 2016) and using many standards that have a range of scattering  
101 and absorption observed in the network (Debus et al., 2019), yet these techniques can still lead  
102 to errors in quantification. Weakley et al., (2018b) demonstrated that calibrations built using one  
103 brand of filter can be accurately extended to another brand of PTFE filter with numerically  
104 marginal but statistically significant increase in method error (e.g., +2% error for  $\alpha=0.05$ ).  
105 However, these studies are insufficient to generalize findings to all types of sampling filters.

106 The goal of this work is to assess the capability of using FT-IR to measure the aerosol chemical  
107 composition at all IMPROVE sites. FT-IR quickly and non-destructively collects information-rich  
108 spectra from routinely collected PTFE filter samples. Ambient samples from strategically-  
109 selected IMPROVE sites are used for calibration and reasonably mimic the composition, matrix  
110 effects and substrates of the unknowns, all of which theoretically lead to accurate estimations of  
111 concentrations. Using all samples from selected sites reduces maintenance, shipping, processing

112 and coordinating required to maintain intermittent quartz and nylon filter sampling at every site.  
113 Sites are selected using data from 2015 and are used for calibrating samples from 2015-2017.  
114 Samples from all other (non-calibration) IMPROVE sites are predicted and compared to routine  
115 IMPROVE data to assess the quality of prediction. Aerosol components to be measured include  
116 TC, OC, EC, inorganic ions, soil elements, particulate mass, and light absorption.

## 117 2 Methods

### 118 2.1 Network data

119 IMPROVE samples collected every third day at all North American sites (Section S1) from January  
120 2015 through December 2017 are included in this study. Fine particulate matter (aerodynamic  
121 diameter less than 2.5 micrometers) is deposited on 25 mm diameter filters  
122 polytetrafluoroethylene (PTFE, Teflo, Pall Gelman) and quartz filters by sampling air at a nominal  
123 flowrate of 22.8 liters per minute from midnight to midnight local time. Parallel 37 mm nylon  
124 filters are collected at the same flow flowrate. PTFE filters are analyzed by multiple instruments  
125 and archived for future analysis. Nylon filters and a portion of each quartz filter undergoes  
126 destructive analysis and a remaining part of the quartz filters are retained for archive.

127 Over the period covered in this study, two different TOR instruments were employed to measure  
128 OC, EC and TC. Quartz filters sampled prior to 2016 were analyzed on a DRI Model 2001 thermal  
129 optical carbon analyzers (Chow et al., 1993) while filters collected beginning in January of 2016  
130 were analyzed on a DRI Model 2015 multi-wavelength thermal optical carbon instrument (Magee  
131 Scientific – Berkley, USA)(Chow et al., 2015). Both instruments use the IMPROVE\_A protocol  
132 (Chow et al., 2007b), which outlines the temperature step, gaseous environment in the  
133 instrument and that reflectance is used to define the split point between OC and EC. To correct  
134 for gas phase adsorption onto the quartz filter, the monthly median field blank OC concentration  
135 is subtracted from each OC measurement during that sample month. Carbon concentrations are  
136 reported in  $\mu\text{g}/\text{m}^3$ .

137 An in-house Hybrid Integrating Plate and Sphere (HIPS) system evaluates light absorption from  
138 the PTFE filters in the IMPROVE network (White et al., 2016). In this work, the measured  
139 absorption coefficient ( $F_{abs}$ ) is converted into a TOR EC equivalent concentration assuming a  
140  $F_{abs} / EC$  ratio of  $10 \text{ m}^2\text{g}^{-1}$  (Malm et al., 1994). The resulting value, referred to as HIPS Black  
141 Carbon (HIPS BC), is used as part of a quality control procedure to evaluate potential outliers in  
142 TOR EC measurements.

143 Data from gravimetry and X-ray fluorescence (XRF) analysis obtained from PTFE filters and ion  
144 chromatography from the nylon filters are also used in this study. Additional information on  
145 routine IMPROVE methods can be found on the IMPROVE website  
146 (<http://vista.cira.colostate.edu/improve/>). IMPROVE data are available online at  
147 (<http://views.cira.colostate.edu/fed>).

## 148 2.2 Outlier removal

149 Data were screened for outliers to eliminate their influence on the results. Out of the ~61,500  
150 total number of samples in the three-year period, fewer than 800 were excluded from the  
151 analysis due sampling issues or missing TOR, XRF or IC data. In addition, 65 samples collected at  
152 the Wheeler Peak Wilderness (New Mexico) site between November 2015 and April 2016 were  
153 excluded due to an EC contamination caused by a diesel-powered ski lift.

154 Potential outliers in TOR measurements were investigated by regressing TOR EC against HIPS BC  
155 concentrations. Samples with differences exceeding a predefined threshold value ( $0.68 \mu\text{g}/\text{m}^3$ )  
156 were flagged as potential outliers (section S2). The status of these samples was confirmed by  
157 building separate TOR EC and HIPS BC calibrations. The poor agreement between TOR EC and FT-  
158 IR EC concentrations contrasts with the nearly 1:1 relationship HIPS BC and FT-IR BC predicted  
159 values indicating that TOR EC concentrations were likely compromised (Section S2). For the  
160 period considered in this study, 112 samples with faulty TOR EC values were identified and  
161 excluded from further analysis. The number of valid sample spectra retained in this study is  
162 61,462.

## 163 2.3 Fourier-transform infrared (FT-IR) analyses

164 Since 2015, all PTFE in the IMPROVE network have been analyzed by infrared spectroscopy for  
165 research and evaluation purposes. FT-IR measurement occurs after gravimetric analysis and prior  
166 to XRF and HIPS to prevent possible loss of volatile species under the mild vacuum in XRF. Three  
167 FT-IR spectrometers including one Tensor 27 and two Tensor 2 instruments (Bruker Optics,  
168 Billerica, MA) equipped with a pre-aligned mid-IR source and a liquid nitrogen-cooled wide-band  
169 mercury cadmium telluride (MCT) detector were used for spectra acquisition in the range  $4000 -$   
170  $420 \text{ cm}^{-1}$  by averaging 512 scans at a nominal resolution of  $4 \text{ cm}^{-1}$ . The single beam signal  
171 associated with each PTFE filter was converted to an absorbance spectrum using the most recent  
172 zero reference signal, updated hourly.

173 Previously, it was determined that calibration transfer between multiple FT-IR instruments is not  
174 required as long as their spectral response is carefully matched by controlling a set of key  
175 environmental and instrumental parameters (Debus et al., 2019). Briefly, each mercury cadmium  
176 telluride (MCT) detector is connected to an automatic liquid nitrogen micro dosing system  
177 (NORHOF, Ede, Netherlands) designed to improve signal stability and maintain a high signal to  
178 noise ratio. The repeatability and reproducibility of the filter position relative to the IR beam is  
179 controlled via a house-built sample chamber ( $4.0 \times 5.1 \times 4.5 \text{ cm}$ ) mounted inside the instrument  
180 sample compartment. Details regarding the chamber design have been published elsewhere  
181 (Debus et al., 2019). Finally, the contribution of water vapor and carbon dioxide to the signal was  
182 minimized by continuously purging both the sample chamber and the optical bench with a VCD  
183 Series  $\text{CO}_2$  adsorber / dryer system (PureGas LLC, Broomfield, CO). For each sample, the  
184 acquisition procedure involves a 4 minutes purge period followed by a spectrum collection lasting

185 about 1 minute. An in-house macro interfaced to the OPUS software (Bruker Optics, Billerica,  
186 MA) controls each step. PTFE filters were measured in transmission mode without sample  
187 preparation. No interpolated data (from zero-filling) are included in the final raw spectra.  
188 Collected spectra are subjected to weekly quality control procedures detailed in (Debus et al.,  
189 2019). Duplicate and replicate measurements were also performed to evaluate instrument  
190 stability and found to be within +/- 10%.

#### 191 2.4 Multivariate Calibration Model - Partial Least Squares (PLS) Regression

192 While the presence of certain category of atmospheric compounds can be identified qualitatively  
193 from an FT-IR spectrum, an accurate quantification of their concentration requires calibration.  
194 PLS is a commonly used algorithm to relate a multi-wavenumber measurement to any particular  
195 sample properties such as concentration (Wold et al., 2001). In brief, PLS maximizes the co-  
196 variance between a set of response variables (species measurements) and a reference  
197 measurement (FT-IR spectra) from which equivalent predicted values are desired. In so doing,  
198 the optimal combination of response variables best describing the reference measurement is  
199 identified and the selected features are used to build a multivariate calibration. With all least-  
200 squares calibration methodologies, concentration-dependent biases in residuals that are  
201 determined by the quality of fit ( $R^2$ ) and dynamic range of the data are expected due to the nature  
202 of least-squares estimation (Besalú et al., 2006; Draper and Smith, 1998, pp. 63-64,173,638). For  
203 further discussion of these biases, see Section S1.

204 The applicability of PLS to quantify carbonaceous aerosol species (Reggente et al., 2016; Weakley  
205 et al., 2016, 2018a) or functional groups (Boris et al., 2019; Ruthenburg et al., 2014) collected on  
206 PTFE filters in various monitoring networks and field campaigns has been successfully  
207 demonstrated. A complete review of the implementation of PLSR calibration in the framework  
208 of atmospheric particulate matter characterization has been recently published (Takahama et al.,  
209 2019).

210 To evaluate model performance, FT-IR predicted concentrations were regressed against their  
211 reference measurement to quantify residuals and a series of metrics. Reported figures of merit  
212 include the coefficient of determination ( $R^2$ ), bias, error and the method detection limit (MDL).  
213 Residuals are defined as the difference between predicted and reference concentrations, bias  
214 corresponds to the median residual while error is the median absolute residual. To facilitate inter-  
215 model comparison, relative performance metrics were calculated by normalizing the values by  
216 their reference value. FT-IR PLSR calibration MDL was estimated from field blank predicted  
217 concentrations as the 95<sup>th</sup> percentile minus the median residuals, as is done for other species in  
218 the IMPROVE network [http://vista.cira.colostate.edu/improve/wp-](http://vista.cira.colostate.edu/improve/wp-content/uploads/2021/07/IMPROVE-SOP-351_Data-Processing-and-Validation_2021_final.pdf)  
219 [content/uploads/2021/07/IMPROVE-SOP-351\\_Data-Processing-and-Validation\\_2021\\_final.pdf](http://vista.cira.colostate.edu/improve/wp-content/uploads/2021/07/IMPROVE-SOP-351_Data-Processing-and-Validation_2021_final.pdf).  
220 Performance is reported for all samples together regardless if the samples were included in the  
221 calibration. This enables comparison between models with different samples used for calibration.

222 For further insight into model prediction accuracy, the distribution in FT-IR residuals is  
223 qualitatively compared with residuals from collocated measurements. Collocated quartz filters  
224 are collected at the Everglades (FL), Hercules-Glades (MO), Medicine Lake (MT) and Phoenix (AZ)  
225 sites. Similarly, collocated Teflon filters are sampled at Mesa Verde (CO), Proctor Maple Research  
226 Facility (VT), Saint Marks National Wildlife Refuge (FL), Yosemite (CA) and Phoenix (AZ) sites while  
227 collocated nylon filters are featured at the Phoenix (AZ), Frostburg Reservoir (MD), Mammoth  
228 Cave (KY) and San Gabriel (CA) sites.

229 Data handling and analysis was performed in Matlab R2018a (The MathWorks, Inc, Natick, MA,  
230 United States) using the statistics and signal processing toolboxes. PLS was computed via the  
231 libPLS Matlab package (v1.9) (Li et al., 2018).

## 232 2.5 FT-IR Calibrations for Predicting PM Composition

233 This section presents the design of calibrations for quantifying the concentration of major  
234 atmospheric species by taking advantage of the composition-based information embedded  
235 within an FT-IR spectrum. In practice, spectra are calibrated against reference measurements  
236 from TOR, XRF, IC, HIPS and gravimetric analysis with the aim of predicting concentrations of  
237 atmospheric constituents using only spectra of PTFE filters as input.

238 A multilevel model (Snijders and Bosker, 2011; Takahama et al., 2019) is proposed in which  
239 dedicated calibration models for subgroups of samples are constructed, and applied according  
240 to a predetermined selection criterion for each sample. This model considers two subgroups: i)  
241 samples determined to be dominated by biomass burning, which are calibrated with similar  
242 samples, and ii) the remaining samples, which are calibrated with samples from a limited number  
243 of sites.

244 To establish baseline performance metrics for comparison, a “Global model” in which a single  
245 calibration (for each species) is constructed from all samples considered together is described in  
246 Section S1 (Supplement).

247 The first step in the development of the Multilevel model consists of screening for biomass  
248 burning samples. These samples are removed from consideration during the site selection  
249 process. A simple detection method combining estimates of key functional group spectral peak  
250 areas and spectral dissimilarity metrics were used to segregate biomass burning samples from all  
251 other samples. Next, a Gaussian Mixture Model (GMM) was applied to the spectra of all non-  
252 biomass burning samples. The GMM exploits the specificity of the infrared signal for organic and  
253 inorganic species. The GMM was implemented with the aim of clustering the non-biomass  
254 burning FT-IR spectra into groups sharing similar spectral features (Section 2.5.2). Those groups  
255 were later used as part of the methodology for selecting sites with representative atmospheric  
256 composition. Spectra from the year 2015 were used as a benchmark to validate the biomass  
257 burning detection strategy, build the GMM and establish the list of representative sites where

258 multi-filter collection/multi-analyses should be retained (section 2.5.2). The identified biomass  
259 burning samples are used to build a calibration for biomass burning samples (Section 2.5.1).

### 260 2.5.1 Biomass burning model

261 FT-IR spectra were used to estimate functional group areas and calculate spectral dissimilarities  
262 metrics to segregate biomass burning samples from all other samples. Although this paper  
263 focuses on using FT-IR to measure the major aerosol components in routine speciated aerosol  
264 monitoring networks, FT-IR is more frequently used to measure organic functional groups (e.g.  
265 (Russell et al., 2011; Ruthenburg et al., 2014; Boris et al., 2019). Specific regions in the IR spectra  
266 correspond to specific functional groups. Peak areas, calculated from baseline corrected spectra  
267 (see Section S3 for baseline procedure), for carbonyl, OH and CH were used rather than functional  
268 group calibrations for simplicity. Because the relative functional group peak area tends to  
269 increase significantly as the cumulative peak area decreases, typically for low mass deposition  
270 samples, an estimate of spectral dissimilarities, the squared Mahalanobis distance ( $D_i^2$ ), for each  
271 site is also considered to minimize false detection. The Mahalanobis distance (Mahalanobis,  
272 1936; Cios et al., 1998) is a measure of the spectral dissimilarity between a given spectrum at a  
273 site and the mean spectrum at the site. Taking advantage of  $D_i^2$  and relative functional group  
274 areas, a set of criteria were established from observations at known wildfire sites during wildfire  
275 season (O'Dell et al., 2019). First, samples collected under heavy smoke conditions whose spectra  
276 fulfill  $C-H \geq 2\%$ ,  $C=O \geq 15\%$  and  $D_i^2 \geq 3 \overline{D^2}$  were detected (Section S3). This group of spectra  
277 tend to have large  $D_i^2$  values and, consequently, the  $3 \overline{D^2}$  threshold often excludes samples with  
278 low to moderate biomass burning contributions. For a more inclusive detection, spectra from the  
279 first group were removed from consideration, the  $D_i^2$  values are updated for each sample and  
280 the plots were regenerated. The cut-off value for the relative carbonyl functional group area was  
281 lowered to 8 % while other parameters were not changed. Spectra identified by the first and  
282 second rounds are considered biomass burning samples. This procedure is performed for each  
283 site and for each year of sample collection (Section S.3)

284 Recent work has shown that smoke samples may be identified using techniques such as cluster  
285 analysis and labeling (Burki et al., 2020) similar to the GMM used here and through detection of  
286 molecular markers – levoglucosan and lignin – or peak profiles in FT-IR spectra (Yazdani et al.,  
287 2021a, b). For the large data set in this work (~20,000 samples in 2015), cluster analysis  
288 resulted in multiple clusters that could be associated with smoke-impacted samples likely due  
289 to the variations in fuel, oxidation conditions, and contributions from other sources. Therefore,  
290 for this work we selected a single group of smoke-impacted samples based on specific organic  
291 features known to be present in FT-IR spectra. While the criteria for smoke-impact labeling can  
292 be defined differently according to each intended purpose, the method presented here is  
293 demonstrated to sufficiently partition the samples for building accurate submodels to predict  
294 concentrations of PM constituents.

295 While ions and crustal species are not necessary correlated with wildfire emissions, the Biomass  
296 Burning sub-model accounts for interferences that are necessary to track in order to maintain  
297 high prediction accuracy for samples collected on smoky days.

### 298 2.5.2 Limited Sites Model

299 To assess major PM<sub>2.5</sub> composition regimes in the network and to identify representative sites to  
300 use as calibration standards in the Limited Sites model, screening of all FT-IR spectra (except  
301 samples identified as biomass burning samples) across all locations and seasons was performed  
302 by building a Gaussian Mixture Model (GMM) (Bilmes, J. A., 1998; Hastie, T et al., 2009). The basic  
303 idea behind GMM is to group FT-IR spectra into clusters of similar spectral shape using a  
304 probabilistic approach describing the likelihood that any given spectrum belongs to a particular  
305 class. To minimize the concentration dependence and emphasize composition, raw spectra were  
306 transformed to second derivative spectra using a 2<sup>nd</sup> order, 21 point, Savitzky-Golay filter  
307 (Savitzky and Golay, 1964), differenced with filter blank spectra and divided by their respective  
308 Euclidean norm (Bro and Smilde, 2003). Additional details about the GMM pre-processing and  
309 implementation as well as cluster interpretation are provided in Section S4.

310 After classification, a single site per cluster was selected to represent the atmospheric  
311 composition captured in that cluster. For any given cluster, the retained location was defined as  
312 the site with the largest number of classified spectra with the highest probabilities of belonging  
313 to that cluster. To prevent misleading site selection and enhance spatial coverage, the following  
314 set of decision rules were used: *i)* if the same site is representative of two clusters, it is ascribed  
315 to the cluster with the largest number of classified spectra from that site, *ii)* if none of the  
316 retained sites accounts for a given spatial region or known source type in the network, an  
317 additional site with the highest number of classified spectra is selected from a nearby cluster,  
318 and *iii)* only sites under continuous operation between 2015 and 2017 are eligible for selection.  
319 Criteria *ii)* was invoked once to add a site in the Midwest to improve spatial coverage in that  
320 region and to capture prescribed fire emissions in Kansas. All non-biomass burning samples from  
321 selected sites were used as FT-IR calibration standards for all species and all non-biomass burning  
322 samples are predicted with these models. Once established, the selected sites are not re-  
323 evaluated but instead were used in all subsequent years as would occur in practice.

### 324 2.5.3 Application of Multilevel Model

325 The Multilevel model is the combined FT-IR predicted concentrations from the Limited sites and  
326 Biomass burning models. Multilevel modeling will be discussed in the context of carbonaceous  
327 aerosols before extending the modeling to other atmospheric constituents with detectable  
328 infrared signatures. In addition to OC and EC, species evaluated for FT-IR prediction include PM<sub>2.5</sub>  
329 mass, soil elements (silicon, aluminum, calcium, titanium, iron), anions (sulfate, nitrate) and HIPS  
330 BC. As mentioned previously, NaCl is not IR active and so there is no direct measure of seasalt  
331 from FT-IR. Next, the years 2016 and 2017 will be examined to assess the long-term stability of

332 the proposed Multilevel strategy by screening for smoke samples and re-calibrating each year  
333 using the sites selected using 2015 data.

### 334 3 Results and discussion

335 In the following sections, the quality of FT-IR based calibrations for quantifying aerosol  
336 composition across continental US and their long-term applicability to large speciation  
337 monitoring networks will be assessed. Section 3.1 describes the selected calibration samples for  
338 the Biomass Burning and Limited Sites models. In Section 3.2, Biomass Burning and Limited  
339 model performance will be briefly reviewed before exploring the Multilevel FT-IR predictions for  
340 all samples. Initially focused on carbonaceous species on PTFE samples collected in 2015, FT-IR  
341 predictions will be extended to other atmospheric constituents and years.

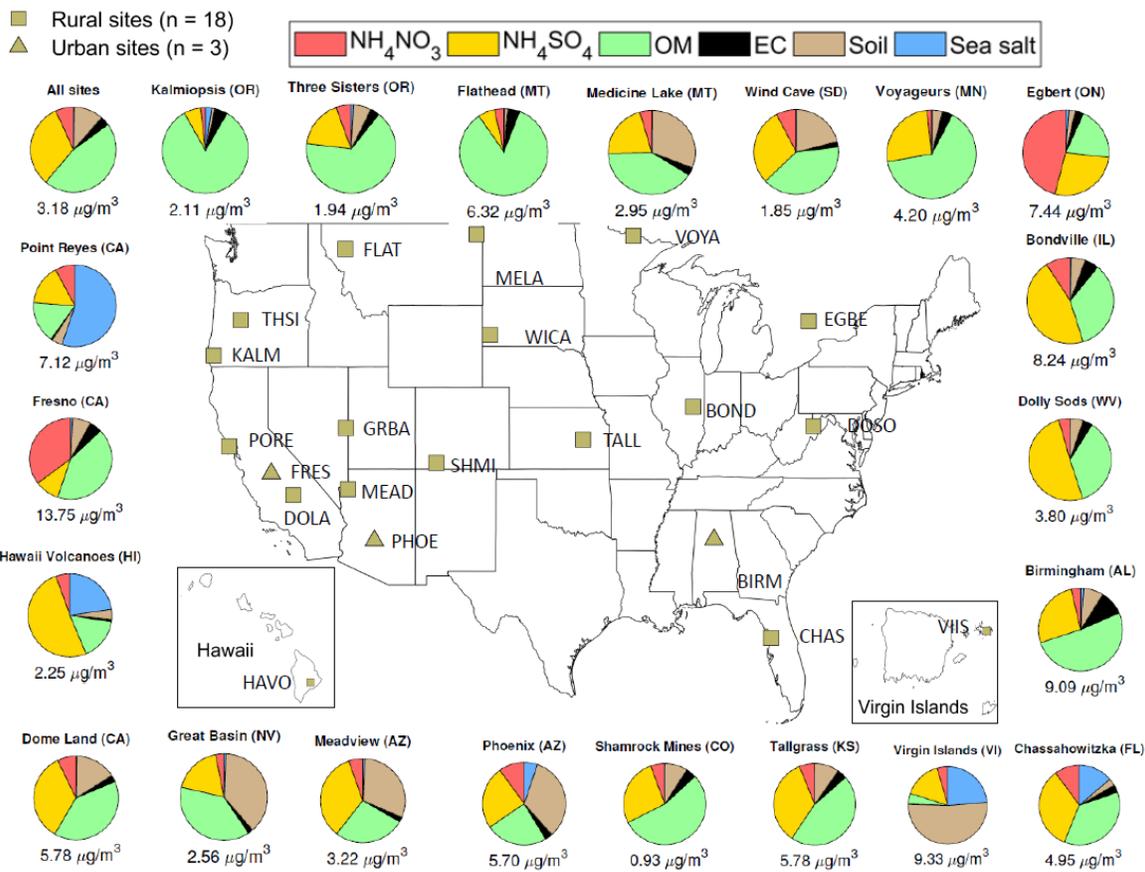

#### 342 3.1 Multilevel modeling – Calibration sample selection

##### 343 3.1.1 Biomass burning sample selection

344 Using the methods described above, 492 samples impacted by biomass burning emissions were  
345 identified in 2015 (2.5 % of the network), 288 samples in 2016 (1.5 %), and 817 samples in 2017  
346 (3.7 %). The mean OC concentration of the biomass burning samples range was 5.6 – 8.3  $\mu\text{g}/\text{m}^3$   
347 with maximum concentrations extending from 44 to 97  $\mu\text{g}/\text{m}^3$  over the three year period.  
348 Similarly, per year, the mean EC concentration varies between 0.6 – 0.9  $\mu\text{g}/\text{m}^3$  with maximums  
349 up to 2.9 – 3.9  $\mu\text{g}/\text{m}^3$ . Mean OC/EC ratios are larger than 7, in agreement with past literature  
350 (Schichtel et al., 2008; Sorooshian et al., 2011). Analysis of the detected samples shows reliable  
351 spatial and seasonal distributions, consistent with biomass burning emissions predominantly in  
352 summer and fall across the Pacific North West and Northwestern US (Section S3). Two-thirds of  
353 the identified samples were selected (Section S5) as calibration standards for the calibration and  
354 resulting model was applied to the remaining third of the smoke impacted samples.

##### 355 3.1.2 Limited Sites model – clusters and retained sites

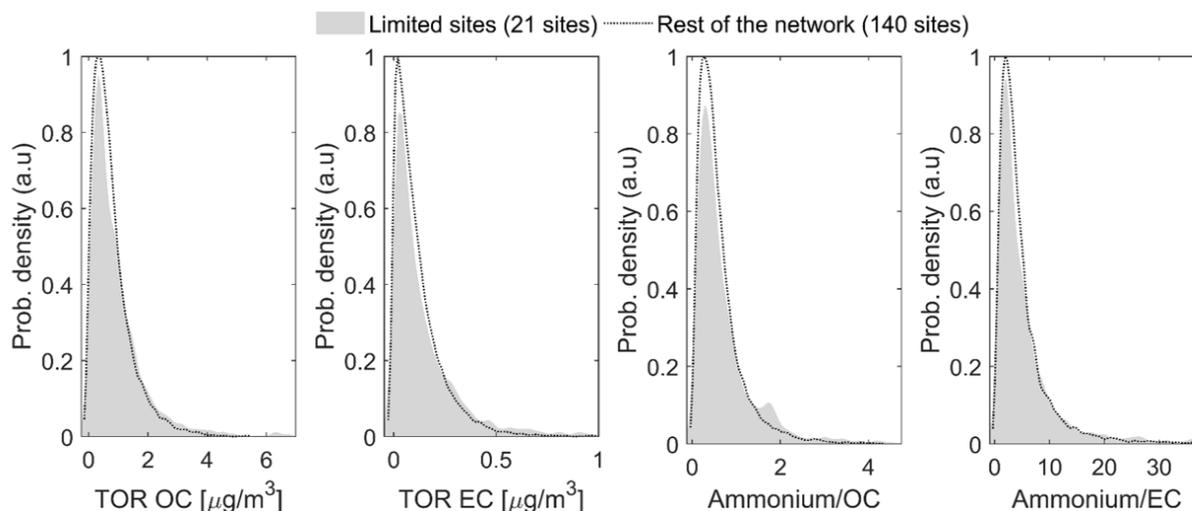

356 Figure 1 shows the spatial distribution and annual average composition (from routine IMPROVE  
357 data) of the 21 sites selected for the Limited sites model calibration. From a spatial standpoint,  
358 retained sites appear reasonably scattered across the network including Hawaii and the Virgin  
359 Islands. Clusters are represented by a distribution of urban and rural sites. One urban cluster is  
360 represented by Fresno and contains mostly urban samples from Fresno and Phoenix. All other  
361 clusters contain mostly rural and pristine sites. However, two other urban sites were retained,  
362 Phoenix and Birmingham. The Phoenix cluster contains samples from the southwest in the  
363 spring. The Birmingham site along with the Tallgrass site represent a non-western cluster in the  
364 spring and summer.

367 **Figure 1:** Spatial distribution, median PM<sub>2.5</sub> concentration and composition of the 21  
 368 representative sites. The composition is obtained from routine IMPROVE (non-FT-IR)  
 369 measurements and the IMPROVE reconstructed fine mass equation  
 370 (<http://vista.cira.colostate.edu/Improve/reconstructed-fine-mass/>) to calculate soil and seasalt.  
 371 Sites are identified by the four letter site code which is the first four letters of a single word site  
 372 name (Fresno = FRES) or the first two letters of the first and second word for two word site names  
 373 (Dome Land = DOLA). The top left pie chart representing the median PM<sub>2.5</sub> composition across  
 374 all sites and samples is given for comparison.

375 The clusters are also seasonally distributed (Section S6): five clusters are dominated by fall -  
 376 winter samples, ten clusters containing summer samples (along with varying number of spring  
 377 and fall samples), two clusters are predominately spring and one is spring - fall. Three clusters  
 378 have little seasonality.

379 Because FT-IR spectra are clustered based on composition, the first step in assessing the  
 380 representativeness of the 21 sites is to compare the concentration ranges. For this purpose,  
 381 distributions in TOR OC and EC concentrations excluding biomass burning samples are compared  
 382 for the 21 sites used for calibration and the 140 remaining sites. In Fig. 2, the two probability  
 383 density functions are very similar for both OC and EC despite large differences in sample  
 384 populations (2572 and 16,543, respectively). In addition to matching the range of carbonaceous  
 385 concentrations observed in the rest of the network, the presence of species interfering with  
 386 organic functional groups should also be accounted for by the calibration. Because ammonium  
 387 absorptions overlap with carbonaceous absorptions, situations where ammonium to OC and  
 388 ammonium to EC ratios are different between calibration samples and samples to be predicted  
 389 were associated with additional sources of bias and error (Dillner and Takahama, 2015a, b).  
 390 Although not measured in IMPROVE, ammonium concentration is approximated from nitrate and  
 391 sulfate assuming both species are fully neutralized. The corresponding probability distribution in  
 392 Fig. 2 confirms the equivalence between the ranges of ammonium/OC and ammonium/EC  
 393 concentrations spanned by the Limited sites samples and the overall network. In section S6, Fig.  
 394 S6-3 shows reasonable agreement between the selected sites and the rest of the network for  
 395 PM<sub>2.5</sub> mass, ions, elements and HIPS BC. Together, these results suggest the list of 21 sites is a  
 396 suitable representation of network variations in OC and EC and their relative proportion to  
 397 ammonium, and for all other predicted constituents.

399 **Figure 2:** Comparison of probability density function for OC, EC and ammonium concentrations  
 400 in 2015 between the 21 sites retained for Limited calibration and the rest of the network.

401 The spatial and seasonal as well as the urban and rural diversity supports the compositional  
 402 diversity of the selected sites as shown in Fig. 1. The three urban sites have distinct  
 403 characteristics. At the Fresno, CA site, the composition is dominated by nitrate (35 %) and organic

404 matter (42 %) with an autumn – winter pattern consistent with agriculture and residential wood  
405 burning activities (Ngo et al., 2010) as well as with the formation of secondary aerosols during  
406 stagnation events and a low inversion layer (Watson and Chow, 2002). Phoenix, AZ site features  
407 a strong soil component (33%) associated with spring dust storms and windblown dust and equal  
408 proportions of ammonium sulfate (25 %) and OM (24 %) occurring mostly in spring and summer.  
409 The ammonium sulfate and organic matter has been attributed to regional power production and  
410 traffic (Brown et al. 2007). In contrast, Birmingham samples show little seasonal trend with  
411 elevated OM (52 %) and EC (10 %) fractions originating from various combustion processes  
412 including vehicle exhaust, biomass burning and biogenic secondary organic aerosols (Blanchard  
413 et al. 2016). The other dominant species at this site is ammonium sulfate (26 %), characteristic of  
414 coal burning and industrial activities in the East (Watson et al. 2015).

415 Among rural sites, four noticeable patterns in PM<sub>2.5</sub> composition are distinguishable. The first  
416 corresponds to OM fractions accounting for more than two-thirds of the filter mass. High OM  
417 samples are encountered at four locations in Northwestern US, namely the Kalmiopsis (OR),  
418 Three Sisters (OR), Flathead (MT) and Voyageurs (MT) sites. Samples from Voyageurs (MN) and  
419 Flathead (MT) sites are from Summer-Fall and present elevated median PM<sub>2.5</sub> concentrations  
420 (4.20 µg/m<sup>3</sup> and 6.32 µg/m<sup>3</sup>, respectively) and very large percentage of OM consistent with  
421 biomass burning emissions. Kalmiopsis (OR) and Three Sisters (OR) samples have a lower and  
422 nearly identical median PM<sub>2.5</sub> concentration (≈ 2 µg/m<sup>3</sup>) but differ in their monthly distribution  
423 with the former displaying more winter samples than any other season whereas the later shows  
424 little seasonality.

425 The second type of sites have high OM and sulfate concentrations. Both Shamrock Mines (CO)  
426 and Tallgrass Prairie (KS) sites have larger OM than sulfate content. However, the Colorado site  
427 has more autumn – winter samples, represents samples in the Rockies and Alaska and an overall  
428 small median PM<sub>2.5</sub> concentration (< 1 µg/m<sup>3</sup>). The Kansas site has a majority of spring samples,  
429 representing non-western samples and has a significantly larger PM<sub>2.5</sub> concentration (≈ 6 µg/m<sup>3</sup>)  
430 that is attributed to prescribed burning near the Tallgrass site (Whitehill et al. 2019). Other sites  
431 have higher median sulfate concentrations (~50%) than OM concentrations (~40%) such as Dolly  
432 Sods (WV) and Bondville (IL). The monthly sample distribution indicates seasonal influences:  
433 Bondville (IL) samples are mostly from the summer and the concentrations are relatively high  
434 while the Dolly Sods (WV) site samples are mostly not in the summer with lower concentrations.  
435 Because the spectra were normalized to minimize influence of concentration, these two clusters  
436 likely have different organic composition even though the relative amount of OM is the same.  
437 Finally, situations where sulfate and OM are present in equal proportions (≈ 36 %) are reported  
438 at the Dome Land (CA) and Chassahowitzka (FL) pristine sites mainly featuring spring – summer  
439 and winter samples, respectively.

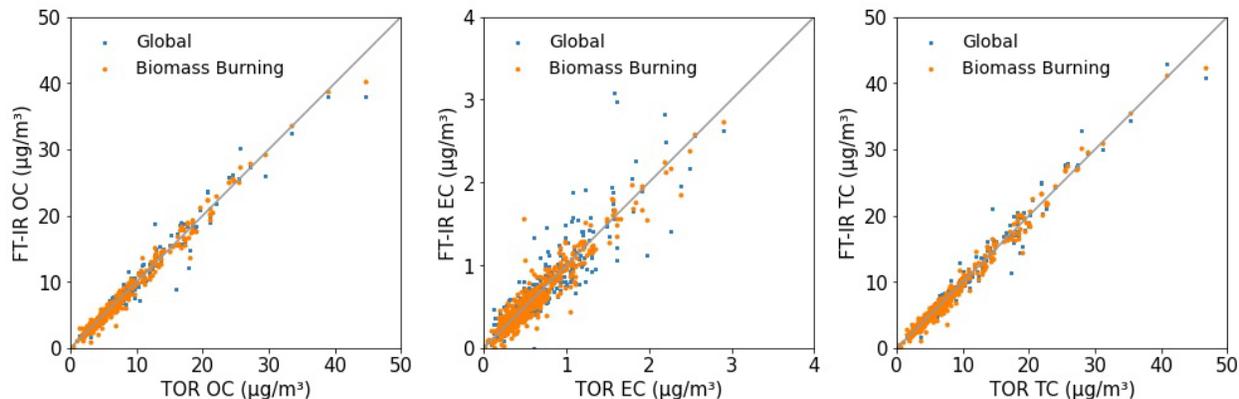

440 A third group of noteworthy PM<sub>2.5</sub> compositions at rural sites contain a large fraction of (> 20 %  
441 of the total mass). The Virgin Islands (VI) site presents the highest soil fraction across the network  
442 52 % of the total PM<sub>2.5</sub> mass, mostly originating from long-range Sahara soil dust transport  
443 (Holmes and Miller 2004). In addition to sulfate and OM, elevated soil contributions are observed  
444 for the Wind Cave (SD), Meadview (AZ), Medicine Lake (MT), and Great Basin (NV) sites with soil  
445 content between 20 and 40%. Although the seasonality is somewhat different between these  
446 sites, they all have many samples from the spring suggesting the dust is due at least in part to  
447 spring dust storms and may also contain resuspended road dust and more localized dust sources.

448 A fourth and final distinct category of PM<sub>2.5</sub> composition includes a collection of sites with unique  
449 local atmospheric pollution sources, specific to those locations. The Hawaii Volcanoes (HI) site  
450 where sulfur emitted as part as the volcanic activity, contains 51% sulfate along with sea salt (23  
451 %). Another location with unique composition is the Point Reyes (CA) site where the sea salt  
452 contribution reaches 55% of the median filter mass for the clustered samples, larger than any  
453 other marine site in the network. Finally, the Egbert (ON) Canadian site, representing the upper  
454 Midwest in winter is dominated by nitrate (46 %), sulfate (27 %) and OM (20 %).

455 As described above, the 21 sites retained for the Limited sites sub-calibration present seasonal,  
456 regional and compositional features consistent with known or expected trends in PM<sub>2.5</sub> across  
457 the network. The median PM<sub>2.5</sub> mass at those locations covers a broad range of concentrations  
458 ranging from 0.93 µg/m<sup>3</sup> to 13.75 µg/m<sup>3</sup> and includes both urban and rural sites. Capturing the  
459 large variability in PM<sub>2.5</sub> composition and concentration is essential to ensure the proposed site  
460 list is a representative subset of the parent network. However, it should be mentioned that the  
461 proposed site list is not unique but is one of the many feasible solutions since sites whose samples  
462 clustered together in the GMM are likely inter-exchangeable.

### 463 3.2 Evaluation of Biomass Burning Model

464 Prior to describing the overall results from the Multilevel model, the Biomass Burning model is  
465 evaluated to determine if the biomass burning model improves predictions for those samples.  
466 To evaluate the quality of the biomass burning model, the predictions are compared to a global  
467 model (section S1) which contains a few samples from all 160 sites which are mostly non-smoke  
468 samples but does contain a few smoke samples. Visual inspection of Fig. 3 suggests the  
469 equivalence of the biomass burning models to the global model at the lower end of the  
470 concentration range. However, improvement in prediction accuracy can be claimed at high  
471 concentrations for the Biomass Burning model. The gain in model performance is subtle for OC  
472 and TC; however, for EC, predictions benefit from having a dedicated calibration for samples  
473 impacted by wildfire emissions, with an increase in R<sup>2</sup> from 0.747 to 0.902 (Section S7).

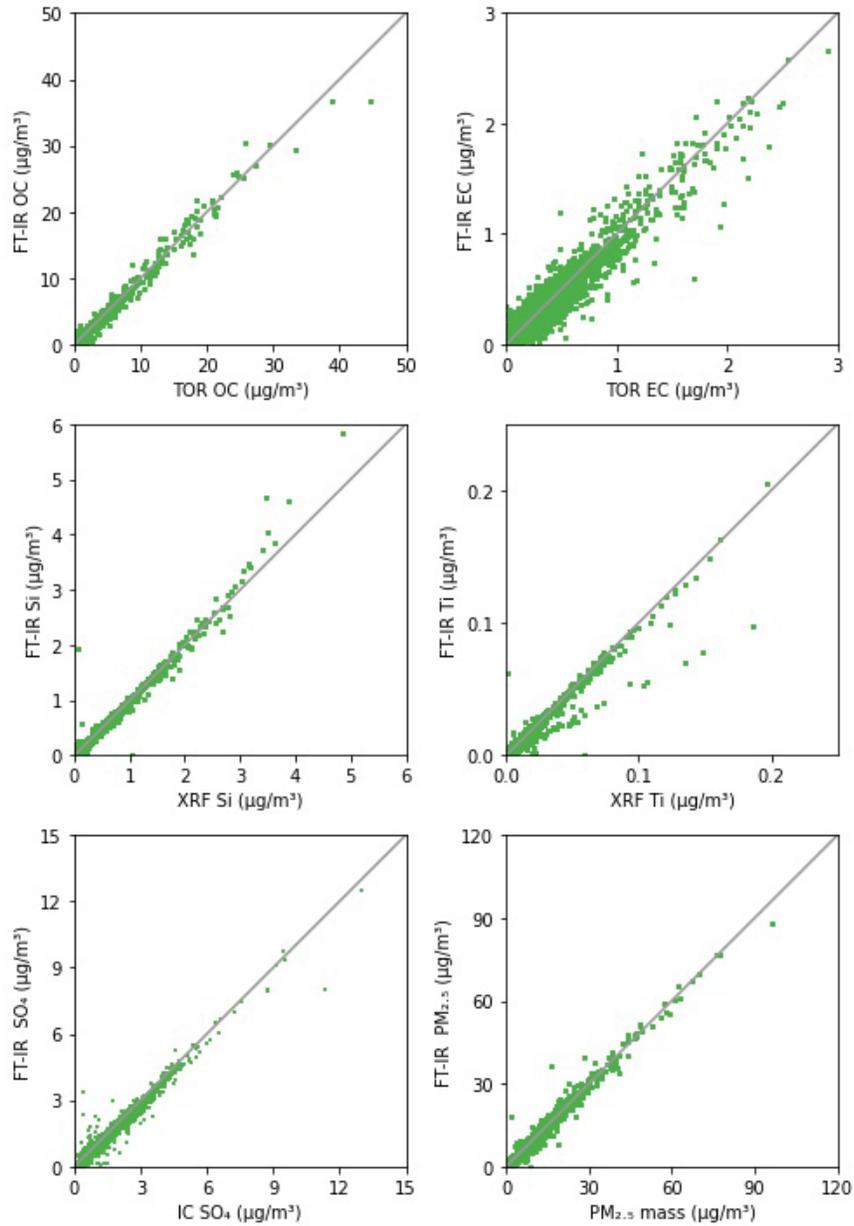

475 **Figure 3:** Inter-model OC (left), EC (middle), TC (right) comparison between global (section S1)  
 476 and Biomass Burning predicted concentrations for the 492 samples classified as biomass burning  
 477 in 2015. EC prediction, in particular, benefit from having a dedicated Biomass Burning calibration  
 478 model.

479 Therefore, we retain the biomass burning model as part of the multilevel model and present  
 480 the results for the Multilevel model below.

### 481 3.3 Multilevel modeling – Performance evaluation

#### 482 3.3.1 Carbonaceous aerosol predictions

483 Figure 4 shows the correspondence between FT-IR Multilevel concentrations for OC and EC and  
 484 TOR measurements for 2015 (plot for TC can be found in Section S9) and Table 1 lists the  
 485 prediction metrics for all 3 carbonaceous components. The visual agreement between FT-IR  
 486 and the reference measurements of OC and EC is high but EC shows higher scatter than the  
 487 other measurements. Table 1 indicates that FT-IR OC and TC has higher prediction quality than  
 488 EC but both perform satisfactorily. FT-IR OC and TC error is on par with TOR precisions (Table 1)  
 489 indicating that on average FT-IR does not add significant additional error to the measurement.  
 490 FT-IR EC predictions, however, have higher error than TOR precision. With respect to reference  
 491 (TOR) measurements, concentration-dependent biases in residuals that are determined by the  
 492 quality of fit ( $R^2$ ) and dynamic range of the data are expected due to the nature of least-squares  
 493 estimation (Besalú et al., 2006; Draper and Smith, 1998). For bias defined as FT-IR predictions  
 494 minus the reference (TOR) measurement, least-squares estimator causes an apparent linear  
 495 bias which is positive at the low end of the concentration range and negative at the high end of  
 496 the concentration range (see Section S8 for further discussion). The satisfactory agreement  
 497 between FT-IR and TOR concentrations as well as the equivalence agreements using the global  
 498 model (Section S1) support the validity of the proposed Multilevel modeling in the context of  
 499 carbonaceous aerosols prediction from PTFE filters in large speciation networks.

501 **Figure 4:** Comparison of predicted FT-IR OC, EC, Si, Ti,  $\text{SO}_4$  and mass concentrations using the  
 502 Multilevel model against their reference measurements. Each subplot contains all 19,608  
 503 samples collected in the year 2015.

504

505 **Table 1:** Summary of Multilevel model performance for IR-active atmospheric constituents for  
 506 19,608 spectra analyzed by FT-IR in the year 2015.

Species	R <sup>2</sup>	Bias [µg/m <sup>3</sup> ]	Bias (%)	Error [µg/m <sup>3</sup> ]	Error (%)	Reference Data Error <sup>1</sup> (%)	MDL [µg/m <sup>3</sup> ]	< MDL (%)
<i>OC</i>	0.983	0.01	1.6	0.08	12	10	0.06	0.9
<i>EC</i>	0.912	0	1.7	0.02	30	15	0.04	20.7
<i>TC</i>	0.984	0.01	1.2	0.08	12	11	0.07	1.3
<i>BC</i>	0.92	0	-0.3	0.03	23	---	0.04	19.3
<i>Si</i>	0.983	0	2.2	0.01	11	13	0.01	9.7
<i>Al</i>	0.985	0	2.2	0	12	10	0	4.7
<i>Ca</i>	0.979	0	1.1	0	13	9	0	6.9
<i>Ti</i>	0.941	0	2.7	0	21	16	0	14.9
<i>Fe</i>	0.95	0	1.1	0	25	8	0.01	19
<i>SO<sub>4</sub></i>	0.983	0	0.1	0.03	6	2	0.03	0.9
<i>NO<sub>3</sub></i>	0.927	0.02	15.3	0.07	54	8	0.07	21.8
<i>PM<sub>2.5</sub> Mass</i>	0.985	0.03	1	0.18	6	6	0.25	1.1

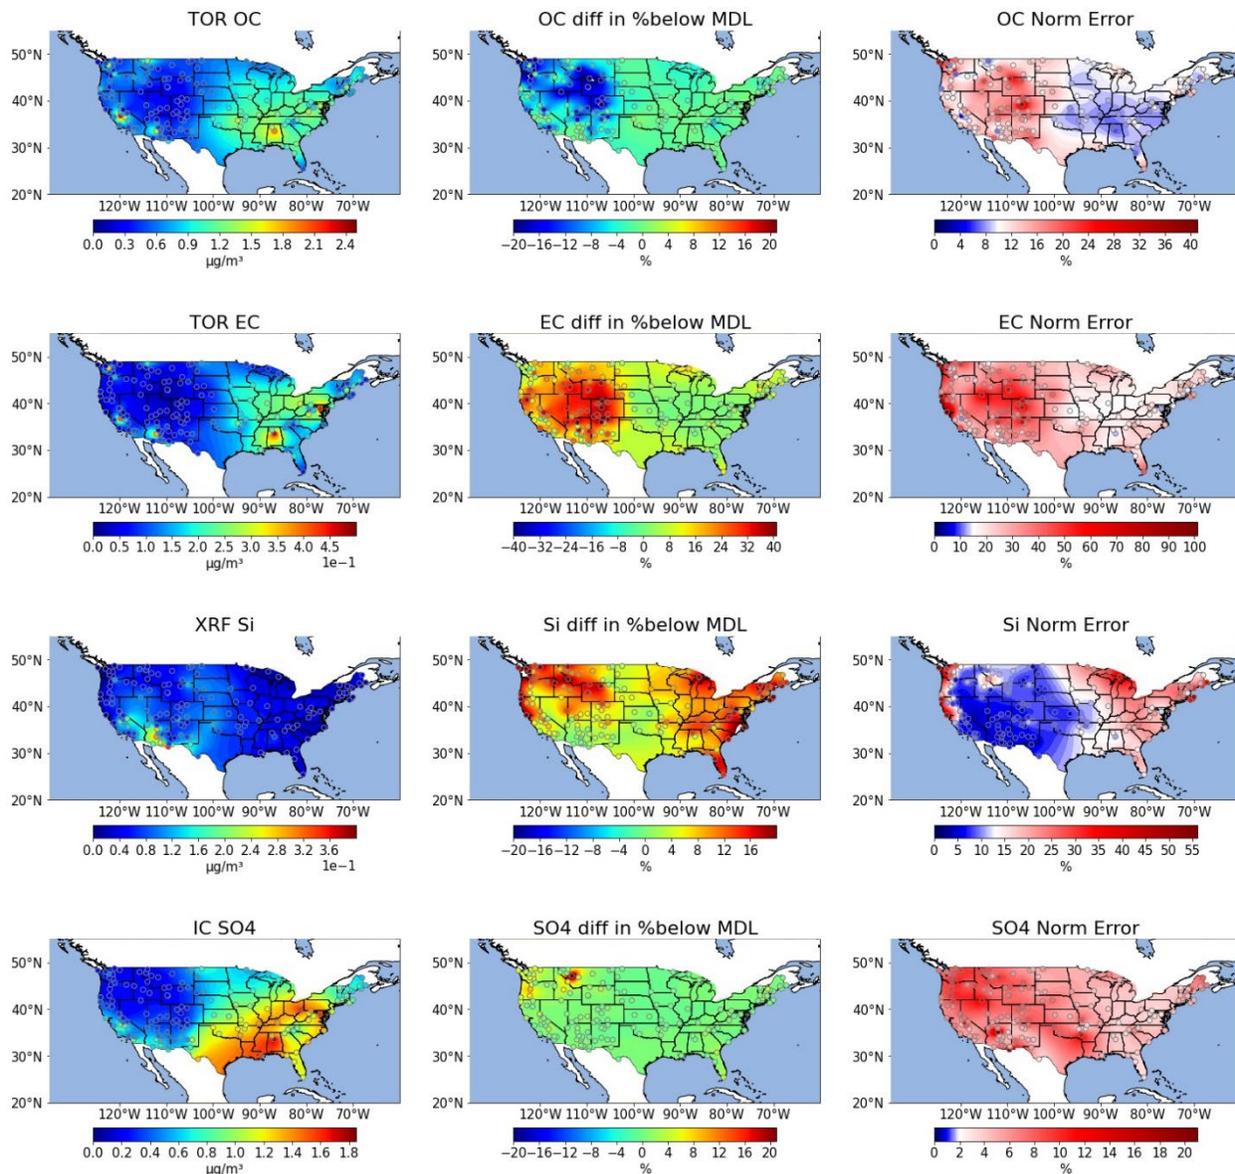

507 <sup>1</sup>Median relative error for TOR, XRF, IC and gravimetric analysis. OC, EC and TC median relative error estimated  
 508 from collocated sampling as measurement error/uncertainty is not reported by IMPROVE for this components.  
 509 For all other components, the normalized error was calculated as the uncertainty divided by the concentration  
 510 prior to selecting the median. BC is not reported by IMPROVE so measurement error is not estimated.

511 In addition to OC, EC and TC, light absorption which is predominantly due to black carbon, is also  
 512 a measure of one fraction of the carbonaceous aerosol. FT-IR calibrations are found to be  
 513 adequate for replicating HIPS BC measurements (Section S9). As expected, the corresponding  
 514 model is similar in performance to EC with R<sup>2</sup> and relative error of 0.920 and 23.3 %, respectively  
 515 (Table 1). FT-IR BC residuals have a broader interquartile range than in the HIPS BC collocated  
 516 data (Section S9). We attribute this effect to a difference in signal to noise ratio and sensitivity to  
 517 chemical interferences between the two analytical techniques. While HIPS exploits the strong  
 518 absorption properties of refractory carbon in the visible domain, the weak absorptivity of EC in  
 519 the mid-infrared domain (Niyogi et al., 2006) and the presence of overlapping species makes the  
 520 quantification less accurate.

521 Further exploration of the regional and site by site quality of data is made via contiguous United  
 522 States (CONUS) maps of annual median reference method concentrations (left), difference in %  
 523 below MDL between FTIR and reference method (middle) and relative error (right) are shown in  
 524 Figure 5 for OC and EC. TC is very similar to OC and BC is very similar to EC.

525 Maps for all constituents with annual median FTIR and reference method concentrations, as well  
526 as annual median prediction metrics are shown in Section S10.

527

529 Figure 5. Annual median reference method concentrations (left), difference in % below MDL  
 530 (middle) and normalized relative error (right) per site for OC, EC, silicon, and sulfate for CONUS  
 531 for 2015. For the MDL plot, sites in green and blue indicate that the FTIR has the same or fewer  
 532 samples below MDL than the reference method. Sites in yellow and red have more samples  
 533 below MDL for FTIR than for the reference method. For the relative error maps, the median  
 534 relative error of the reference method estimated using methods described in Table 1 is  
 535 white. For sites in blue, FTIR has lower relative error than the reference method and sites in  
 536 red are higher.

537 Annual median maps of FT-IR OC and TOR OC as well as maps of FT-IR EC and TOR EC  
538 (Supplemental material S10) are nearly identical. As shown in Figure 5, annual median OC and  
539 EC concentrations are highest at the four urban IMPROVE sites of Seattle, WA, Fresno, CA,  
540 Phoenix, AZ and Birmingham, AL than the rural sites and are higher in the east than in the west.  
541 For OC, the relative error is lower than the TOR relative error in the east (where concentrations  
542 are higher) and higher than TOR relative error in the west. OC has an equal or lower number of  
543 samples below MDL than TOR at all sites. For EC, FTIR relative error is higher than TOR relative  
544 error at almost all sites. The percentage of samples of EC that are below MDL for FTIR is similar  
545 to are slightly higher than TOR in the eastern US where EC concentrations are higher and are  
546 significantly higher than TOR in the western US where concentrations are lower. These  
547 patterns indicate that FTIR does not add error to OC measurements when concentrations are  
548 above  $0.75 \mu\text{g}/\text{m}^3$  but does add some error at lower OC concentrations and for EC  
549 measurements.

### 550 3.3.2 Elemental oxide predictions

551  
552 Taking advantage of known mineral absorbance bands in the mid-infrared range (Hahn et al.,  
553 2018; Madejová and Komadel, 2001; Senthil Kumar and Rajkumar, 2013) (Section S9), Multilevel  
554 calibrations for soil elements were evaluated for the five crustal elements commonly used to  
555 estimate soil: silicon, aluminum, calcium, titanium, and iron (Table 1 and Fig. 4 for Si and Ti). All  
556 models present a satisfactory agreement between XRF and FT-IR predicted concentrations ( $R^2 >$   
557  $0.94$ ). The quality of prediction of the elemental oxides falls into two groups. The first group  
558 includes silicon, aluminum and calcium and is characterized by moderate relative errors (11 – 13  
559 %), similar in magnitude to the FT-IR OC model (12 %) and have similar errors to XRF  
560 measurements. This indicates that like OC and TC, on-average FT-IR does not add additional  
561 uncertainty. The second group includes titanium and iron which have larger relative errors (20.9  
562 – 24.8 %), analogous to HIPS BC and EC models (23.3 – 30 %). Comparing residuals to collocated  
563 XRF measurements (Section S9) shows that the FT-IR based models have a larger interquartile  
564 range. For Fe, XRF uncertainty is quite low and FT-IR adds additional uncertainty to the  
565 measurement. XRF Ti measurements have higher error than the other elements but there is an  
566 incremental increase in error due to FT-IR. In addition, cross plots of titanium concentrations  
567 show a bifurcation (Fig. 4). While most samples fall near their expected titanium concentration,  
568 samples collected at the Sycamore Canyon (AZ) site present a systematic negative bias, consistent  
569 across years, tentatively attributed to a site-specific soil composition not accounted for by the  
570 Limited calibration. Takahama et al. (2019) demonstrated several methods to identify the  
571 possible occurrence of anomalous predictions in OC and EC based on comparison of new sample  
572 spectra to calibration spectra based on projected PLS scores and regression residual vectors.

573 These samples with systematic negative bias in titanium predictions can presumably be identified  
574 using such an approach, provided that compositional differences are detected in the IR spectrum.  
575 Although distinct IR fingerprints exist, FT-IR calibrations for quantifying mineral contents should  
576 be interpreted with care as specific elements may be indirectly quantified through their  
577 correlation with another element even in the absence of clear IR signature (Hahn et al., 2018).  
578 For instance, the variable importance in projection (VIP) scores for the Si, Al, and Ti calibrations  
579 suggests use of similar spectral variables, with small differences, for prediction of these species  
580 (Section S9). However, the 21 GMM sites coverage still meet the necessary requirements for  
581 providing a reliable insight into soil composition in the IMPROVE network.

582 Figure 5 shows the distribution of concentrations of XRF Si across CONUS. The highest annual  
583 median concentrations are in the southwest. Similar patterns are found for Al, Ca, Ti and Fe  
584 except that high Fe concentrations are also observed at the urban sites, particularly Fresno, CA  
585 and Birmingham, AL (Figures S10-6 through S10-9). For Si, FTIR normalized error is lower than  
586 XRF in the west where concentrations are higher. For Ca, Ti and Al, FT-IR normalized error is  
587 lower only in the southwest. For Fe, FT-IR is above XRF normalized error. The percentage of  
588 samples below MDL are similar to XRF (0-10% different) in the southwest and central US and  
589 modestly higher (15-20%) in the northwest and eastern US for Si. For Fe, the spatial pattern is  
590 similar but the FTIR % below MDL is up to 50 % higher than XRF. However, for Al, Ca, and Ti, FTIR  
591 percent below MDL is approximately the same or lower than XRF at all sites.

### 592 3.3.3 Inorganic ions

593 The two most abundant inorganic anions quantified in the network: nitrate and sulfate can also  
594 be measured by FT-IR (absorption bands used for prediction are discussed in Section S9). FT-IR  
595 sulfate concentrations display a satisfactory agreement with the reference IR measurements  
596 (Fig. 4). Model performance metrics include  $R^2$  above 0.98 and relative error of 6 %. The relative  
597 error is the same as for FT-IR  $PM_{2.5}$  and lower than OC, TC, and Si (Table 1). However, IC  
598 measurements have even lower error than FT-IR sulfate. Compared to sulfate, FT-IR nitrate  
599 concentrations (Section S9) are characterized by a moderate drop in the overall model  
600 performance ( $R^2 = 0.927$ ) while relative bias and error exceed 15 % and 50 %, respectively and  
601 the error far exceeds reference IC nitrate measurement error. A direct comparison against  
602 differential nitrate concentrations at collocated sites highlights the broad uncertainty in  
603 determining nitrate content from PTFE filters (Section S9, Figure S9-3). Unlike nylon filters for  
604 which nitrate is trapped on the surface, nitrate is known to evaporate from PTFE filters and the  
605 extent of volatilization is dependent on temperature and relative humidity during and after  
606 sampling. This causes a discrepancy between the mass of nitrate deposited onto the nylon filter  
607 and the mass of nitrate on the PTFE filter (Eldred and Ashbaugh, 2004), therefore FT-IR  
608 calibrations with the nitrate measurements by IC from nylon filters as the reference should be  
609 used with caution. Although there are physical limitations to measuring ambient nitrate on

610 PTFE filters, a measure of nitrate on PTFE filters which corresponds to its contribution to the  
611 gravimetric mass is useful for mass closure and data validation. FT-IR has been shown to be  
612 useful for measuring and evaluating nitrate under controlled laboratory conditions (ex. Wu et  
613 al., 2007). For network samples, nitrate could be measured using laboratory calibration  
614 standards and this effort will be addressed in future work.

615 The annual median sulfate concentration by IC is shown in Figure 5. Annual median  
616 concentrations are highest in the southeast and eastern US with a gradient in concentrations  
617 observed across the midwest. The median relative error for sulfate by IC is only 2% and all FTIR  
618 sulfate has higher relative error. There are however, spatial differences. In the eastern US  
619 sulfate relative error is less than 15% but in the west, it is considerably higher, peaking in  
620 Wyoming where concentrations are very low. The % below MDL is very similar for FTIR and IC  
621 across the continent. Due to volatility of nitrate, the nitrate metrics for FTIR are poor compared  
622 to sulfate (Figure S10-11).

### 623 3.3.4 PM<sub>2.5</sub> mass predictions

624 Since the major aerosol species are shown to be reasonably well measured by FT-IR, it was  
625 anticipated that PM<sub>2.5</sub> mass calibration would perform well. The PM<sub>2.5</sub> model presents reliable  
626 filter mass predictions ( $R^2 = 0.985$ ) characterized by relative bias and error that are 1/3 to 1/2 of  
627 those for OC and on par with gravimetric error (Table 1). The cross plot of gravimetric mass and  
628 FT-IR predictions (Fig. 4) and maps of predictions metrics (Figure S10-12) show that PM<sub>2.5</sub> mass  
629 can be accurately predicted across a broad concentration range indicating that FT-IR spectra of  
630 PTFE filters do not contain interferences or other limitations that make PM mass predictions error  
631 prone.

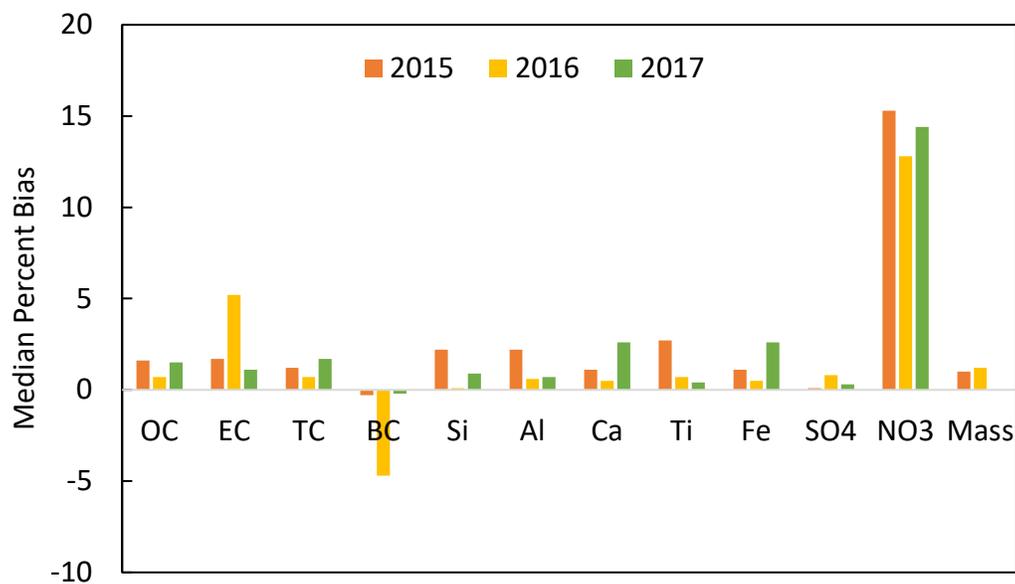

### 632 3.4 Long term stability

633 Finally, Multilevel calibrations are extended to 2016 and 2017 to evaluate the inter-year  
634 consistency and determine if the assumptions behind Limited Sites and Biomass Burning models  
635 remain valid over time. For each sampling year, new calibrations were developed following the  
636 framework established for 2015. Models were recalibrated with data from the 21 sites and  
637 biomass burning samples were detected by the functional group screening procedure. Fig. 6  
638 shows the median relative bias (top) and error (bottom) for the three years of data (cross plots  
639 and prediction metrics shown for all predicted species for 2016 and 2017 in Section S11). These  
640 results indicate that the modeling methodology provided reasonably consistent results across all  
641 three years.

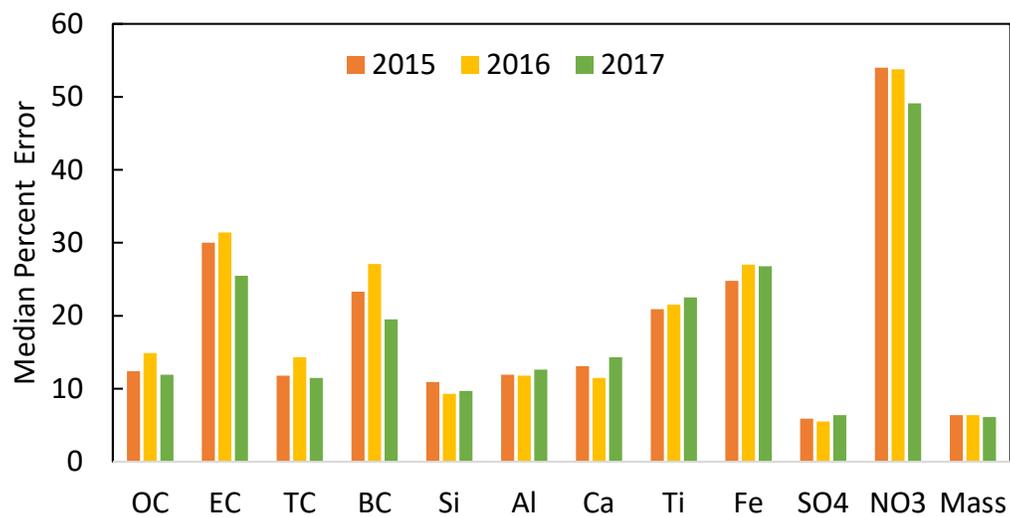

642 Normalized bias for most species is below 3% and normalized error is consistent for all species  
643 across all three years. The relative bias for EC and BC are similar to other species in 2015 and  
644 2017 but in 2016 they are larger in magnitude than the other two years and different in sign.

645 2016 is the first year of TOR data from the multiwavelength TOR instruments (Chow et al., 2015)  
646 so higher bias could be potentially be related to the new instruments. However, the HIPS  
647 instrument was overhauled beginning in 2017 which provides no explanation for high bias in 2016  
648 ([http://vista.cira.colostate.edu/improve/Data/QA\\_QC/Advisory/da0041/da0041\\_HIPSmodifications.pdf](http://vista.cira.colostate.edu/improve/Data/QA_QC/Advisory/da0041/da0041_HIPSmodifications.pdf)).  
649 Further, the EC and BC calibrations are independent of each other except for using  
650 the same filters for calibrations (as all species do) so the fact that the median bias is roughly equal  
651 but opposite in sign is not due to codependence of the models.

652 In future work, calibrations models will be updated more frequently than annually with the most  
653 recent year of ambient samples which may smooth biases and errors due to changes to  
654 atmospheric condition and instrument drift.

655

656

 658 measured for each year.

659

## 660 4 Conclusion

661 In this paper, we investigate the feasibility of an FT-IR method that uses ambient samples as  
 662 calibration standards for use by a large monitoring network. In this method, all sites in the

663 network collect PTFE filters for FT-IR analysis. A few select sites, used for calibration, would retain  
664 all sampling and analyses of current IMPROVE sites to enable re-calibration of the FTIR method  
665 on a routine basis. Re-calibration is especially important as atmospheric changes occur and as  
666 conditions in the network evolve over time, for example new reference instruments, new or  
667 significantly modified FT-IR instruments, changes to sampling protocol or possibly change in filter  
668 material. The validity of such a design was evaluated with all PTFE filters collecting PM<sub>2.5</sub> aerosols  
669 at 161 IMPROVE sites in 2015 and then tested for all filters in 2016 and 2017.

670 A multi-level modeling algorithm was used whereby smoke impacted samples are identified and  
671 predicted by one model and the rest of the samples are predicted by another model developed  
672 from 21 selected IMPROVE sites. The data from the two models are combined to evaluate  
673 performance of the FT-IR method. The selection of sites was performed such that if one of the  
674 21 sites ceases to operate, another site, selected from the same compositional cluster can be  
675 used for calibration.

676 The cross-plots and prediction metrics indicate that the Multilevel model is equivalent to  
677 conventional calibrations built from samples from every available site. Reliable performance in  
678 predicted concentrations were reported for a broad range of atmospheric constituents with  
679 detectable infrared signatures such as OC, EC, TC, sulfate, soil elements (Si, Al, Ca, Ti, Fe), light  
680 absorption, and PM<sub>2.5</sub> mass. Due to volatilization off the PTFE filter, nitrate measurements were  
681 found to be unsatisfactory. The calibration method was developed using data from 2015, and the  
682 same methodology was applied to 2016 and 2017. The model performance metrics in all three  
683 years were similar. Results across ~61,500 FT-IR spectra highlight the suitability of the Multilevel  
684 calibration design to quantify multiple atmospheric PM<sub>2.5</sub> species in large monitoring networks.

685 This work presents an alternative, lower cost, filter analysis method to measure speciated aerosol  
686 in a routine monitoring network. This could be a valuable addition to routine speciated aerosol  
687 monitoring networks, such as IMPROVE, by incorporating monitoring sites that collect samples  
688 on only a PTFE filter for subsequent analysis. This would provide the opportunity to have a subset  
689 of less expensive monitoring sites, which could be used for scoping studies to understand the  
690 aerosol composition in unmonitored locations. It could also serve as a network cost savings  
691 method by having a subset of network sites collect aerosol samples on only a Teflon filter.  
692 However, the inability to measure particulate nitrate is a significant deficiency for using this  
693 method to replace existing monitoring sites. The FTIR derived aerosol concentrations are also a  
694 semi-independent measurement from the routine speciated aerosol measurements. Therefore,  
695 routine FTIR measurements would provide valuable QA/QC information for any speciated  
696 monitoring network. In addition, FTIR derived concentrations could be used to substitute for  
697 missing concentrations in the case where the Teflon sample is valid, but filter samples or analyses  
698 on the nylon or quartz fiber filters are not.

699 For IMPROVE's urban counterpart, the CSN network, after evaluation of the quality of  
700 predictions in CSN, this framework could be used to accomplish goals similar to those of  
701 IMPROVE. Additionally, this method could be used to predict samples collected in the Federal  
702 Reference Method (FRM) network which is a PM mass only network. In addition, this method,  
703 with appropriate ambient standards, could be applied at other regional or international  
704 monitoring networks or sites to provide low-cost comprehensive composition data. As shown  
705 in our previous work, additional data, including an estimate of organic matter and its functional  
706 group composition, can also be obtained from FT-IR spectra of PTFE filters, further increasing  
707 the utility of infrared spectroscopy of aerosol samples.

## 708 5 Data availability

709 Data is available at <https://doi.org/10.25338/B8TP8V>.

## 710 6 Author contribution

711 BD developed the software, performed the formal analysis and visualization for much of the  
712 manuscript and wrote the original draft of the manuscript, ATW developed software, performed  
713 formal analysis and visualization of the GMM work, ST participated in conceptualization,  
714 methodology software, visualization and reviewing and editing the manuscript. KMG developed  
715 parts of the biomass burning identification methodology. AAF performed the final visualizations  
716 for parts of the paper and was responsible for additional visualizations made to the paper based  
717 on reviewer comments. BS, SC and ASW, provided input throughout the project and reviewed  
718 and edited the manuscript, AMD conceptualized of and acquired funding for this project,  
719 developed methodology, performed project administration and supervision and reviewed,  
720 edited and finalized the manuscript.

## 721 7 Competing interests

722 The authors declare that they have no conflict of interest.

## 723 8 Acknowledgments

724 The authors acknowledge funding from the National Park Service in cooperation with the  
725 Environmental Protection Agency (P18AC01222). Thanks to Anahita Amiri Farahani for assisting  
726 with figures. We are particularly grateful to Kelsey Seibert for overseeing daily FT-IR operations  
727 at the University of California Davis and to the numerous undergraduate students who  
728 performed spectra collection from 2015 to 2017.
