Abstract. During the Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC) expedition, meteorological conditions over the lowest 1 km of the atmosphere were sampled with the DataHawk2 (DH2) fixed_ wing uncrewed aircraft system (UAS). These in situ observations of the central Arctic atmosphere are some of the most extensive to date and provide unique insight into the atmospheric boundary layer (ABL) structure. The ABL is an important component of the Arctic climate, as it can be closely coupled to cloud properties, surface fluxes, and the atmospheric radiation budget. The high temporal resolution of the UAS observations allows us to manually identify

- 20 the ABL height (Z_{ABL}) for 65 out of the total 89 flights conducted over the central Arctic Ocean between 23 March and 26 July 2020 by visually analyzing profiles of virtual potential temperature, humidity, and bulk Richardson number. Comparing this subjective Z_{ABL} with Z_{ABL} identified by various previously published automated objective methods allows us to determine which objective methods are most successful at accurately identifying Z_{ABL} in the central Arctic environment. The objective methods we use are the Liu-Liang, Heffter, virtual potential temperature
- 25 gradient maximum, and bulk Richardson number methods. In the process of testing these objective methods on the DH2 data, numerical thresholds were adapted to work best for the UAS-based sampling. To determine if conclusions are robust across different measurement platforms, the subjective and objective Z_{ABL} determination processes were repeated using the radiosonde profile closest in time to each DH2 flight. For both the DH2 and radiosonde data, it is determined that the bulk Richardson number method is the most successful at identifying Z_{ABL} while the Liu-Liang method is least successful. The results of this study are expected to be beneficial for upcoming observational and modeling efforts regarding the central Arctic ABL.

1 Introduction

The transfer of energy between the Earth's surface and the overlying atmosphere, particularly at high latitudes, remains an area of substantial uncertainty in our understanding of the global climate system (de Boer et al., 2012; Tjernström

- 35
- et al., 2012; Karlsson and Svensson, 2013). The consequences of this uncertainty are significant, with global climate model projections of present-day sea ice demonstrated to fall short of simulating the observed rate of change (Stroeve et al., 2007; Stroeve et al., 2012). The thermodynamic structure of the lower atmosphere plays a central role in

regulating cloud lifecycle and radiative transfer, and their influence on atmospheric energy transport (Tjernström et al., 2004; Karlsson and Svensson, 2013; Brooks et al., 2017). Significant insight can be gained by measurements collected over the central Arctic Ocean pack ice, focused on the structure of the lower atmosphere, its spatial and temporal variability, the intensity of turbulent energy fluxes, and its connection to surface features. To provide such measurements, uncrewed aircraft were deployed in the lower atmosphere during legs 3 (March through May 2020) and 4 (June through August 2020) of MOSAiC (Multidisciplinary drifting Observatory for the Study of Arctic Climate; Shupe et al. 2020), a year-long expedition that took place from October 2019 to September 2020 in which the icebreaker RV *Polarstern* (Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, 2017) was frozen into the central Arctic ocean sea ice pack and allowed to passively drift across the central Arctic for an

60 entire year (Fig. 1). Additional information on measurements taken of the atmosphere and sea ice during MOSAiC can be found at Shupe et al. (2022) and Nicolaus et al. (2022) respectively.

55

One important indicator of the extent to which energy may be transferred between the Earth's surface and overlying atmosphere is the atmospheric boundary layer (ABL) height. The ABL is the turbulent lowest part of the atmosphere that is directly influenced by the Earth's surface (Stull, 1988; Marsik et al., 1995). In the central Arctic, the ABL is impacted by interactions between the atmosphere and sea ice pack features, which can cause either buoyantly or

- 65 impacted by interactions between the atmosphere and sea ice pack features, which can cause either buoyantly or mechanically produced turbulence. The generation of buoyant turbulence can occur through surface energy fluxes emitted from open water regions such as leads (Lüpkes et al., 2008), cold air advection (Vihma et al., 2005), or turbulent mixing below cloud base due to cloud top radiative cooling (Tjernström et al., 2004). Mechanical generation, which is the dominant driver, of turbulence in the central Arctic (Brooks et al., 2017), can occur due to the presence of
- 70 a low-level jet (Brooks et al., 2017; Banta, 2003), sea ice features such as ridges and ice edges (Andreas et al., 2010) or oceanic waves (Jenkins et al., 2012). Solar heating of the Earth's surface and the subsequent formation of buoyant thermals, which is a dominant forcing of the ABL in most parts of the planet (Marsik et al., 1995), does not often play a role in the central Arctic due to the relatively reflective surfaces found there.

The Arctic ABL is usually either stable or near-neutral (Brooks et al., 2017; Esau and Sorokina, 2009). A stable
boundary layer forms when there is a deficit of radiation at the surface or when warmer air is advected over a cooler surface, and can range from being nearly well-mixed with moderate turbulence to nearly laminar (Stull, 1988). A neutral boundary layer occurs when air at the surface is neutrally buoyant (Sivaraman et al., 2013) due primarily to mechanically generated turbulence which mixes air between the surface and above atmosphere (Brooks et al., 2017). A convective boundary layer forms when convective thermals create positive buoyancy (Liu and Liang, 2010) and an air parcel at the surface rises adiabatically until becoming neutrally buoyant; this phenomenon is rare in the central Arctic. While the various forms that the Arctic ABL may take are complex, most of the time, the Arctic ABL is capped by a potential temperature inversion, marking the entrainment zone, which is a stable layer between the ABL and free atmosphere (Stull, 1988). One important difference between the Arctic ABL and that in the mid-latitudes is that there is usually no residual layer above a stable Arctic ABL, due to the lack of a diurnal cycle. Additionally, the Arctic ABL

85 is typically much shallower than that at mid-latitudes (Esau and Sorokina, 2009). These discrepancies cause certain ABL height detection methods to fail when applied to Arctic data. (Deleted: ice pack

Knowing the height of the Arctic ABL is important for many applications. First, it is a metric which represents the altitude up to which the atmosphere is directly impacted by surface processes. This can then inform the extent to which the surface interacts with atmospheric features such as clouds (and their influence on radiative transfer in the lower atmosphere), low level jets (LLJs), and temperature inversion layers, which all have important implications for Arctic warming (Serreze and Barry, 2011). For example, a shallow, stable ABL is more likely to be observed with clear skies above (Brooks et al., 2017), which promotes longwave cooling of the surface and decoupling from the above atmosphere. In this instance, a surface-based temperature inversion is likely to constrain warming to the surface, which contributes to Arctic amplification (Lesins et al., 2012). ABL height (hereafter Z₄ABL) plays an important role in many other applications including transfer of air pollutants and weather forecasting (Garratt, 1994). Since any determination of Z_{ABL} is simply an approximation, the most value can be gained if this approximation is as accurate as possible. The goal of the current work is to determine which methods can best accomplish this.

The depth of the ABL has been previously defined using a variety of approaches that involve visualizing the profiles of different variables. Table 1 lists some of the thermodynamic and kinematic variables that have previously been used to identify $Z_{ABL_{p}}$ as well as some examples of associated literature that references use of that variable. Each of these profiles typically exhibits a distinct change in structure at the top of the ABL_m Additional methods may exist, such as analyzing the vertical gradient of aerosol content, but are not listed since the current study focuses on $Z_{ABL_{p}}$

determination using thermodynamic and kinematic processes.

Due to the different atmospheric dynamics involved in each of the above approaches, the definition of Z_{ABL} is often debatable amongst experts. Depending on one's purpose for knowing Z_{ABL} , different approaches may be most applicable. Of these methods, some of the most widely used ones, and the ones applied in the current analysis of a central Arctic dataset to determine Z_{ABL} are the ones that involve analysis of virtual potential temperature (θ_v), vertical Formatted: Indent: Left: 0", Space After: 1 line, Add space between paragraphs of the same style

gradient of virtual potential temperature (dθ_v/dz), humidity <u>(relative and absolute)</u>, bulk Richardson number (Ri_b), and wind speed profiles. The current focus is on these variables because the physical basis for each one as an indication of <u>Z_{ABL}</u> is relevant for the Arctic atmosphere. Specifically, θ_v helps identify the entrainment zone above the ABL, the vertical gradient of humidity either decreases or increases noticeably above the ABL (Dai et al., 2014), Ri_b helps identify where turbulence (<u>usually caused</u> by strong wind shear or surface roughness in the Arctic ABL (Grachev et al., 2005), ceases above the ABL, and wind speed helps identify the top of the ABL when it is capped by an <u>JLJ</u> as the ABL top is often at or just below the LLJ core (Stull, 1988). Other methods, such as that using temperature

- inversion top to identify Z_{ABL} (Collaud Coen et al., 2014), do not perform well in the Arctic where a weak temperature inversion can extend well above the ABL. Though turbulent kinetic energy is recognized as perhaps the most valuable profile for Z_{ABL} identification (Stull, 1988; Siebert et al., 2000; Dai et al., 2014; Zhang et al., 2014), these data are not available to aid in the current study
- 160 High resolution data collected by the DataHawk2_uncrewed aircraft system (UAS) allows for determination of ZABL with high accuracy through manual visual analysis. However, visually determining ZABL case-by-case is time consuming for processing a large dataset. Therefore, the UAS-derived dataset is leveraged to compare manually (or 'subjectively') determined ZABL with that identified through previously published automated (or 'objective') methods. While this subjective ZABL may not necessarily be the 'true' ABL top, as the definition of this quantity can be debatable among experts and is not constant over time, it is the best estimate of ZABL given the available data. This evaluation is
- among experts and is not constant over time, it is the best estimate of Z_{ABL} given the available data. This evaluation is completed to identify objective methods that can accurately diagnose Z_{ABL} across a larger dataset of central Arctic atmospheric conditions.

To subjectively identify Z_{ABL} in each atmospheric profile from DH2 data, the stability regime of the ABL (stable, neutral, or convective) is categorized and Z_{ABL} is visually identified through combined evaluation of θ_v, humidity
(both relative humidity (RH) and mixing ratio), and Ri_b profiles. Objective identification of Z_{ABL} is derived through the application of four previously published methods; the Liu-Liang method (Liu and Liang, 2010), the Heffter method (Heffter, 1980), the virtual potential temperature gradient maximum (TGRDM) method (Dai et al., 2014), and the Ri_b method (Sivaraman et al., 2013), adapted to best suit the DH2 profiles examined. Then, statistical comparisons between the objective and subjective Z_{ABL} are conducted. Next, the objective methods are applied in their adapted
form to radiosonde profiles nearest in time to each DH2 flight to determine if these methods are robust across different measurement platforms for central Arctic conditions. Finally, discussion is included on the features that do or do not lend themselves to accurate identification of Z_{ABL} by the objective methods, and findings are summarized to support future studies seeking to identify Z_{ABL} quickly, objectively, and accurately across large atmospheric datasets collected in the central Arctic.

2 Data and methods

2.1 The DataHawk2

225

Data presented in this <u>study</u> were obtained between 23 March and 26 July 2020 using the University of Colorado DataHawk2 (DH2) UAS (de Boer et al. submitted). Flights were conducted from the sea ice alongside the *Polarstern*, known as the MOSAiC floe, ranging in location from 86.2° N, 15.8° E on 23 March, to 79.8° N, 1.9° W on 26 July 2020 (Fig. 1). Throughout this period, the MOSAiC floe evolved from snow-covered rigid ice situated in the high Arctic to being covered with melt ponds and leads close to the sea ice edge. The surface atmospheric temperatures also transitioned from nearly -35 °C at the beginning of leg 3 to hovering <u>near 0 °C</u> throughout the entirety of leg 4.

- 230 Figure 1: (Left) The drift track of the *Polarstern*, separated by color into the 5 different legs. The black "transit" line indicates when the ship was travelling under its own power between legs 3 and 4 and between legs 4 and 5. (Right) The zoomed in portion of the *Polarstern* drift during which DH2 flights were conducted (legs 3 and 4). The locations of all of the DH2 flights are overlaid on the drift track and color coded by date, with blue-tinted dots indicating flights conducted during leg 3 and yellow-tinted dots indicating flights conducted during leg 4.
- The DH2 (Hamilton et al., <u>submitted</u>) is a fixed-wing, battery powered UAS (1.1 m wingspan, 1.8 kg weight, 40 min, endurance) carrying various meteorological sensors, <u>which measure the state of the atmosphere in Earth-relative coordinates</u>. Instrumentation includes a fine wire array providing high frequency (800 Hz) information on temperature and air speed, multiple sensors for temperature and relative humidity (Vaisala RSS421 measuring at 5 Hz and SHT-85 measuring at 100 Hz), and up- and downward looking thermopile sensors to provide infrared brightness temperatures of the sky and surface. Air pressure is measured at 5 Hz by the Vaisala RSS421 sensor. Measurements of attitude, airspeed, ground speed, and altitude support the derivation of high-frequency (10 Hz) 3D wind estimates, which are time-lag-corrected to account for differences in time constants of the GPS system and onboard inertial measurement unit (IMU), true airspeed (TAS)-corrected to eliminate errors in the measurement of TAS, and corrected.

for potential angular offsets between the aircraft, IMU, and pitot probe. Additional detail on the derivation of these winds, as well as processing methods of the additional variables are described in detail in the metadata for the DH2
 dataset used for the current study (Jozef et al., 2021), the manuscript describing UAS data collection during MOSAiC (de Boer et al., submitted) and the technical manuscript describing the DH2 aircraft (Hamilton et al., submitted). Despite these corrections, near-surface wind measurements (below ~30 m) are usually unreliable due to manual, rather than autopilot, takeoffs and landings, which conflict with the measurements and calculations of the winds. Therefore, we do not use DH2 wind speeds below 30 m in the current study.

265 Combined, these sensors provide a comprehensive picture of atmospheric thermodynamic and kinematic state along* with some context on the surface and sky condition under which these measurements were obtained. Table 2 lists the resolution, repeatability (standard deviation of difference between two successive repeated calibrations), and response time for the Vaisala RSS421 sensor. Uncertainty in the wind speed estimation is not provided, as determining this is still in progress.

Table 2: Accuracy and reliability of the variables recorded by the Vaisala RSS421 sensors used in this study.

Variable	Resolution	Repeatability	Response Time	•
Pressure	<u>0.01 hPa</u>	<u>0.4 hPa</u>	±	•
<u>Temperature</u>	<u>0.01 °C</u>	<u>0.1 °C</u>	<u>0.5 s</u>	•
Humidity	<u>0.1 %RH</u>	<u>2 %RH</u>	<u><0.3 s (at 20 °C) to <10 s (at -40 °C)</u>	•

Measurements collected by the DH2 are logged at different frequencies, requiring the implementation of a time alignment process to assure that the time index for each datapoint of each variable is consistent with all other measurements. Additionally, the wind measurements have been filtered to remove the impact of the angle and ground speed of the aircraft to provide estimates of the true wind speed (de Boer et al., <u>submitted</u>). Data collected by the DH2 during MOSAiC are available for public download through the <u>National Science Foundation</u> Arctic Data Center at <u>https://doi.org/10.18739/A2Z60C34R</u> (Jozef et al., 2021)

280

275

During MOSAiC, DH2 flights were conducted whenever flight weather criteria were met and when the team was ablest to access the ice alongside the *Polarstern*. The weather criteria include wind speeds with a sustained average below 10 m s⁻¹, and gusts below 14 m s⁻¹, as well as sufficient visibility to maintain visual contact with the aircraft at all times during flight. In addition, DH2 flights required coordination with other MOSAiC activities, especially those impacting air space over the MOSAiC floe, including manned helicopter flights and other UAS and tethersonde operations.

285

The most common flight pattern conducted with the DH2, and the flight pattern from which data for this analysis were acquired, was a profiling flight in which the plane flew a spiral ascent and descent pattern, with a radius of 75-100 m between the surface and 1 km altitude (or cloud base, if lower than 1 km), with the aircraft ascending and descending at a rate of 2 m s⁻¹ and flying at an airspeed of 14-18 m s⁻¹. Each profiling flight lasted an average of 30 min, with some shorter flights when the air temperature was at its coldest (\sim -35 °C) near the beginning of leg 3, and some longer

B05 flights when the air temperature was much warmer (~0 °C) during leg 4. Throughout <u>the measurement period</u>, 89 flights were conducted with the DH2. In the present study, 65 of these flights are found to have <u>a clearly identifiable</u> ZABL within the altitude range sampled. The remaining flights sampled only the lowest portion of the atmosphere due to cloud cover or other environmental conditions and therefore did not observe the full depth of the ABL.

2.1.1, Preparing the DataHawk2 data for analysis

- 310 The primary profiles of interest for subjective and objective Z_{ABL} identification are θ_v , humidity (RH and mixing ratio), wind speed, Rib, and $d\theta_v/dz$. θ_v was calculated using RSS421 temperature, pressure, and RH. Differences in response times of the RSS421 temperature and RH sensors has a negligible impact on the calculation of θ_v because the moisture content in the Arctic atmosphere is so low that θ and θ_v values typically differ on the order of less than 1 K. Regardless, the addition of humidity does not change the structure and location of features in the θ_v profile, which is what is
- 315 important for Z_{ABL} identification. For proper visualization, we average the θ_x, humidity, and wind speed variables over <u>1 m altitude bins throughout the entire flight to further eliminate the effects of differences in sensor response times</u> during ascent and descent (e.g., values at 10.5 m are averaged from 10 to 11 m). This also mitigates the effect of changes in atmospheric conditions near the surface throughout the span of a flight, though the near-surface observations largely remained constant during a given flight. 1 m is chosen as an averaging bin because using a greater
- bin value would eliminate much of the fine scale detail in the θ_v and humidity profiles which the DH2 provides, and which makes its data a valuable resource in honing Z_{ABL} detection methods. However, since fine scale fluctuations in wind speeds evident at the 1 m scale are usually artifacts of the wind estimation routines applied to a circular flight pattern, we additionally apply a 60 m running mean, which eliminates small-scale wiggles while retaining the important large-scale features. Next, we exclude periods of manual flight during takeoff and landing (this is usually at a tlittudes below 5 m) since measurements during manual flight are prone to inaccuracies due to the irregular flight pattern. Lastly, we exclude the first 5 seconds of flight, as the initial measurements after takeoff may be faulty due to

hysteresis associated with the sensor sitting still at the surface before launch.

Using the 1 m averaged θ_x and wind speed component profiles, we calculate the Rip profile. Rip is calculated at altitude, z, using the following equation from Stull (1988);

330
$$Ri_{\rm h}(z) = \frac{\left(\frac{g}{\Theta_{\overline{\nu}}}\right)\Delta\Theta_{\nu}}{2}$$

where g is acceleration due to gravity, $\theta_{\overline{\nu}}$ is mean virtual potential temperature over the altitude range being considered, z is altitude, u is zonal wind, v is meridional wind, and Δ represents the difference over the altitude range used to calculate Ri_b throughout the profile. The only way that Ri_b can be negative is if the value for $\Delta \theta_{\nu}$ is negative, indicating a convective atmosphere with buoyancy-driven generation of the turbulence. Ri_b profiles are created by calculating Ri_b over a 30 m altitude range (Δ), at 5 m resolution (i.e., between 30 and 60 m, then between 35 and 65 m, and so on). Since we do not use DH2 winds below 30 m, and intermediate Ri_b value between the surface and 30 m is calculated using an assumed zero wind at the surface. It is not crucial to consider the drift speed of the ice for the

335

340 <u>calculation of this initial Ri_b value since the ice drift speed during MOSAiC was on average less than 0.1 m s⁻¹. (Krumpen et al., 2021), a value much smaller than that of the observed wind speeds. Lastly, the dθ_v/dz profile is similarly created by calculating dθ_v/dz over an altitude range of 30 m, at 5 m resolution.</u>

The above profiles are used to determine stability regime, visually identify Z_{ABL} using criteria founded in this⁴
 manuscript, and objectively identify Z_{ABL} using the four published methods. For the remainder of this manuscript,
 Z_{ABL} determined from manual visual identification is referred to as the subjective Z_{ABL} and that determined by the / published methods (which are automated algorithms performed by computers) are referred to as objective Z_{ABL}. Z_{ABL} determined is a simplification to differentiate between manual and automated methods, though they both rely on much of the same underlying physical processes for Z_{ABL} identification.

2.2 Determining stability regime

Some of the methods for both subjectively and objectively identifying Z_{ABL} differ depending on the stability regime, so the sampled regime is first identified for each DH2 flight. The three possible stability regimes considered include a convective boundary layer (CBL), stable boundary layer (SBL), and neutral boundary layer (NBL; Liu and Liang, 2010). In a CBL, θ_v near the surface is greater than that of the overlying ABL (Stull, 1988). In an SBL, the vertical gradient of θ_v is positive (Stull, 1988). In an NBL, θ_v at the surface is approximately the same value as that of the overlying remainder of the ABL (Stull, 1988).

<u>Therefore</u>, stability regimes are identified by comparing θ_v between the lowest altitude sampled by the DH2 (<u>'i' in the below equations</u>; typically ~5m since altitudes below this are usually sampled with manual flight) and 40 m above, using Eq. (2)-(4) below adapted from Liu and Liang (2010).

 $\theta_{v_{i+40m}} - \theta_{v_i} < -\delta_s = CBL$

 $360 \qquad \theta_{v_{i+40m}} - \theta_{v_i} > +\delta_s = SBL$

365

370

 $-\delta_{s} \leq \theta_{v_{i+40m}} - \theta_{v_{i}} \leq +\delta_{s} = \text{NBL}$

In these equations, δ_s is a stability threshold that represents the minimum positive or negative vertical gradient of θ_v near the surface necessary for the ABL to qualify as an SBL or CBL respectively. If this minimum is not either negatively (in the case of a CBL) or positively (in the case of an SBL) reached, the ABL is identified as an NBL (Liu and Liang, 2010). In an idealized case, δ_s would be zero. However, in practice it must be specified as a small positive number, and this number depends on the surface characteristics as well as inherent uncertainties or noise in the measurements. For profiles over ocean/ice, this number has been defined to be 0.2 K (Liu and Liang, 2010),

While Liu and Liang (2010) compare θ_v between pressure levels that equate to approximately 40 and 160 m in the conditions we sampled, this range was found to be inadequate for differentiating between an SBL, NBL or CBL in the Arctic, where the top of the ABL is often below 160 m, and sometimes even below 40 m. Therefore, considering the

 θ_v change below ~45 m more accurately reflects the stability regime of the Arctic ABL Once the stability regime is identified, criteria based on the θ_v , humidity, and Ri_b profiles are applied to subjectively determine Z_{ABL}. For the current dataset, 31 SBL cases, 32 NBL cases, and 2 CBL cases were identified

2.3 Subjective identification of atmospheric boundary layer height

- 680 There is no one best method for subjectively identifying Z_{ABL} that is agreed upon throughout the scientific community, evident by the many methods outlined in Table 1, and therefore a subjectively determined Z_{ABL} is prone to error. The best we can do to increase the confidence in a subjectively determined ZABL is to take into account several of the most commonly used methods and establish criteria which are applied consistently across all profiles. We describe these criteria below.
- 685 To subjectively identify Z_{ABL} , the θ_v profile is first analyzed, as the θ_v profile changes structure above the ABL (Stull, 1988). For a CBL and NBL, above the ABL, θ_v changes from decreasing or constant with height, to increasing with height, marking the entrainment zone (Stull, 1988). The structure of an SBL, however, can vary a lot more (Mayer et al., 2012; Steeneveld et al., 2007; Zilitinkevich and Baklanov, 2002). In an ideal SBL case, the θ_v inversion is at its strongest (greatest vertical gradient of θ_v) near the surface and transitions to the free atmosphere (nearly constant or 690 gradually increasing θ_v with altitude) above the SBL, with no entrainment zone (Stull, 1988). ZABL is then identified as the altitude of the shift from the surface-based θ_v inversion to the free atmosphere (Stull, 1988). In reality, the structure of an SBL is often not that simple, and the height of an SBL can be difficult to identify based on θ_v alone (Stull, 1988; Zhang et al., 2014). SBLs in the DH2 dataset often include a weaker surface-based θ_v inversion capped by a layer of enhanced stability (stronger θ_v inversion), reminiscent of an entrainment zone, likely because of surface-695 drag induced turbulence close to the surface. ABLs with this structure form as the near-surface atmosphere fluctuates between weakly stable and near-neutral (Brooks et al., 2017). In more difficult cases such as these, the top of the SBL can be better determined by supplementing the θ_v profile with the RH and mixing ratio profiles, which usually have an obvious transition at the top of the ABL (Dai et al., 2014). This transition can manifest as either a shift from zero or positive to negative vertical gradient of humidity, or as a humidity inversion. Use of the humidity profiles can also 700 increase the confidence in identification of CBL and NBL height.

In addition, the Ri_b profile can aid in Z_{ABL} identification (Zhang et al., 2014). Ri_b is the ratio between buoyantly produced (from thermals) or suppressed (from static stability) turbulence, and mechanically produced turbulence (from wind shear; Sivaraman et al., 2013). Therefore, Rib can help to identify the top of the ABL under the assumption that turbulence ceases above the ABL (Stull, 1988). In the limit of layer thickness becoming small, Rib can be 705 compared to a critical value of ~0.25 (Stull, 1988), with Rib below the critical value indicating an atmosphere that is likely to become or remain turbulent, and Rib above the critical value indicating that an already laminar layer will not become turbulent, as static stability is strong enough to suppress mechanically generated turbulence. However, Rib does not assume a small layer thickness, so a critical value is not well defined for Rib. Thus, for Rib near the critical value, there is uncertainty in the likelihood of turbulence (AMS Glossary of Meteorology). Different studies have 710 found the appropriate critical Richardson number to range from as low as 0.15 to as high as 7.2 in coarse resolution

models (Dai et al., 2014), but across the board, lower Rib is expected in the ABL, and higher Rib is expected above the ABL (Seibert et al., 2000). This increase in Rib above the ABL is in large part due to the decrease in wind shear. By examining Rib profiles for the DH2 flights, this transition from low values (near zero) to high values (with an increase of a few digits above the lower altitude values) can aid in identifying the top of the ABL.

Table 3 below outlines the criteria applied to determine Z_{ABL} depending on stability regime, which are separated depending on how many kinks there are in the θ_v profile that might indicate the entrainment zone. The term 'kink' refers to a dramatic shift in slope (i.e., drastic change in vertical gradient). The primary methods applied to determine Z_{ABL} are those in which there are either one or two θ_v kinks, where we rely most heavily on the θ_v profile, and secondarily on the humidity profile. Only in few especially difficult cases were the Ri_b profiles used heavily.

Bulk Richardson number is the ratio between buoyantly (from thermals) and mechanically (from wind shear) produced turbulence (Sivaraman et al., 2013). The buoyancy term can also indicate that stability is suppressing turbulence. Therefore, $R_{\rm b}$ can help to identify the top of the ABL under the assumption that turbulence ceases above of the ABL (Stull, 1988), and thus, Ris will exceed a critical value (typically 0.25; Stull, 1988) at the top of the ABL (Seibert et al., 2000). $R_{\rm b}$ is calculated at altitude, z, using the following equation from Stull (1988):

where g is acceleration due to gravity, is mean virtual potential temperature over the altitude bin being considered, z is altitude, u is zonal wind, v is meridional wind, and Δ represents the difference over the altitude bin used to calculate Ri_b throughout the profile. The only way that Ri_b can be negative is if the value for Δ is negative, indicating a convective atmosphere with buoyancy-driven generation of the turbulence. \P

Ri_b values below the critical threshold (often taken as ~ 0.25) indicate a turbulent atmosphere, while values above this threshold indicate that an already laminar layer will not become turbulent, as static stability is strong enough to suppress mechanically generated turbulence. While the critical value of 0.25 is not always the exact number that corresponds to the transition between turbulent and laminar conditions (different studies have used critical Richardson numbers ranging from as low as 0.15 to as high as 7.2 in coarse resolution models; Dai et al., 2014), low Rib is generally expected in the ABL, and high Rib is expected above the ABL. By examining Rib profiles for our DH2 flights, this transition from values near or below 0.25 to well above 0.25 can be identified to mark the top of the ABL. Rib profiles are created by calculating Ri_b over 30 m bins, at 5 m resolution 9

2.3.1 Subjective atmospheric boundary layer height for a CBL¶

To determine the ABL height of a CBL, we identify the bottom of the entrainment zone. From the surface, the θ_v of a CBL decreases with altitude (Stull, 1988). Therefore, to identify the height of a CBL, we identify the altitude at which the potential temperature has returned to its su(...[10])

<u>30 m.</u> Uncertainty in the height of a kink in an individual profile is only subject to the vertical averaging procedure and sensor response time, and thus is on the order of only \sim 1 m.

2.4 Objective identification of atmospheric boundary layer height

The strength of the subjective methods described above is the knowledge of the expert, which cannot be automated. However, such expert knowledge and the time necessary to individually assess profiles is not always available. Thus, an automated method may often be preferred. Four such methods for objectively determining Z_{ABL} are applied and evaluated. Each of these methods relies on profiles of either dθ_v/dz or Ri_b, some in combination with the θ_v and/or wind speed profiles. Because the dθ_v/dz and Ri_b profiles are calculated over an altitude range of 30 m with 5 m resolution, objective Z_{ABL} detection methods which ultimately rely on these profiles can be determined with a resolution of 5 m. If they ultimately rely on the θ_v or wind speed profiles, Z_{ABL} can be determined with 1 m resolution. Figure 3 at the end of Sect. 2.4 shows the application of all objective methods for an SBL and NBL case. A CBL case is not shown, as there were only two CBLs identified in the DH2 profiles, and they are rare in the central Arctic.

2.4.1 Liu-Liang method

The application of the Liu-Liang method depends on whether the profile includes a CBL, SBL, or NBL, which is determined using Eq. (2)-(4). To implement the Liu-Liang method for a CBL profile, we first find the lowest altitude at which θ_v exceeds its the lowest DH2 value by 0.1 K. Then, Z_{ABL} is identified at the next lowest altitude in which dθ_v/dz exceeds 0.05 K 100 m⁻¹ (Liu and Liang, 2010). For an NBL, Z_{ABL} is identified as the altitude at which dθ_v/dz first exceeds 2.5 K 100 m⁻¹, which is adapted from a threshold of 0.05 K 100 m⁻¹ used in Liu and Liang (2010), as this
threshold was found to be inappropriate for the current dataset (Z_{ABL} found with the original threshold was always far too low; this may be due to differences in the vertical resolution or smoothing of our data versus that used by Liu and Liang (2010)). The basis of this method is to identify the entrainment zone at the top of the ABL through an increased value of dθ_v/dz.

For an SBL, the Liu-Liang method searches for a potential Z_{ABL} associated with either minimal turbulence due to the
915 lack of buoyancy within the ABL, or greater turbulence in the ABL due to the presence of wind shear (Liu and Liang, 2010), both scenarios which may dictate Z_{ABL} for an SBL (Stull, 1988). Thus, SBL height is defined as either the top of the bulk stable (θ_v inversion) layer starting from the ground, or the height of the LLLmaximum if present, whichever is lower (Liu and Liang, 2010). The top of the bulk stable layer is identified where the surface-based θ_v inversion has consistently diminished, and LLJ presence is identified by searching for wind speeds reaching a maximum that is at least 2 m s⁻¹ stronger than the local minima above and below (Stull, 1988; Liu and Liang, 2010). For greater detail on these methods, and the guiding equations, see Liu and Liang (2010). Supplementary Figure S1 shows an example of the Liu-Liang method applied to a case for each stability regime.

2.4.2 Heffter method

1055

1060

The Heffter method uses θ_v difference across a θ_v inversion ($d\theta_v$) as an indication of Z_{ABL} (Sivaraman et al., 2013), by identifying the lowest θ_v inversion layer where $d\theta_v/dz$ is greater than 0.5 K 100 m⁻¹ throughout the θ_v inversion, and $d\theta_v$ is at least 2 K (Heffter, 1980; Pesenson, 2003; Sivaraman et al., 2013), Within this θ_v inversion, the altitude at which θ_v first becomes more than 2 K greater than θ_v at the bottom of the θ_v inversion is labelled as Z_{ABL} (Marsik et al., 1995; Delle Monache et al., 2004; Snyder and Strawbridge, 2004; Sivaraman et al., 2013).

For a CBL or NBL, this method is meant to determine the altitude of the elevated θ_v inversion marking the entrainment zone between the <u>well-mixed ABL</u> and free atmosphere (Pesenson, 2003). For an SBL, this method determines where the change in strength of the surface θ_v inversion marks the transition from the ABL to residual layer (if one exists) or free atmosphere above (Stull, 1988). For greater detail on this method, and the guiding equations, see Heffter (1980) or Sivaraman et al. (2013). Supplementary Figure S2 shows an example of the Heffter method applied to a case for each stability regime

2.4.3 Virtual potential temperature gradient maximum (TGRDM) method

The final $d\theta_v/dz$ -based method used to find Z_{ABL} , is the virtual potential temperature gradient maximum (TGRDM) / method (Dai et al., 2014). Since the ABL is typically capped by a well-defined θ_v inversion layer (Stull, 1988), even in a weakly stable case, we expect to see a <u>local maximum</u> in the $d\theta_v/dz$ profile at this point. By finding the maximum / in the $d\theta_v/dz$ profile, the altitude at which the θ_v inversion is at its strongest and weakens above is identified. To apply / this method, <u>local maxima</u> in the $d\theta_v/dz$ profile where $d\theta_v/dz$ is at least 1.75 K_l00 m⁻¹ greater than the local minimum / $d\theta_v/dz$ above are identified. <u>Z_{ABL}</u> is set to the altitude of this lowest peak. <u>Supplementary Figure S3 shows an example</u> / **1070** of the TGRDM method applied to a case for each stability regime.

2.4.4 Bulk Richardson number method

Finally, a bulk Richardson number method for finding the ABL top is applied by determining the altitude at which Rib exceeds a critical value, which indicates where turbulence was likely no longer able to form in a laminar atmosphere. Previous literature suggests a wide range of critical values with 0.25 (Stull, 1988) being the most widely accepted
value, though a value of 0.5 is also often used (Sivaraman et al., 2013; Zhang et al., 2014). To determine a viable threshold value for the identifying Z_{ABL} in the DH2 data, a comparison between Z_{ABL} determined from a range of threshold values (we used 0.25, 0.5, 0.75, 1.0, 1.25, and 1.5) and the subjective Z_{ABL} was conducted. In identifying Z_{ABL} from these different threshold values, the level above which Rib was consistently greater than the threshold value was found. For this dataset, four consecutive datapoints (20 m) were required to be above the threshold value. The altitude of the lowest of these four consecutive points is identified as Z_{ABL}. The threshold values deemed to identify Z_{ABL} closest to that identified by the subjective methods was 0.5 followed by 0.75. Therefore, further Z_{ABL} presented using the Rib method is calculated with critical values of 0.5 (hereafter called Rib(0.5)) and 0.75 (hereafter called Rib(0.5)). Supplementary Figure S4 shows an example of the Rib method applied to a case for each stability regime.

2.5 Applying the objective methods to radiosonde profiles

As discussed above, some of the objective methods used in this study were modified from their original descriptions to better work with the Arctic UAS data. Primarily, this includes changing the altitude range for determining stability regime, adjusting the threshold for calculating Liu-Liang NBL height, adding the 1.75 K 100 m⁻¹ criterion to the 1210 TGRDM method, and choosing the best threshold values as well as specifying the necessary vertical distance for the Rib method. These adaptations are necessary in part because previous implementations involved analysis of radiosonde profiles, which have a lower resolution than the DH2 profiles, and in mid-latitude locations, where the ABL structure is often quite different than that observed in the Arctic (due to the lack of daytime convection or a diurnal cycle in the Arctic most of the time). Thus, profiles of θ_x , humidity, and wind speed from the balloon-borne radiosondes that were 1215 launched at least four times per day from the deck of the Polarstern (Maturilli et al., 2021) during MOSAiC are leveraged to determine if the objective methods used to identify ZABL from the UAS data are robust across platforms, despite differences in sampling methods.

To do this, radiosonde profiles with launch times closest to the DH2 flight times (within at most ~3 hours) are used, repeating the same processes for subjective and objective Z_{ABL} identification and comparison. In eight instances, there 1220 were two DH2 flights in closest time proximity to the same radiosonde launch, so we use data from a total of 57 different radiosonde profiles. The specs for the Vaisala RS41-SGP sensor, which recorded the radiosonde variables, are the same as those listed in Table 2 for the DH2's RSS421 sensor, with the addition of a wind uncertainty and resolution of 0.15 m s⁻¹ and 0.1 m s⁻¹ respectively for velocity, and of 2 ° and 0.1 ° respectively for direction. Before proceeding with analysis, profiles of temperature, wind, and humidity from the radiosondes were visually compared 1225 to those from the corresponding DH2 flight to confirm that the measurements were similar to each other.

Prior to applying the objective methods, data below 23 m altitude were removed, as the lowest part of the radiosonde profiles were found to show inaccurately warm temperatures for several cases (Maturilli et al., 2021), due to the Polarstern acting as a "heat island." Additionally, in some cases, the radiosonde data showed anomalously warm measurements some distance above 23 m, which is assumed to be the result of the balloon passing through the 1230 Polarstern's exhaust plume. These measurements were adjusted by interpolating the temperature between the closest good measurements above and below where the radiosonde was presumably in the ship's plume. Applying these adjustment means that radiosonde data near the surface are not available for determination of stability regime. Therefore, we adapt the methods applied to the DH2 data in Eq. (2)-(4) and instead calculate $d\theta_v$ between the lowest radiosonde measurement and 30 m above, or the subjective Z_{ABL} if lower. We then compare this $d\theta_v$ to the appropriate 1235 threshold value, δ_s , that is equal to (0.2 K/40 m = 0.005 K m⁻¹) x the altitude range used. For example, if the 30 m altitude range is used, the value of δ_s is 0.15 K.

Figure 3, shows two examples (one SBL and one NBL) of all of the objective methods applied to both a DH2 flight and its corresponding radiosonde. These examples show that the subjective ZABL identified using the DH2 and radiosonde data are similar (differ by only 2 m for the SBL and 12 m for the NBL), and that the objective methods

As discussed above, some of the objective methods used in this study had to be modified from their original descriptions to work with the Arctic UAS data. This is in part because previous implementations involved analysis of radiosonde profiles and in mid-latitude locations. To determine if these modifications are robust across sensing platforms, they are additionally applied to identify ABL height using radiosonde data from the MOSAiC expedition (Maturilli et al., 2021). To do this, data from radiosondes launched within 3 hours of each DH2 flight were used to repeat the processes outlined in section 2.3 for subjectively identifying ABL height using the θ_v, humidity, and Ri_b profiles.

The best fit linear regression for each method shows that as time between the DH2 and radiosonde launch increases, the differences in ZABL height increase as well. However, the increase in percent difference difference between subjective ZABL ABL height (... [31])

1B75 resulting from a paired two sample T-test. For instances in which there were two DH2 flights in closest time proximity to the same radiosonde launch, the results from that radiosonde profile are plotted only once.

The R² value demonstrates how much of the variation in objective Z_{ABL} can be explained by the difference in subjective Z_{ABL} . Z_{ABL} Slope values are also included to help evaluate the level of correspondence between the subjective and objective Z_{ABL} . Z_{ABL} Additionally, looking at the intercept combined with the slope value tells us whether the objective method tends to over- or underestimate Z_{ABL} compared to the subjective method. Lastly, the p-value tells us whether the relationship / between subjective and objective Z_{ABL} can be considered statistically significant at the 5% significance level (a p-/ value less than 0.05 indicates that there is a 95% chance the relationship is due to true correlation).

1380

Based on the DH2 data in these scatter plots, the method that gives the greatest R² value is the Ri_b(0.5) method (R² of 0.653, Fig. 5d), followed by the Ri_b(0.75) method (R² of 0.537, Fig. 5e). These are followed closely by the Heffter method (R² of 0.485, Fig. 5b). The TGRDM method has the fourth highest R² value (R² of 0.316, Fig. 5c). The only objective method with a very low R² value is the Liu-Liang method (R² of 0.0007, Fig. 5a). The slope values for all methods are within 0.3 of 1, the closest to 1 being the Ri_b(0.75) method (slope of 1.02), followed by the TGRDM method (slope of 1.12). These slope values greater than 1 and positive intercept indicate that these methods generally overestimate ZABL when applied to the DH2 data, compared to the subjective ZABL. The results of the Ri_b(0.5) method and the Liu-Liang method, however, are more complex, as the slope values are both less than 1 (0.721, and 0.708, respectively), but the intercepts are both positive. This indicates that these methods overestimate ZABL but underestimate, it for a deep ABL when applied to the DH2 data. Comparing the p-values for all relationships to the 5% significance level, the relationship between subjective and objective ZABL is significant for every method (p-value is less than 0.05). These p-values follow the same order as the /// subjective zABL by the same order as the /// subjective zABL by the same order as the /// subjective zABL by the same order as the /// subjective zABL by same order as the //// subjective zABL by same order as the //// subject

1395 R² values, with the lowest p-value found for the <u>Ri⊧(0.5)</u> (indicating the highest significance) and the highest p-value for the Liu-Liang method (indicating the lowest significance).

The radiosonde data gives a slightly different conclusion. Here, the method that gives the greatest R² value is the Heffter method (R² of 0,558, Fig. 5b), followed by the Ri_b(0.5) method (R² of 0,42, Fig. 5d). The Ri_b(0.75) method and the TGRDM method have lower R² values (0.207, and 0.225 in Fig. 5e and 5c, respectively). As was the case for the DH2 data, the only objective method with a very low R² is the Liu-Liang method (R² of 0,00597, Fig. 5a), which, is also echoed by a slope value far from 1, of 0,171. The slope values for the rest of the methods are not as close to 1 as they are for the DH2 data, but they are all within 0.5 of 1. The TGRDM has a slope value of 1, and the method with the next closest value to 1 is the Heffter method at 1.13. Both of these methods have a positive intercept, which indicates that these, method tends to overestimate ZABL when applied to the radiosonde data used in the current study.
1405 The rest of the methods have a slope of less than 1 and positive intercept, indicating that they tend to overestimate ZABL for a shallow ABL but underestimate it for a deep ABL when applied to the radiosonde data used in the current / study Lastly, the p-values follow the same order as the R² values, with the lowest p-value found for the Heffter method / (indicating the highest significance) and the highest p-value for the Liu-Liang method (indicating the lowest

significance). Unlike the DH2 results, for the radiosonde, the p-values for all relationships compared to the 5%

significance level show that the relationship between subjective and objective ZABL is significant for every method except the Liu-Liang method, in which the p-value is greater than 0.05,

1745

Lastly, Fig. 5f compares subjective Z_{ABL} from the radiosondes to subjective Z_{ABL} from the DH2. The high R² value (0.752) indicates a strong correlation between subjective Z_{ABL} from both platforms, which demonstrates that Z_{AB} usually did not change much between the DH2 and radiosonde launches in each case. Interestingly, there is enhanced deviation from the line of best fit for a shallower ABL, and better agreement for a deeper ABL, However, this might simply be due to the greater number of samples with ZABL below ~200 m. The very low p-value of 2.62e-18 demonstrates the high significance in the relationship between ZABL from the DH2 and radiosondes.

shows results for only SBLs, and S71 shows results for only NBLs. The primary takeaways from separating the results 1760 into stability regime is that, for SBLs, the Heffter and TGRDM methods have the highest R² values, and for NBLs, the Rip(0.5) and Rib(0.75) methods have the highest R² values for the DH2 data. For the radiosonde data, the Heffter and Rib(0.5) methods have the highest R² values for SBLs; for NBLs, the same methods, plus the Liu-Liang method, have the highest R² values.

[39]) Additional analysis was completed to assess the <u>cumulative frequency distribution for the difference in objective Z_{ABL} </u>, relative to the subjective Z_{ABL} . To do this, relative difference between the objective and subjective Z_{ABL} in each case and for each method was determined. These results are included in Fig. 6a for the DH2 profiles, and in Fig. 6b for the radiosonde profiles. For example, about 26% of the time, the Liu-Liang Z_{ABL} within 10% of the subjective Z_{ABL} for the DH2 data.

1855

Figure 6a shows that, for the DH2 profiles, the Rib(0.75) method results in the highest percent of cases to be within 10% of the subjective ZABL followed by the Rib(0.5) method. Interestingly, the Liu-Liang method results in the third highest percent of cases to be within 10% of the subjective ZABL However, the Liu-Liang method falls behind other methods as the percent difference range is increased above 20%. Additionally, the Liu-Liang method has the highest percent of cases in which no ZABL is found at all for the DH2 profiles, as well as about 20% of cases that have greater than 100% difference from the subjective ZABL. This trend indicates that, while the Liu-Liang method sometimes works to find a ZABL close to the subjective ZABL. This trend indicates that, while the Liu-Liang method sometimes works to find a ZABL close to the subjective ZABL. This trend indicates that, while the Liu-Liang method sometimes works to find a ZABL close to the subjective ZABL. This trend indicates that while the Liu-Liang method sometimes works to find a ZABL close to the subjective ZABL. This trend indicates that while the Liu-Liang method sometimes works to find a zabl close to the subjective ZABL with a so fails to find a zabl close to the subjective ZABL or to find any ZABL in many cases. Another important finding is that the Rib method using either critical value never fails to find a ZABL and the number of cases within each relative difference range is greater for the Rib method than that for all other methods.

The information presented in the bar graph for the radiosonde profiles (Fig. 6b) leads to a similar conclusion. As for the DH2 profiles, the Ri_b method results in the highest percent of cases to be within 10% of the subjective Z_{ABL} (but for this platform, the Rib(0.5) method does best). Here, the Liu-Liang method results in the fourth highest percent of cases to be within 10% of the subjective $\underline{Z_{ABL_{a}}}$ and performs more poorly as the percent difference range is increased. 1870 The Liu-Liang method also has the highest percent of cases in which no ZABL is found at all, followed by the Heffter and TGRDM methods, which was also true for the DH2 data. As for the DH2, there are no radiosonde cases in which the Rib method with either critical value finds no ZABL, The main difference between Fig. 6b of the radiosonde data and Fig. 6a of the DH2 data is that, while the Rib(0.75) method applied to the DH2 data was always more successful than the $Ri_{b}(0.5)$ method for percent difference ranges below 70%, for the radiosonde data, the $Ri_{b}(0.5)$ method proves 1875 to always be more successful than the Rib(0.75) method. We suspect that this results from the radiosonde data being more smoothed, which produces less sporadic Rib values as the atmosphere transitions from the ABL to the free atmosphere, compared to the less smoothed DH2 data. This smoothing of the radiosonde data is applied by the Vaisala software to remove any effect of the chaotic pendulum swing directly after launch, while the wire unwinds. Thus, a lower critical Righthreshold value may be better applicable when more smoothing or filtering procedures are applied

1880

Supplementary Figures S72 and S73 show the results presented in Fig. 6, but separated by stability regime, where S72 shows results for only SBLs, and S73 shows results for only NBLs. The primary takeaways from separating the results into stability regime is that, for both the DH2 and radiosonde, the Rig method has the most cases and the Liu-Liang method has the least cases with objective ZABL within 10% of the subjective ZABL for SBLs, though the Heffter and TGRDM methods also do well. For NBLs, the Liu-Liang method actually has the most cases with objective ZABL

within 10% of the subjective ZABL, followed by the Rib method, for both platforms.

2110

After comparing Z_{ABL} from the different objective methods to the subjective Z_{ABL} for both the DH2 and the radiosondes (Fig. 5-f), it is found that, with the exception of the Liu-Liang method, all other methods generally provide a reasonable estimate of Z_{ABL} for both datasets, with the Ri_b method being most favorable. This is in agreement with Siebert et al. (2000), Dai et al. (2014) and Zhang et al. (2014) which found an Ri_b-based method to be preferred when mechanically-produced turbulence dominates, as is true in the central Arctic (Brooks et al., 2017). Additionally, the

efficacy of each method is similar for the DH2 and the radiosonde data, as is indicated by similar patterns in the scatter plots (Fig. 5) and bar plots (Fig. 6), despite occasional differences in radiosonde versus DH2-based Z_{ABL} estimates, which likely result from the differences in sampling methods between the two platforms. Most specifically, the DH2 samples directly from the surface in most cases, so it observes important ABL features that support accurate stability and Z_{ABL} identification, whereas the radiosonde, which only samples down to 23 m at the lowest, may miss these features. Additionally, the DH2 samples with higher resolution, again contributing to its ability to record complex fine scale features which the radiosonde might miss. However, the similarity in efficacy of the objective methods between both platforms supports the fact that the objective Z_{ABL} identification methods that were improved using the high resolution DH2 data are indeed robust across platforms with different sampling methods.

This is further explored by re-running the analysis with DH2 profiles averaged over 5 m, 10 m, and 20 m bins instead of 1 m bins, to determine how sensitive the efficacy of the methods is to the vertical resolution of the data. When comparing objective Z_{ABL} found using the coarser data to the original subjective Z_{ABL} for each method, the F-test reveals that generally the R² values do not differ significantly from those found using 1 m binned data at the 5% significance level. The only exceptions are the Liu-Liang method at all larger bin sizes, and the Heffter method when using a 10 or 20 m bin size, which all manifest in lower R² value than those found using 1 m binned data. This reveals that the Liu-Liang method performs even more poorly at lower vertical resolution, and the Heffter method starts to perform more poorly at a vertical resolution of 10 m. On the other hand, the Rig and TGRDM methods remain just as

successful when vertical resolution is reduced, and the preferred R_{lb} critical value does not appear to depend on vertical resolution. For vertical resolution of 30 m or coarser, the altitude range over which R_{lb} is calculated would have to be increased, and at this point a higher critical R_{lb} value may be more applicable.

2140 **3.2 When the objective methods fail**

 While the Liu-Liang method sometimes works well, it is not reliable across a wide range of different profile structures. Table 4 lists the most common features which cause the Liu-Liang method to fail, along with the corresponding failure (either over- or underestimation, or no Z_{ABL} found) and an example of such a situation shown in the Supplementary Figures. Option 1a causes failure because the dθ_v/dz criteria are not met anywhere in the profile, meaning that the method reverts to using the LLJ core height as Z_{ABL}. However, the LLJ core was observed to usually be above the subjective Z_{ABL} (supported by Stull, 1988; Jakobson et al., 2013; and Mahrt et al., 2014). This cause for failure agrees with Dai et al. (2011) which found that using LLJ core height to define SBL top produces results inconsistent with those from other methods.

2150 Any of the other objective methods would be a good choice for objectively determining Z_{ABL} for a dataset similar to 2150 the DH2 and radiosonde datasets (high resolution profiles in the central Arctic environment). However, each method still struggles in some situations. As for the Liu-Liang method, this information is shared for all other objective methods in Table 4. The primary downfall of the Heffter method is that it identifies Z_{ABL} as the point where θ_x is 2 K warmer than θ_y at the bottom of the θ_y inversion. Failures noted in options 1-3 in Table 4 all occur when this criterion does not accurately identify the ABL top. The primary downfall of the TGRDM method, as noted in options 1-2 in

Deleted: While the Liu-Liang method sometimes works well, it is not consistent enough to be reliable across a wide range of different profile structures. Specifically, this method often struggles to accurately predict ABL height of SBLs because the $d\theta_v/dz$ criteria are not met anywhere in the profile, usually because a weak θ_v inversion persists throughout the whole $d\theta_v/dz$ profile, meaning that the method reverts to using the LLJ height as the ABL height. However, the LLJ is usually above the ABL, so this predicts the ABL height to be too high (example: Supplementary Fig S2 on 24 March at 12:09 UTC). If there is no LLJ in the profile and a weak θ_v inversion persists throughout the whole $d\theta_v/dz$ profile, then the Liu-Liang method will not identify any ABL height (example: Supplementary Fig. S29 on 30 April at 14:07 UTC). In most NBL cases, the Liu-Liang method is very successful, but it fails when there is a gradual transition between the ABL and the entrainment zone, as opposed to a sharp change in θ_v slope at the top of the ABL (example: Supplementary Fig. S50 on 17 July at 13:30 UTC).

Any of the other objective methods would be a good choice for objectively determining ABL height for a dataset similar to the DH2 and radiosonde datasets (high resolution profiles in the central Arctic environment). However, each method still struggles in some situations, which leads them to either over- or underestimate ABL height. The Heffter method sometimes estimates an ABL height above what is identified as the subjective ABL height when there is a neutral ABL with constant θ_v with altitude, capped by a weak θ_v inversion (minimal θ_v change with altitude). Because the Heffter method identifies the ABL height as the point where θ_v is 2 K warmer than θ_v at the bottom of the θ_v inversion then, in such a scenario this method would identify the ABL as part way through the entrainment zone, while the subjective criteria identify the top of the ABL to be the bottom of the entrainment zone (example: Supplementary Fig. S52 on 18 July 13:10 UTC). The Heffter method also struggles to identify the ABL height of a SBL where the ABL may extend beyond the altitude at which θ_v is 2 K warmer than θ_v at the surface (example: Supplementary Fig. S1 on 23 March at 13:52 UTC) or may not extend all the way to the altitude at which θ_v is 2 K warmer than θ_v at the surface (example: Supplementary Fig. S38 on 21 June at 13:13 UTC).

The TGRDM method sometimes struggles to identify the correct ABL height, since it identifies the strongest point of the θ_v inversion as the ABL height. While this often occurs at the altitude identified as the subjective ABL height, it also sometimes occurs part way through the entrainment z(...[46])

When applying these objective methods to a large dataset to automatically identify Z_{ABL}, it is recommended that some level of pre-screening is applied to flag cases that contain the features or structural patterns summarized in Table 4 that would make certain objective methods have difficulty identifying Z_{ABL} and choosing which objective method to use based on that.

2300 On the simplest level, one could choose which objective Z_{ABL} detection method to use based on stability regime. Given⁴ the results in Supplementary Figures S70-73, the best choice to use for SBLs might be the Heffter method (highest R² and higher frequency of cases within 10% of the subjective Z_{ABL} when compared to NBL cases, from both the DH2 and radiosonde data) and the best choice to use for NBLs might be the Rib method with either critical value (highest R²'s from the DH2 data and higher frequency of cases within 10% of the subjective Z_{ABL}, when compared to SBL cases, from both the DH2 and radiosonde data). However, when separating out the efficacy of the objective methods depending on stability regime, the Rib method has a combination of a high R² values and a high percentage of cases with objective Z_{ABL} within 10% of the subjective Z_{ABL} for both stability regimes, so this would be the best choice to apply to all profiles if one wanted to choose a single method, preferably with critical value of 0.5.

Overall, the objective methods are more likely to agree with each other as well as with the subjective Z_{ABL} for cases
 with more simplistic structures, such as those with strong θ_v inversions with a base at or just below the top of the ABL, those with LLJ core altitude at or just above the top of the ABL, and those with consistently and somewhat gradually increasing θ_v with altitude above the entrainment zone.

4. Summary and conclusions

2315

2320

By comparing subjective Z_{ABL} identified visually in θ_v , humidity (both RH and mixing ratio), and Rib profiles to objectively determined Z_{ABL} it the performance of several published methods (i.e., Liu-Liang, Heffter, TGRDM, and Rib) are evaluated across 65 DH2 UAS profiles. When comparing objective to subjective Z_{ABL} for each DH2 case, the method that is most successful (combination of high R² value, low p-value, and slope close to 1) is the Rib method with either critical value of 0.5 or 0.75 (Fig. 5). When calculating the percent of DH2 cases in which the objective Z_{ABL} is within certain percent difference ranges from the subjective Z_{ABL} the Rib method is also most successful (Fig. ϕ). The Heffter and TGRDM methods also produce reasonable results according to Fig. 5 and 6. The only objective method that Jargely fails at accurately identifying Z_{ABL} is the Liu-Liang method.

In the process of applying these different objective methods to the DH2 data, some threshold and qualifying values were modified to be better applicable to the UAS dataset. While these adjustments were made to best suit the 65 DH2 profiles analyzed in this study which occurred between March and July of 2020, these adjustments should yield better results for identifying Z_{ABL} over sea ice during any season and location in the central Arctic. We hypothesize this because the ABL structures sampled by the DH2 in the current study were diverse and encompass the variety of ABL structures commonly observed in the central Arctic (which are typically shallow and either stable or neutral) throughout the entire year. Additionally, since the locations of the DH2 flights in this study range from deep in the sea

2350 ice pack to near the sea ice edge, we are confident that the adjustments made will be applicable for identifying ZABL in either environment.

Testing these adjustments outside of the 65 DH2 flights, the modified techniques were also applied to the radiosonde profiles closest in time to each DH2 flight, to determine if the methods work similarly on data from another sensing platform with different sampling methods. Radiosonde profiles closest in time proximity to the DH2 flights were used under the assumption that the ABL structure would change minimally between the launch of the two platforms (supported by Fig. 4), and thus applying the methods of subjective and objective ZABL detection would lead to a similar conclusion. For the radiosonde data, the Heffter and Rib methods prove most successful in terms of having a high R² value, low p-value, and slope closest to 1 when compared to the other objective methods (Fig. 5). Additionally, the Rib method also proves most successful when looking at the percent of cases in which the objective ZABL was within different percent difference ranges for the radiosondes, as it did for the DH2 (Fig. 6). Once again, the only method that consistently provided unfavorable results is the Liu-Liang method. These similar conclusions demonstrate that the adapted objective methods are indeed robust across platforms despite differences in sampling method, which suggest that one can take the methods and apply them to UAS, radiosonde, or other profile data alike, without having to tweak them.

2365 These findings show that no single method works well 100% of the time. Given this, the best way to accurately identify Z_{ABL} across a variety of conditions in the Arctic atmosphere is to visually analyze the θ_v , humidity, and Ri_b profiles for each case individually. However, as subjective identification is time consuming and requires expert knowledge of the physical processes that dictate ABL structure, then in the case of large datasets that require automated processing techniques, the current study reveals that the Rib, Heffter, or TGRDM methods are most suitable for such a task, with 2B70 the preferred method being the Rib method with critical value of 0.5. For data with vertical resolution of 10 m or coarser, the Heffter method is no longer recommended. The Liu-Liang method does not provide consistent results in accurately identifying Arctic ZABL in many cases, especially for SBLs (Fig. \$72). The most common occurrence of failure of the objective methods exists for NBLs capped by a weak θ_v inversion, so that a clear θ_v slope change between the ABL and entrainment zone is difficult for automated methods to find. In such cases, the Rib method was found to 2375 be most reliable for identifying ZABL, A full list of features which cause each objective method to fail is provided in Table 4 above. The objective methods may also fail if the near-surface atmosphere is not well sampled, for example in the case of the radiosonde data; if ABL stability is defined by what is happening near the surface (e.g., a shallow convective layer), then this is missed by radiosonde profiles which only begin 23 m or higher, and stability regime could be incorrectly diagnosed. This highlights the value of platforms which can sample the near-surface atmosphere, 2380 such as the DH2. To accommodate the above problems, a semi-automatic approach may be beneficial in which one would apply all the recommended objective methods, and visually inspect only the profiles for which the resulting

The methods and results of this study for stability regime and Z_{ABL} identification are currently being applied to the entire year of radiosonde data collected during the MOSAiC expedition (October 2019 – September 2020) to create a

data product containing year-long statistics on ABL characteristics in the central Arctic. Additional metrics, such as JLJ height and speed and temperature inversion layer depth and strength will be included in this product for eventual publication. Value from the DH2 data and methods used in the current study comes from the uniqueness of the location and timing of the profiles collected. Therefore, these data provide a unique opportunity to evaluate any additional ZABL detection schemes that were not addressed in this study, or that have yet to be developed, as well as can be used to learn about the intricacies of additional structural components of the Arctic atmosphere such as the entrainment zone. Lastly, we are working to derive turbulence parameters from the DH2 fine wire measurements which will enhance the value of the DH2 data in ABL studies.

Data availability

2420 All DataHawk2 data used in this study are openly available from the National Science Foundation Arctic Data Center⁴ at https://doi.org/10.18739/A2Z60C34R (Jozef et al., 2021) as described in de Boer et al. (submitted). The radiosonde data are available at the PANGAEA Data Publisher at https://doi.org/10.1594/PANGAEA.928656 (Maturilli et al., 2021). These data are subject to the MOSAiC Data Policy (Immerz et al., 2019) and will be openly available after 1 January 2023,

2425 Author contributions

GdB and JC planned the DH2 data collection and acquired funding; GJ and JC conducted DH2 flights; <u>SD provided</u> <u>the radiosonde data</u>; GJ, JC, and GdB conceptualized the analysis presented in this paper; GJ analyzed the data; GJ wrote the manuscript; JC, <u>GdB</u>, and <u>SD</u> reviewed and edited the manuscript.
