24 **Abstract.**

25 To investigate the cloud phase and macrophysical properties over the Southern Ocean (SO), the  
26 Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) Mobile Facility  
27 (AMF2) was installed on the Australian icebreaker *Aurora Australis* during the MARCUS field  
28 campaign [41 to 69 °S; 60 to 160 °E] from October 2017 to March 2018. To examine cloud  
29 properties over the mid-latitude and Polar regions, the study domain is separated into northern  
30 (NSO) and southern (SSO) parts of the SO with a demarcation line of 60 °S. The total cloud  
31 fractions (*CFs*) were 77.9 %, 67.6 %, and 90.3 % for the entire domain, NSO and SSO, respectively,  
32 indicating that higher *CFs* were observed in the Polar region. Low-level clouds and deep  
33 convective clouds are the two most common cloud types over the SO.

34 A new method was developed to classify liquid, mixed-phase and ice clouds in single-layered  
35 low-level clouds (LOW) where mixed-phase clouds dominate with an occurrence frequency (*Freq*)  
36 of 54.5 %, while the *Freq* of the liquid and ice clouds were 10.1 % (most drizzling) and 17.4 %  
37 (least drizzling). The meridional distributions of low-level cloud boundaries are nearly  
38 independent of latitude, whereas the cloud temperatures increased ~8 K and atmospheric  
39 precipitable water vapor increased from ~5 mm at 69 °S to ~18 mm at 43 °S. The mean cloud liquid  
40 water paths over NSO were much larger than those over SSO. Most liquid clouds occurred over  
41 NSO with very few over SSO, whereas more mixed-phase clouds occurred over SSO than over  
42 NSO. There were no significant differences for ice cloud *Freq* between NSO and SSO. The ice  
43 particle sizes are comparable to cloud droplets and drizzle drops, and well mixed in the cloud layer.  
44 These results will be valuable for advancing our understanding of the meridional and vertical  
45 distributions of clouds and can be used to improve model simulations over the SO.

47 **1. Introduction**

48 The Southern Ocean (SO) is one of the cloudiest and stormiest regions on the Earth (Mace et  
49 al., 2009; Chubb et al., 2013). Over the SO, most of the aerosols are naturally produced via oceanic  
50 sources given the remote environment. The uncertainties of aerosol forcing caused by natural  
51 emissions have larger variances than anthropogenic emissions, especially the dimethyl sulfide  
52 (DMS) flux contributes significantly to the bias (Carslaw et al., 2013). The SO is a unique natural  
53 laboratory to address the natural aerosol emissions and their contributions to the biases because it  
54 has rich ecosystems and is remote to human activities (McCoy et al., 2015). However, we have  
55 limited knowledge about cloud formation processes within such clean environments and their  
56 associated aerosol and cloud properties. The unique nature of the SO region features low-level  
57 supercooled liquid and mixed-phase clouds, which is significantly different from the subtropical  
58 marine boundary layer (MBL) clouds where warm liquid clouds are dominant (Dong et al., 2014;  
59 Wu et al., 2020; Zhao et al., 2020), and also different to the Arctic mixed-phase clouds which are  
60 featured with the liquid-topped cloud layer with ice cloud layer beneath (Qiu et al., 2015).

61 Large biases in cloud amount and microphysics over the SO in the Coupled Model  
62 Intercomparison Project phase 5 (CMIP5) climate models result in a near  $30 \text{ W m}^{-2}$  shortwave  
63 radiation deficit at the top of the atmosphere (TOA) (Marchand et al., 2014; Stanfield et al., 2014,  
64 2015), which further leads to unrealistic cloud feedbacks and equilibrium climate sensitivity (Bony  
65 et al., 2015; Stocker et al., 2013). Meanwhile, the efficiency of aerosol-cloud interaction (ACI)  
66 over the SO was found to be crucial for the models' sensitivities to the radiation budget. A new  
67 aerosol scheme in the Hadley Centre Global Environmental model can dampen the ACI and  
68 suppress negative clear-sky shortwave feedback, both of which contribute to a larger climate  
69 sensitivity (Bodas-Salcedo et a., 2019).

70 A climate sensitivity study using CMIP6 general circulation models (GCMs) shows much  
71 higher temperature variations across 27 GCMs in response to doubled CO<sub>2</sub> than those in CMIP5,  
72 which may have resulted from the decreased extratropical low-level cloud cover and cloud albedo  
73 over the SO in CMIP6 (Zelinka et al., 2020). Low-level clouds are a key climate uncertainty and  
74 can explain 50 % of the inter-model variations (Klein et al., 2017) because conversion from liquid  
75 cloud droplets to ice cloud particles decreases the cloud albedo and reduces the reflected shortwave  
76 radiation at TOA. Models, however, have difficulties accurately partitioning the cloud phase  
77 (Kalesse et al., 2016). The phase changes in mixed-phase clouds over the Arctic have proved to  
78 affect the cloud lifetime and radiative properties significantly, that is, converting from ice cloud  
79 particles to liquid cloud droplets may increase the cloud optical depth and the reflected shortwave  
80 radiation at TOA (Morrison et al., 2012). In contrast, models that allow mixed-phase clouds to  
81 glaciate rapidly can produce 30% more warming from doubling CO<sub>2</sub> (McCoy et al., 2014).

82 Phase transition processes have been investigated by several groups using both satellite and  
83 ground-based measurements. For instance, Mace and Protat (2018) found that there are more  
84 mixed-phase clouds over the SO measured from the ship than retrieved from CloudSat and  
85 CALIPSO measurements because the satellites cannot accurately measure clouds below ~1 km.  
86 Lang et al. (2018) used a model to investigate the clouds under post cold frontal systems and found  
87 large biases in model simulations and concluded that the cloud cover and radiative biases over the  
88 SO are highly regime dependent. Of all cloud types, low-level clouds are primarily responsible for  
89 the biases in the model simulations due to the lack of reliable measurements, which leads to a poor  
90 understanding of the conditions where these clouds form and the phase(s) that result. In other  
91 words, a physical representation of clouds, especially for low-level clouds, is unclear but truly  
92 necessary for improving model simulations. Therefore, reliable observations of the cloud macro-

93 and micro-physical properties from ground-based active and passive remote sensors are crucial for  
94 the improvement of model simulations.

95 Previous studies show that cloud phase is primarily dependent on cloud temperature, and the  
96 transition from one cloud phase to another will modify the cloud optical properties, which further  
97 affects the radiation budgets (Hu et al., 2010; Intrieri et al., 2002; Morrison et al., 2012). Based on  
98 satellite observations and retrievals, Hu et al. (2010) found that supercooled liquid water (SLW)  
99 clouds are most common in the low-level clouds over the SO, where 80% of low-level clouds  
100 contain SLW in a wide range of cloud temperatures from 0°C to -40°C. The formation of SLW  
101 clouds is usually related to strong boundary layer convection. However, when ice nuclei exist in  
102 the mixed-phase clouds, the ice particles can grow quickly and become bigger through consuming  
103 supercooled liquid water drops. The SLW is inherently unstable due to the higher vapor pressure  
104 over liquid than over ice and the quicker vapor deposition on ice particles than on liquid droplets  
105 (Intrieri et al., 2002). As the supercooled liquid cloud droplets glaciate to ice particles, the cloud  
106 layer becomes darker because the ice particles scatter less shortwave radiation and absorb more  
107 radiation in the near IR wavelength regime. It is unclear, however, what role these ice particles  
108 play in the low-level clouds over the SO, which includes the impact on drizzle development.  
109 During HIAPER Pole-to-Pole Observation (HIPPO) campaigns, Chubb et al. (2013) found that  
110 there are rarely ice particles in non-drizzling and light drizzling clouds over the SO, which may  
111 imply that the ice particles in the mixed-phase clouds may modulate the drizzle formation.

112 To investigate the aerosol and cloud properties over the SO, a field campaign called the  
113 Measurements of Aerosols, Radiation, and Clouds over the Southern Ocean (MARCUS) was  
114 conducted using the ship-based measurements between Hobart, Australia, and the Antarctic during  
115 the period October 2017-March 2018. The Department of Energy (DOE) Atmospheric Radiation

116 Measurement (ARM) Mobile Facility (AMF2) was installed on the Australian icebreaker *Aurora*  
117 *Australis*, which voyaged from Hobart, Tasmania to the Australian Antarctic stations of Casey,  
118 Mawson, and Davis, as well as Macquarie Island as illustrated in Fig. 1. Another field campaign,  
119 called South Ocean Clouds, Radiation, Aerosol Transport Experimental Study (SOCRATES) field  
120 campaign was conducted during austral summer from January 15 to February 26, 2018. In this  
121 study, the aircraft in-situ measurements during SOCRAATES are used as the reference for the  
122 analysis. The SOCRAATES domain is shown in the black dotted rectangle box in Fig. 1. The  
123 objectives of the MARCUS campaign are to investigate the vertical distribution of boundary layer  
124 clouds and reveal the reasons why the mixed-phase clouds are common in the warm season  
125 (McFarquhar et al., 2016; McFarquhar et al., 2021). Our study will focus on cloud macrophysical  
126 properties and cloud phase along the shiptracks during MARCUS.

127 MARCUS ship-based instruments include AMF2 cloud radar, lidar, microwave radiometer,  
128 micropulse lidar, radiosonde sounding, precision solar pyranometer and precision infrared  
129 radiometer, as well as aerosol sensors. Through these comprehensive observations over the SO,  
130 we are tentatively answering the following three scientific questions:

- 131 (1) What is the total cloud fraction over the SO during MARCUS, as well as vertical and  
132 meridional variations in cloud fraction?
- 133 (2) What are the dominant cloud types over the SO, their associated cloud phase and  
134 macrophysical properties, as well as their vertical and meridional distributions?
- 135 (3) What are the vertical and meridional distributions of the low-level clouds over the SO?

136 This manuscript is organized as follows: the data and method and introduced in section 2. The  
137 statistical results for all clouds during MARCUS are summarized in section 3. The low-level cloud

138 phase and macrophysical properties are described in section 4, followed by a summary and  
139 conclusions in section 5.

140 **2. Data and Method**

141 **2.1 Ship-based measurements used in this study**

142 The AMF2 instruments, measurements, and their corresponding uncertainties and references  
143 are listed in Table 1. Because AMF2 was designed to support shipboard deployments, the baseline  
144 suite of instruments are marine-focused, including the 95-GHz W-band cloud radar (WACR),  
145 ceilometer, micropulse lidar (MPL), microwave radiometer (MWR), aerosol observation system  
146 (AOS), meteorological measurements (MET, includes the following data: temperature, pressure,  
147 specific humidity, wind direction and speed) on the ship, rain gauge and the radiosonde soundings.  
148 The combined cloud radar and ceilometer measurements can provide the cloud boundaries as long  
149 as there are no optically thin clouds and the cloud-base heights ( $H_{base}$ ) are not greater than the  
150 upper limit (7.7 km) of the ceilometer. The micropulse lidar will be used to identify optically thin  
151 clouds and the clouds with  $H_{base} > 7.7$  km. A previous study has shown that these additional clouds  
152 detected by the micropulse lidar can be a non-negligible supplement to the total cloud fraction  
153 (Mace et al., 2021). A detailed description of the instruments and the cloud parameters during  
154 MARCUS can be found in Mace et al. (2021) and McFarquhar et al. (2016 and 2021).

155 The cloud occurrence frequency can be determined through two steps: the column cloud  
156 fraction is simply the ratio of cloudy samples to the total observations in every 5-min; the  
157 occurrence frequency for each type of cloud during the entire time period equals the ratio of the  
158 number where column cloud fraction is greater than zero to the total 5-min samples. In order to  
159 accurately estimate the cloud temperatures, we adopted a linear interpolation method based on the  
160 daily balloon soundings (4 to 5 times per day) to achieve a better temporal resolution of the vertical

161 profiles of temperature, pressure, and specific humidity. The method considers MET  
162 measurements to ensure vertical continuity and adjacent soundings for temporal continuity. Using  
163 these interpolated atmospheric profiles, cloud temperatures can be obtained at a 5-min temporal  
164 resolution.

165 The cloud liquid water path (*LWP*) and atmospheric precipitable water vapor (*PWV*) are  
166 retrieved based on a physical-iterative algorithm using observations of the microwave radiometer  
167 brightness temperatures at 23.8 and 31.4 GHz with uncertainties ranging from 15 to 30 g m<sup>-2</sup>  
168 (Marchand et al., 2003). It is important to note that the brightness temperature biases switch signs  
169 among different climatological regions because a threshold of 5 °C in cloud-base temperature was  
170 used in their physical retrievals. Since the retrieved LWP and PWV are based on the MWR  
171 measured brightness temperatures at two frequencies, any biases on the brightness temperatures  
172 will affect these retrievals. Therefore, we propose an extra step to determine the uncertainties  
173 during MARCUS. Based on the temperature profiles, we can identify clouds that are not likely to  
174 contain liquid (e.g., pure ice-cloud), then we can estimate the LWP uncertainty based on their  
175 corresponding retrieved LWP values. From the probability density function (PDF\_ analysis, the  
176 LWP uncertainty is estimated as 10 g m<sup>-2</sup> for MARCUS.

177 To determine the precipitation status, the AOS and rain gauge measurements were used to  
178 determine whether rain is reaching the surface qualitatively, but not quantitatively in this study.  
179 All the measurements were averaged over 5 minutes, except the radar reflectivity, Doppler velocity,  
180 and spectrum width used in Section 4.3.

## 181 **2.2 Cloud type classification and single-layer low cloud phases**

182 A classification method developed in Xi et al. (2010) was used to categorize different types of  
183 clouds using ARM radar-lidar estimated cloud base ( $H_{\text{base}}$ ) and top ( $H_{\text{top}}$ ) heights and cloud

184 thickness ( $\Delta H$ ). A brief description of the classification of cloud types is as follows (Table 1 and  
185 Figure 6 in Xi et al., 2010). The single-layered low-level clouds (LOW) is the fraction of time  
186 when low clouds with  $H_{\text{top}} \leq 3$  km occur without clouds above them. Middle clouds (MID) range  
187 from 3 to 6 km without any clouds below and above, while high clouds (HGH) have  $H_{\text{base}} > 6$  km  
188 with no cloud underneath. Other types of clouds are defined by different combinations of the above  
189 three types, middle over low (MOL), high over low (HOL), high over middle (HOM), and the  
190 cloud column through the entire troposphere is defined as HML. Three types, MOL, HOM, and  
191 HML, include both contiguous and non-contiguous cloud layers, and their thicknesses may be  
192 overestimated when clear layer(s) are present between any two cloud layers.

193 Furthermore, we used the measurements of interpolated sounding, microwave radiometer  
194 retrieved *LWP*, radar reflectivity, Doppler velocity and spectrum width to classify the cloud phase  
195 in each radar range volume of low-level clouds during MARCUS. The detailed classification  
196 method will be introduced in Section 4.1. We also used ERA-Interim reanalysis data to study the  
197 environmental conditions during MARCUS. The lower tropospheric stability (LTS) is calculated  
198 from the potential temperature difference between the surface and 700 hPa to assess the boundary-  
199 layer stabilities when the low-level clouds appeared along the shiptracks. The relative  
200 contributions of mixed-phase, liquid and ice clouds to the single-layered low-level clouds as well  
201 as their drizzling status are also analyzed in this study. The latitudinal and longitudinal variations  
202 of the single-layered low-level clouds as well as their vertical distributions are further explored in  
203 this study.

### 204 **3. Statistical results for all clouds during MARCUS**

205 The occurrence frequencies of total cloud cover and different types of clouds and their  
206 associated properties over the entire study domain during MARCUS are presented in Figs. 2 - 4.

207 In order to examine the cloud properties over the mid-latitude and Polar regions, we separate the  
208 SO domain into northern (NSO, north of 60°S) and southern (SSO, south of 60°S) parts using a  
209 demarcation line of 60°S. A total of 2,447 hours cloud samples were collected during MARCUS  
210 in this study, in which 1,181 hours of samples were located in the NSO and 1,266 hours of samples  
211 were collected from the SSO. It is important to note that adding micropulse lidar measurements  
212 increased the total samples of non-liquid-containing clouds by ~20% because micropulse lidar is  
213 more sensitive to optically thin clouds than cloud radar. However, micropulse lidar signals are  
214 usually attenuated and cannot provide a meaningful signal when the liquid cloud layer is thicker  
215 than a couple of hundred meters (Sassen, 1991).

216 Figure 2 shows the vertical distributions of total cloud cover over the entire domain, as well as  
217 over NSO and SSO. For the vertical distributions, the occurrence frequencies of total cloud  
218 increase from the first radar gate (~ 226 m) to ~700 m, then monotonically decrease with altitude  
219 with a few small increments at different levels, especially over SSO. Comparing the occurrence  
220 frequencies of total cloud between NSO and SSO, we can draw the following conclusions. 1) The  
221 SSO has more cloudiness than the NSO under 7 km, while the NSO has more cloudiness than the  
222 SSO above 7 km. 2) Below 3 km, the occurrence frequencies of clouds over the NSO decrease  
223 dramatically from 37 % at an altitude of ~700 m to 16 % at 3 km and from 45 % to 28 % over the  
224 SSO, which is similar to the vertical distributions of the low-level clouds over some Northern  
225 Hemisphere mid-latitude regions, such as Eastern North Atlantic (ENA, Dong et al., 2014). The  
226 occurrence frequencies measured during MARCUS are much lower than those shown in Fig. 8 of  
227 Mace et al., (2009) throughout the entire vertical column between the same range of latitudes,  
228 especially, the occurrence frequencies during MARCUS are almost half of those measured by  
229 CloudSat and CALIPSO from 1 to 3 km. The reason has been explained in Xi et al., (2010), that

230 is, a comparison of occurrence frequencies between measurements of two different platforms can  
231 only be performed under an equivalent spatial-to-temporal resolution. In other words, our results  
232 were calculated under 5-min temporal resolution, and the results in Mace et al., (2009) were  
233 statistically in the  $2^{\circ}$  gridbox. Therefore, the comparison between these two results is not  
234 reasonable. To make a fair comparison, one has to know the cloud amount at each area or time  
235 step, then the product of amount and frequency is independent of either temporal and spatial  
236 measurement.

237 To compare with other studies, we calculated the cloud fractions (*CFs*) of total and different  
238 types of clouds. The total *CFs* were 77.9 %, 67.6 %, and 90.3 % for the entire domain, NSO and  
239 SSO, respectively, indicating that 22.7 % more clouds occurred in the Polar region than in the mid-  
240 latitude region. The total *CF* over the entire domain is very close to the 76 % calculated by Mace  
241 and Protat (2018) using ship-based measurements during the Cloud, Aerosols, Precipitation,  
242 Radiation and Atmospheric Composition (CAPRICORN) field experiment. The total *CF* over the  
243 SSO is close to that estimated by using the complementarity of CALIOP lidar aboard CALIPSO  
244 and CPR aboard CloudSat (DARDAR version 2 data) from Listowski et al. (2019).

245 Figure 3 shows the occurrence frequencies of categorized clouds and their cloud boundaries  
246 using the maximum  $H_{\text{top}}$  and the minimum  $H_{\text{base}}$  if there are two or more layers in each 5-min  
247 sample. For example, the mean  $H_{\text{base}}$  and  $H_{\text{top}}$  for single-layered low-level (LOW) are 0.92 km and  
248 1.62 km, respectively, listed in Table 2, which are the average values of min  $H_{\text{base}}$  and max  $H_{\text{top}}$  in  
249 LOW category. As illustrated in Fig. 3a, the single-layered low-level (LOW), deep cumulus or  
250 multi-layered (HML), and MOL clouds are the three dominant types of clouds over the SO.  
251 Comparing the clouds between NSO and SSO, all types of clouds in SSO have higher frequency  
252 of occurrence than those in NSO except HOL. The differences range from less than 1 % (LOW)

253 to more than 10 % (MOL). Comparing the clouds over mid-latitude oceans between the two  
254 hemispheres, i.e., between NSO and ARM ENA site (Dong et al., 2014), we find: (1) The total  
255 cloud fractions (*CFs*) are close to each other (67.6 % over NSO vs. 70.1 % at ARM ENA); (2)  
256 LOW *CFs* are 22.9 % vs. 27.1 %, which is the dominant type of cloud in both regions; and (3)  
257 Both MOL and HML clouds, including underneath low clouds, are 14.2 % and 16.5 % over NSO,  
258 much higher than those (4.2 % and 12.1 %) at ARM ENA site, indicating that there are more MOL  
259 and deep convective clouds over NSO than over ENA.

260 Figure 3b shows the vertical locations of different types of cloud layers, which represent the  
261 mean  $H_{\text{top}}$  and  $H_{\text{base}}$  listed in Table 2 for any type of cloud. Nearly all  $H_{\text{top}}$  and cloud thickness ( $\Delta H$ )  
262 values over NSO are higher or deeper than those over SSO, presumably due to stronger solar  
263 radiation and stronger convection over NSO.  $H_{\text{base}}$  values basically followed their cloud-top  
264 counterparts with a couple of exceptions. These cloud macrophysical properties are closely  
265 associated with large-scale dynamic patterns and environmental conditions. By analyzing the  
266 ERA-Interim reanalysis (not shown), the 850 hPa geopotential heights show persistent westerlies  
267 with slightly higher geopotential heights over the northwest corner of the domain, which may  
268 closely relate to the higher  $H_{\text{top}}$  over NSO than over SSO. Furthermore, the boundary layer over  
269 NSO is relatively more stable than over SSO based on lower troposphere stability (LTS) analysis  
270 (12.2-15.32 K over NSO vs. 11.48-13.29 K over SSO).

271 When we plot the probability density functions (PDFs) of cloud *LWPs* for different types of  
272 clouds, we find that the PDFs of *LWPs* for HGH and HOM peak are less than  $10 \text{ g m}^{-2}$ . These  
273 results make physical sense because HGH clouds should not contain any liquid droplets, and most  
274 HOM clouds, especially those over SSO, should be ice phase dominant. In addition, the  $10 \text{ g m}^{-2}$   
275 of *LWP* is close to the uncertainty of the *LWP* retrieval in Marchand et al., (2003). Therefore, this

276 value is used as a threshold for all types of clouds, which leads to less than one percent reduction  
277 of the total samples. As shown in Fig. 4a, the *LWPs* ( $> 10 \text{ g m}^{-2}$ ) for all types of clouds are much  
278 higher over NSO than over SSO because the low-level and MOL clouds in the mid-latitudes  
279 contain more liquid water than those in Polar regions. The mean *LWPs* for liquid containing low-  
280 level and middle-level clouds over NSO, i.e. LOW, MID and HOL, range from  $\sim 130$  to  $150 \text{ g m}^{-2}$   
281, while the mean *LWPs* for MOL and HML are two times higher ( $\sim 270 \text{ g m}^{-2}$ ) than the mean *LWP*  
282 of LOW, MID and HOL. Note that the mean *LWPs* for most types of clouds over the SSO are  
283 much lower than those over the NSO, except for the LOW clouds.

284 The occurrence frequencies of *LWPs* ( $> 10 \text{ g m}^{-2}$ ) over NSO and SSO contradict their cloud  
285 *LWP* values as demonstrated in Fig. 4b. To further investigate the amount of available precipitable  
286 water vapor (*PWV*), we found that mean *PWV* values in SSO are at least 2 to 3 times less than  
287 those in NSO for same types of clouds (figure not shown). Note that the samples of MID, HGH,  
288 and HOM clouds are excluded from this study when they have *LWPs* less than  $10 \text{ g m}^{-2}$ , since  
289 these low *LWPs* are within the retrieval uncertainty of cloud *LWP* and hence may not contain any  
290 liquid cloud droplets. The higher *LWPs*, larger cloud droplets, drizzle drops and ice particles, and  
291 greater drizzling occurrence frequencies over NSO (which is discussed later) will lead to the quick  
292 dissipation of clouds over NSO. In contrast to NSO, the SSO cloud *LWPs* and particle sizes are  
293 much smaller with less drizzling events, which increases cloud lifetime relative to NSO. The 67.6 %  
294 and 90.3 % *CFs* over NSO and SSO provide strong evidence for this argument. We can draw the  
295 following conclusions by comparing the cloud macrophysical properties between NSO and SSO  
296 in Figs. 3 and 4. The LOW fraction, thickness, and *LWP* over NSO and SSO are comparable to  
297 each other. For other types of clouds, cloud thicknesses are similar to each other or slightly deeper  
298 over NSO, but the cloud *LWPs* over NSO are much larger than those over SSO, resulting in more

299 precipitation events over NSO. As pointed out in Albrecht (1989), more precipitation events may  
300 reduce the cloud lifetime. This argument is consistent with the results shown in Figs. 2 and 3a for  
301 all clouds except for HOL. Cloud lifetimes over NSO are shorter than those over SSO, which leads  
302 to lower *CFs* over NSO than over SSO.

303 Table 2 provides a summary of the mean, standard derivation, minimum and maximum for  
304 cloud boundaries, LWP and the percentage of multi-layered cloud for each cloud type over the SO.  
305 Non-contiguous (multi-layer) clouds over the SO occur very frequently, especially for HOM and  
306 HML. The *LWP* for single-layered clouds is greater than that for multi-layered clouds. The *LWP*  
307 for single-layered HML almost doubles that for multi-layered HML.

#### 308 **4. Single-layered low-level clouds**

309 As discussed in Section 3, single-layered low-level clouds (LOW) are the dominant cloud type  
310 in both northern (NSO) and southern (SSO) parts of the SO. Figs. 3 and 4 further reveal that LOW  
311 cloud type is the only one having comparable *CF*, cloud, thickness, *LWP* over both NSO and SSO.  
312 This warrants further study: Are the cloud phases, properties, and vertical and meridional  
313 variations of LOW clouds over these two regions similar to each other or significantly different?

##### 314 **4.1. Cloud phase**

315 In this study, cloud boundaries are determined by combining cloud radar, ceilometer and  
316 micropulse lidar measurements at a temporal resolution of 5-min. The cloud phase, liquid water  
317 droplets or ice particles, are determined in each radar range volume. A flow chart for classifying  
318 the phases of single-layered low-level clouds is drawn in Fig. 5. The determination of warm liquid  
319 clouds is straightforward using both cloud-base ( $T_{\text{base}}$ ) and -top ( $T_{\text{top}}$ ) temperatures greater than 0  
320  $^{\circ}\text{C}$ , and cloud *LWP*s greater than the threshold ( $10 \text{ g m}^{-2}$ ). The determination of supercooled liquid  
321 clouds is slightly complicated. When either  $T_{\text{base}}$  or  $T_{\text{top}}$  is below  $0^{\circ} \text{ C}$ , and cloud *LWP*s are greater

322 than the threshold, the radar Doppler spectrum width (*WID*) and velocity ( $V_d$ ) are used for the  
323 determination of supercooled liquid water clouds. If the majority (10 seconds of original radar  
324 measurements) of *WID* within a 5-min period are less than  $0.4 \text{ m s}^{-1}$  and  $V_d$  are equal to or less than  
325  $0.0 \text{ m s}^{-1}$  (updrafts) in the volume, then this range volume is defined as supercooled liquid clouds.

326 Mixed-phase clouds are determined when the median (calculated from 10 seconds of original  
327 radar measurements) of *WID* is greater than  $0.4 \text{ m s}^{-1}$  or  $V_d$  is greater than  $0.0 \text{ m s}^{-1}$  (downdrafts)  
328 due to the existence of large ice particles in the clouds. If cloud *LWP* is below the threshold, then  
329 it is defined as an ice cloud, otherwise it is defined as a mixed-phase cloud. It is worth mentioning  
330 that large ice particles, which grow through vapor deposition or rime processes, dominate the radar  
331 reflectivity and are heavier than cloud droplets. Therefore, these large ice particles not only  
332 broaden the spectrum width but also have relatively large fall speeds.

333 To further evaluate our classification method, we compared the classified mixed-phase and ice  
334 clouds with the micropulse lidar linear depolarization ratios (*LDR*) as an extra measure. The *LDR*  
335 ranges follow the method in Shupe et al., (2005), which are  $0.11 < LDR < 0.15$  for mixed-phase  
336 clouds, and  $LDR > 0.15$  for ice clouds as listed in Table 1. Table 3a shows the quantitative  
337 comparison of the cloud phase identifications between these two classification methods. The  
338 numbers represent the counts of each matched 5-min sample, where the diagonal numbers indicate  
339 that both methods are identifying the same type of cloud phase. In general, the two methods have  
340 89 % agreement on the phase identification. Secondly, we performed the phase classification  
341 directly from microphysical probes onboard G-1 aircraft during SOCRATES and treated them as  
342 'ground-truth' (Mohrmann et al., 2021). Since the in-situ cloud microphysical measurements can  
343 tell us the phase of the cloud, it allows us to see the percentage variations of cloud phase, by  
344 changing integration time of in-situ sampling to mimic what the radar may observe the cloud for

345 each range volume. Table 3b shows possible cloud phase partitionings that may be detected by  
346 cloud radar. As sampling time increases from 1 second to 30 seconds, more mixed-phase clouds  
347 and fewer single-phase clouds can be observed.

348 Figure 6 shows the determination of mixed-phase and ice clouds through combined  
349 measurements of radar reflectivity and spectrum width, lidar LDR and backscatter, and cloud LWP.  
350 For the classified ice clouds, cloud LWPs are lower than  $10 \text{ gm}^{-2}$  (Fig. 6f), most of the Doppler  
351 spectrum widths range from  $0.08$  to  $0.16 \text{ m s}^{-1}$  (Fig. 6b) and the *LDR* ratios (Fig. 6d) can be greater  
352 than  $\sim 0.15$ , representing a narrow range of ice particle size distribution with higher *LDR* ratios.  
353 For the classified mixed-phase clouds, cloud LWPs are greater than  $10 \text{ gm}^{-2}$  and most of the  
354 Doppler spectrum widths range from  $0.15$  to  $0.5 \text{ m s}^{-1}$ , representing a broad particle size  
355 distribution resulting from the mixture of liquid droplets and ice particles. An interesting result  
356 occurs where both *LDR* signals ( $>0.2$ ) and LWPs are much higher during the drizzling periods  
357 (Fig. 6a), indicating a mixed-phase cloud with cloud droplets within the cloud layer and large  
358 liquid drizzle drops and ice crystals below cloud base.

359 Based on the Doppler velocity, the mode values for both mixed-phase and ice clouds occur at  
360  $\sim 0.5 \text{ m s}^{-1}$ , where the ice particles are dominant in both types of clouds. The broader particle size  
361 distribution with lower *LDR* ratios for mixed-phase clouds and narrower particle size distribution  
362 with higher *LDR* ratios for ice clouds further corroborate that the classified results from this study  
363 are consistent with the traditional micropulse lidar *LDR* method.

364 It is important to note that the micropulse lidar signals are usually attenuated and cannot  
365 provide a meaningful signal when the liquid cloud layer is thicker than a couple of hundred meters  
366 (Sassen, 1991). Arctic mixed-phase clouds are typical with the liquid-dominant layer on the top of  
367 the mixed-phase clouds and the ice-dominant layer underneath. The ceilometer-derived cloud-base

368 height represents the base of the liquid-dominant layer near the cloud top, while MPL-derived  
369 cloud-base height represents the base of the lower ice-dominant layer (Qiu et al., 2015; Shupe,  
370 2007; Shupe et al., 2005). Over the Arctic, the micropulse lidar signals can penetrate through the  
371 ice-dominant layer to the liquid-dominant layer. However, the mixed-phase clouds over the  
372 Southern Ocean are totally different from those over the Arctic region: they are well mixed (liquid  
373 droplets and ice particles) from cloud base to cloud top, which is found in this study. Thus, the  
374 micropulse lidar signals can be attenuated in the mixed-phase clouds over the Southern Ocean.  
375 Statistical results show that 43 % of micropulse lidar signals were attenuated during MARCUS  
376 compared to our classified results.

377 This classification method is further supported by the onboard cloud radar measurements  
378 during the Southern Ocean Clouds Radiation Aerosol Transport Experimental Study (SOCRATES,  
379 not shown). In that campaign, the reflectivity measurements were usually greater, and the spectrum  
380 widths were much wider when the aircraft observed large ice particles compared to the time  
381 periods when liquid cloud droplets were observed. Although the wider spectrum widths might be  
382 caused by Doppler broadening of the moving aircraft, further analysis shows that the onboard radar  
383 sends the signals (assuming the time of transmitted and received signals is short enough comparing  
384 to aircraft speed) in the perpendicular to the movement of the aircraft, that is, there is no relative  
385 movement between radar signals and clouds. Thus, the onboard radar spectrum width  
386 measurements should be not significantly impacted by Doppler broadening (relative movement in  
387 the same direction).

388 In this study, a total of 6,934 5-min single-layered low-level cloud samples were determined  
389 using our classificaiton method, including 697 liquid cloud samples, 3,777 mixed, 1,205 ice, and  
390 1,255 'OTHER' clouds. The category of 'OTHER' clouds represents more than one phase in each

391 column. Note that though the ‘OTHER’ is also mixed-phase cloud, it has different vertical  
392 distribution of liquid compared to the ‘mixed’ cloud. It is also worth mentioning that about 5.5 %  
393 of single-layered low-level cloud phases cannot be determined when the radar measurements were  
394 not available during MARCUS, those were not accounted to “OTHER”.

395 Figure 7 (upper panel) shows the drizzling status for each categorized cloud type, i.e., no rain  
396 (yellow-green), virga (brown) and rain (navy blue). The definition of drizzling status follows the  
397 method in Wu et al., (2015, 2017) where there are radar reflectivity measurements below the  
398 ceilometer/lidar determined cloud base. The major difference for drizzles in the studies of Wu et  
399 al. (2015, 2017) and this study is that drizzle is liquid phase at ARM ENA site but could be both  
400 liquid and ice phases in this study.

401 The percentages shown below the x-axis represent the portion of drizzling status in each type  
402 of clouds, such as liquid, mixed-phase, ice and 'OTHER' clouds. Figure 7 (bottom panel) also  
403 shows the percentages and vertical distributions of classified liquid, mixed-phase, ice, and  
404 'OTHER' clouds for each column in the single-layered low-level clouds, represented by different  
405 colors. After classification, the samples in each category are sorted by their  $H_{top}$ . In detail, Figure  
406 7 demonstrates that the mixed-phase clouds dominate the single-layered low-level cloud category  
407 with an occurrence frequency of 54.5 %. The 'OTHER' and ice clouds have similar occurrence  
408 frequencies of 18.1 % and 17.4 %, respectively, while the liquid clouds have the lowest occurrence  
409 frequency of 10.1 %. The liquid-topped mixed-phase clouds (included in 'OTHER'), which  
410 frequently occur in the Arctic region (Qiu et al., 2015), are rarely found over the SO. The existence  
411 of ice particles in mixed-phase clouds should strongly depend on the distribution of ice nuclei (IN),  
412 whereas spatially unevenly distributed IN may result in the OTHER type of clouds.

413 Based on the results in Fig. 7, we draw the following conclusions. Most of the ice clouds are  
414 without icy precipitation, and the percentages with virga and precipitation below the cloud base  
415 are 12 % and 15 %, respectively. The percentages of non-drizzling, virga and drizzling mixed-  
416 phase clouds are 50 %, 21 %, and 29 %. The liquid and 'OTHER' clouds have similar percentages,  
417 they are 36 %, 25 % and 39 % for liquid clouds, and 35 %, 22 % and 44 % for 'OTHER' clouds.  
418 For liquid and 'OTHER' clouds, the drizzling frequencies are independent of  $H_{\text{top}}$ . In contrast, for  
419 mixed-phase and ice clouds, the drizzling frequencies strongly depend on  $H_{\text{top}}$ , i.e., higher drizzling  
420 frequencies occur mostly at higher  $H_{\text{top}}$ .

421 The properties of single-layered low-level clouds are summarized in Table 4. The liquid clouds  
422 have the lowest  $H_{\text{base}}$  and  $H_{\text{top}}$  but more available water vapor than other types of clouds. Since the  
423 'OTHER' clouds are a transitional stage among mixed-phase, liquid and ice clouds, they have the  
424 highest  $H_{\text{top}}$ , deepest cloud layer and largest  $LWP$ . The ice clouds occur in relatively dry  
425 environments and have the highest  $H_{\text{base}}$  at 1.218 km and thinnest cloud layer. The cloud variables  
426 for mixed-phase clouds fall between Liquid and "OTHER". Since  $LWPs$  in mixed-phase clouds  
427 have larger standard deviation, which implies that SLW is more common at higher  $LWPs$  and ice  
428 is more common at lower  $LWPs$ .

429 **4.2. Meridional variations of cloud properties**

430 Figure 8 shows the meridional variation in single-layered low-level cloud properties during  
431 MARCUS. As illustrated in Fig. 8a, the meridional distributions of  $H_{\text{base}}$ ,  $H_{\text{top}}$  and  $\Delta H$  are nearly  
432 independent of latitude, however, their corresponding temperatures ( $T_{\text{base}}$  and  $T_{\text{top}}$ ) increased about  
433 8 K from 69 °S to 43 °S, though there were slight fluctuations. These results suggest that the cloud  
434 and sea surface temperatures have minimal impact on the cloud boundaries over the SO, which is  
435 consistent with the findings in McFarquhar et al. (2016). The meridional variation of  $LWPs$  follows

436 those of  $T_{\text{base}}$  and  $T_{\text{top}}$ , with an increasing trend from south to north. It is important to point out that  
437 a big drop in  $LWP$  at  $\sim 50^{\circ}\text{S}$  results from fewer occurrences of low-level clouds there, indicating  
438 that the cloud samples at some latitudes are not statistically significant. The atmospheric  $PWV$   
439 increased dramatically from  $\sim 5$  mm at  $69^{\circ}\text{S}$  to  $\sim 18$  mm at  $43^{\circ}\text{S}$ , presumably due to increased sea  
440 surface and atmospheric temperatures.

441 Figure 9 shows the latitudinal and meridional distributions of categorized liquid, mixed-phase,  
442 ice and 'OTHER' in single-layered low-level clouds over the SO during MARCUS. Each circle  
443 represents the exact location and time along the ship track. Mixed-phase clouds occurred  
444 everywhere over the SO during the MARCUS field campaign and became dominant in November,  
445 December and February. Liquid clouds dominated in March, while ice clouds dominated in  
446 January. The 'OTHER' clouds are a kind of transitional phase falling in between the mixed-phase  
447 and ice/liquid clouds because there are no stand-alone occurrences in any month during MARCUS.

#### 448 **4.3 Vertical distribution of cloud properties**

449 The vertical distributions of classified liquid, mixed-phase, and ice clouds in LOW category  
450 are presented in Figs. 10-12. The focus of this section will be comparisons of cloud macrophysical  
451 properties between the north (NSO) and south (SSO) regions of the domain. Figure 10a shows the  
452 vertical distributions of liquid clouds, which were capped at  $\sim 1.6$  km, mostly in the marine  
453 boundary layer. The vertical occurrence frequencies are up to 27 % over NSO, while they were  
454 less than 4 % over SSO, i.e., liquid clouds occurred fairly often over the mid-latitude region, but  
455 very few occurred over the Polar region. On the contrary, the occurrence frequencies of mixed-  
456 phase clouds between NSO and SSO are opposite to liquid clouds as illustrated in Fig. 10b, though  
457 the differences are not so obvious. Mixed-phase clouds increased with altitude until  $\sim 1.6$  km, then  
458 decreased monotonically towards 3 km. The highest frequencies were  $\sim 37$  % at 0.6 km over SSO

459 and ~27 % at 1.5 km over NSO. The vertical distributions of ice clouds are similar to those of  
460 mixed-phase clouds (Fig. 10c), however, there were no significant differences between NSO and  
461 SSO. It is worth mentioning that the vertical distributions of mixed-phased clouds over SO are  
462 quite different to those from DOE ARM Northern Slope Alaska (NSA) site, where the low-level  
463 mixed-phase clouds are commonly featured with a liquid-topped layer. (e.g., Qiu et al., 2015).

464 To further investigate the vertical distributions of classified liquid, mixed-phase, and ice clouds  
465 over NSO and SSO, we plot the normalized vertical distributions (cloud base as 0, cloud top as 1)  
466 of radar reflectivity, Doppler velocity and spectrum width in Figs. 11 and 12, respectively. In this  
467 study, the threshold of -50 dBZ was used to determine the cloud boundary over the SO instead of  
468 the threshold of -40 dBZ radar reflectivity used at the ARM ENA site (Dong et al., 2014). If we  
469 used the threshold of -40 dBZ over the SO, then there would be only 73% cloud samples available.  
470 If we used the threshold of -50 dBZ, then we would have 90.4% cloud samples, which gained  
471 additional 17.4% on top of the -40 dBZ threshold. About 9.6% of radar reflectivities during  
472 MARCUS are lower than -50 dBZ for all LOW cloud samples, but without ceilometer and MPL  
473 lidar signals. Thus these 9.6% cloud samples were eliminated in Figs 11-12.

474 Figures 11a-11c represent the normalized vertical distributions of radar reflectivity, Doppler  
475 velocity and spectrum width of liquid clouds. Liquid clouds had the lowest reflectivity near the  
476 cloud top because of cloud-top entrainment. The reflectivity had a nearly constant median value  
477 of ~ -22 dBZ from cloud top height (~ 0.8 for normalized height) of the cloud layer to the cloud  
478 base. Most of the reflectivities were less than -15 dBZ, which is a threshold to distinguish cloud  
479 droplets and drizzle drops in each radar range volume (Wu et al., 2020). Most of the Doppler  
480 velocities were greater than  $0.0 \text{ m s}^{-1}$ , indicating that downwelling motion is dominant in liquid  
481 clouds. The profiles of Doppler velocity and spectrum width increased smoothly from the cloud

482 top to base, suggesting that larger cloud droplets and broader size distributions exist near the cloud  
483 base, which is attributable to more drizzle drops near the cloud base as illustrated in Fig. 7.

484 The vertical distributions of mixed-phase clouds in Figs. 11d-11f are similar to those of liquid  
485 clouds. The more occurrences of larger reflectivity measurements and larger median values of  
486 spectrum width near the cloud base are most likely due to the presence of moderate ice particles  
487 and/or drizzle drops. The nearly same median values of reflectivity, Doppler velocity and spectrum  
488 width (but slightly larger standard deviations in each level in mixed-phase clouds) in both liquid  
489 and mixed-phase clouds suggest that the ice particle sizes in mixed-phase clouds are comparable  
490 to cloud droplets and drizzle drops. The nearly uniform vertical distributions of Doppler velocity  
491 and spectrum width indicate well-mixed liquid cloud droplets and ice particles throughout the  
492 cloud layer in the mixed-phase clouds over NSO.

493 Compared to liquid and mixed-phase clouds, ice clouds had much lower reflectivities and  
494 narrower spectrum width as shown in Figs. 11g-11i. Almost all reflectivity measurements were  
495 less than -25 dBz with a median value of -35 dBz at the cloud base, resulting from small or  
496 moderate ice particles but much lower concentration. A nearly constant Doppler velocity within  
497 the cloud layer further supports the discussion of mixed-phase clouds above, i.e., the ice particle  
498 sizes are independent of cloud height and comparable to liquid cloud droplets in the low-level  
499 clouds over the SO. Because there are no mechanisms for growing large ice particles in such  
500 shallow ice clouds, the accretion process cannot take place. From the statistical results in Fig. 7,  
501 these ice particles have relatively little chance to become virga or raindrops and usually dissipate  
502 or transition to other types of clouds.

503 Since there are not enough liquid cloud samples over the Polar region, only the mixed-phase  
504 and ice clouds results are shown in Fig. 12. Compared to the vertical distributions of ice clouds

505 over NSO, the median values of reflectivity and Doppler spectrum width over SSO were lower  
506 and narrower, indicating a lack of large ice particles in the Polar region. The small ice particles in  
507 the Polar region were also reflected in their mixed-phase clouds. Compared to the vertical  
508 distributions of the mixed-phased clouds over NSO, the median values of reflectivity and Doppler  
509 spectrum width over SSO were dramatically lower (-35 dBz at SSO vs. -22 dBz at NSO;  $0.25 \text{ m}$   
510  $\text{s}^{-1}$  at SSO vs.  $0.32 \text{ m s}^{-1}$  at NSO). Figure 12 illustrates that the ice particle sizes over SSO are  
511 smaller, their size distributions are narrower than those over NSO, indicative of lack of large ice  
512 particles over SSO.

513 **5. Summary and Conclusions**

514 In this study, we presented the statistical results of clouds over the Southern Ocean (SO), and  
515 its northern (NSO) and southern (SSO) parts during MARCUS Intensive observational period  
516 (IOP). We used the method developed in Xi et al., (2010) to calculate the occurrence frequencies  
517 of different types of clouds and their corresponding cloud macrophysical properties. We developed  
518 a new method to classify liquid, mixed-phased, and ice clouds in the single-layered low-level  
519 clouds as well as their corresponding drizzling status. Lastly, we explored the meridional and  
520 vertical distributions of these classified cloud properties. Analysis of the MARCUS cloud phase  
521 and macrophysical properties has yielded the following conclusions.

522 1) The total cloud fractions (CFs) were 77.9 %, 67.6 %, and 90.3 % for the entire domain, NSO  
523 and SSO, respectively, indicating that 22.7 % more clouds occurred in the Polar region than in  
524 the mid-latitude region. The SSO had more clouds under 7 km, while the NSO had more clouds  
525 above 7 km. Below 3 km, the occurrence frequencies of clouds over NSO decrease  
526 dramatically from 37 % at an altitude of ~0.7 km to 16 % at 3 km, which is similar to the

527 vertical distributions of the low-level clouds over some Northern Hemisphere mid-latitude  
528 regions, such as Eastern North Atlantic.

529 2) The single-layered low-level (LOW), deep convective or multi-layered (HML), and MOL  
530 clouds are the three dominant types of clouds over the SO. Comparing the clouds between  
531 NSO and SSO, all types of clouds in SSO are higher than those in NSO except HOL. The LOW  
532 fraction, thickness, LWP over both NSO and SSO are comparable to each other. The mean  
533 LWP for LOW, MID and HOL clouds over NSO, range from  $\sim 130$  to  $150 \text{ g m}^{-2}$ , while the  
534 mean NSO LWP ( $\sim 270 \text{ g m}^{-2}$ ) for MOL and deep convective clouds (HML) are two times  
535 higher than the same types of clouds over SSO. The mean LWP of clouds over SSO are much  
536 lower than the LWP over NSO. Over the Southern Ocean, the single-layered or contiguous  
537 clouds usually have higher LWP than their counterparts of multi-layered or non-contiguous  
538 clouds. There are more non-contiguous HML and HOM than contiguous ones.

539 3) A new method was developed to classify liquid, mixed-phase and ice clouds in the single-  
540 layered low-level clouds (LOW) based on comprehensive ground-based observations. The  
541 mixed-phase clouds are dominant in the LOW cloud category with an occurrence frequency of  
542 54.5 %. The 'OTHER' and ice clouds had similar occurrence frequencies of 18.1 % and 17.4 %,  
543 respectively, while the liquid clouds had the least occurrence frequency of 10.1 %. The  
544 percentages of non-drizzling, virga and drizzling for mixed-phase clouds were 50 %, 21 %,  
545 and 29 %, and the drizzling frequencies of mixed-phase clouds strongly depend on  $H_{top}$ , that  
546 is, higher drizzling frequencies occurred mostly at higher  $H_{top}$ .

547 4) The meridional distributions of  $H_{base}$ ,  $H_{top}$  and  $\Delta H$  are nearly independent on latitude, however,  
548 their corresponding temperatures increased about 8 K from  $69^{\circ}\text{S}$  to  $43^{\circ}\text{S}$ . The meridional  
549 variation of LWP mimics that of cloud temperatures, having an increasing trend from south

550 to north. The mean *PWV* increased dramatically from ~ 5 mm at 69 °S to ~18 mm at 43 °S due  
551 to increased sea surface and atmospheric temperatures. More liquid clouds occurred over NSO  
552 but very few occurred over SSO, whereas more mixed-phase clouds occurred over SSO than  
553 over NSO. There were no significant differences in ice clouds occurrences between NSO and  
554 SSO.

555 5) The nearly same median values of reflectivity, Doppler velocity and spectrum width in both  
556 liquid and mixed-phase clouds over NSO suggest that the ice particle sizes in mixed-phase  
557 clouds are comparable to cloud droplets and drizzle drops. The uniform vertical distributions  
558 of Doppler velocity and spectrum width suggest well-mixed liquid cloud droplets and ice  
559 particles throughout the cloud layer in the mixed-phase clouds over NSO, which are quite  
560 different from those over the DOE ARM NSA site where the liquid-topped mixed-phase low-  
561 level clouds are common. The median values of reflectivity and Doppler spectrum width over  
562 SSO were lower and narrower than those over NSO, indicating lack of large ice particles in  
563 the polar region.

564 These results provide comprehensive statistical properties of all clouds over the SO during  
565 MARCUS, including the occurrence frequencies of different types of clouds and their  
566 corresponding cloud macrophysical properties. We also examined the meridional and vertical  
567 distributions of the classified cloud properties. These statistics can be used as a ground truth to  
568 evaluate satellite retrieved cloud properties and model simulations over the SO. The results of this  
569 study will help to advance our understanding of the clouds over the SO, which may lead to  
570 improved model simulations, as well as better representation of global climate.

571 *Data availability.* Data used in this study can be accessed from the DOE ARM's Data Discovery at  
572 <https://adc.arm.gov/discovery/>

573

574 *Author contributions.* The idea of this study is discussed by BX, XD, and XZ. BX and XZ performed  
575 the analyses and BX wrote the manuscript. BX, XD, XZ and PW participated in scientific discussions  
576 and provided substantial comments and edits on the paper.

577

578 *Competing interests.* The authors declare that they have no conflict of interest.

Multi-layer percentage %	18.1	39.6	50.0	44.9	73.1	77.7	100

\* The definition of the cloud types as follow: LOW ( $H_{\text{base}}$  and  $H_{\text{top}} \leq 3 \text{ km}$ ); MID ( $H_{\text{base}} > 3 \text{ km}$  and  $H_{\text{top}} \leq 6 \text{ km}$ ); HGH ( $H_{\text{base}} > 6 \text{ km}$ ); MOL ( $H_{\text{base}} < 3 \text{ km}$  and  $H_{\text{top}} \leq 6 \text{ km}$ ); HOM ( $3 \text{ km} < H_{\text{base}} < 6 \text{ km}$  and  $H_{\text{top}} > 6 \text{ km}$ ); HML ( $H_{\text{base}} < 3 \text{ km}$ ,  $H_{\text{top}} \geq 6 \text{ km}$  with a MID layer); HOL (LOW and HGH appear at the same time).

**Table 3a. Comparison of cloud phase identifications between our classification method and Shupe et al. (2005) method in each 5-min measurements, the unit is number of 5-min samples**

Shupe \this study	Liquid (this study)	Mixed-phase (this study)	Ice (this study)
<b>Liquid</b>	<b>468</b>	<b>490</b>	<b>0</b>
<b>Mixed-phase</b>	<b>98</b>	<b>3840</b>	<b>0</b>
<b>Ice</b>	<b>81</b>	<b>0</b>	<b>1195</b>

\*Numbers denote the cloud sample classifications between two methods. For example, the number 98 denote a total of 98 samples are classified as Mixed-phase using Shupe's method, while are classified as Liquid using this study's method.

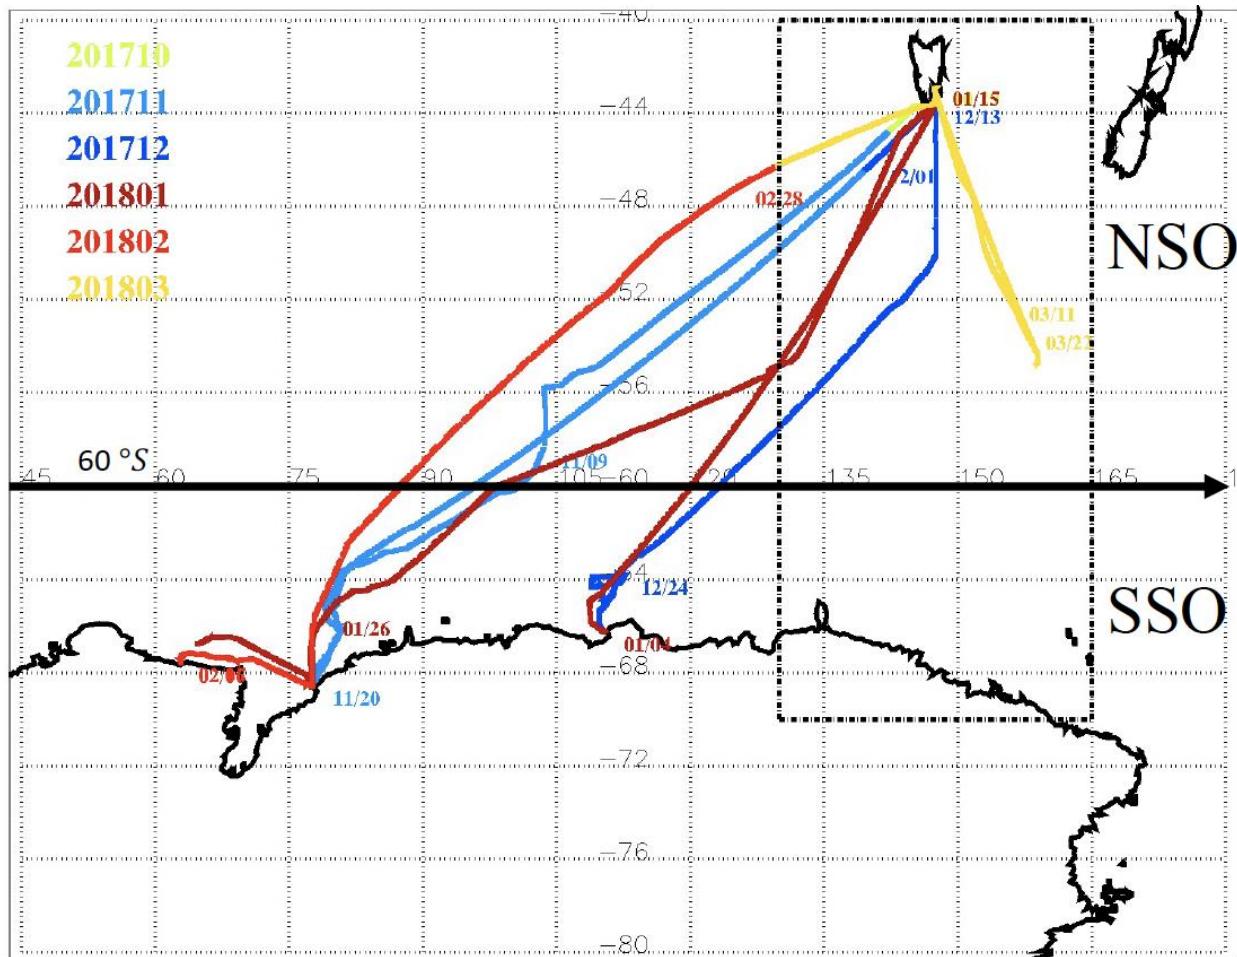

**Table 3b. The cloud phase partitioning from CDP and 2DS during SOCRATES**

Phase partitioning	1 second	10 seconds	30 seconds
<b>Samples #</b>	<b>27,280</b>	<b>2,255</b>	<b>836</b>
<b>Liquid, %</b>	<b>58.8</b>	<b>26.2</b>	<b>18.8</b>
<b>Mixed-phase, %</b>	<b>38.9</b>	<b>69.1</b>	<b>77.0</b>
<b>Ice, %</b>	<b>2.3</b>	<b>4.7</b>	<b>4.2</b>

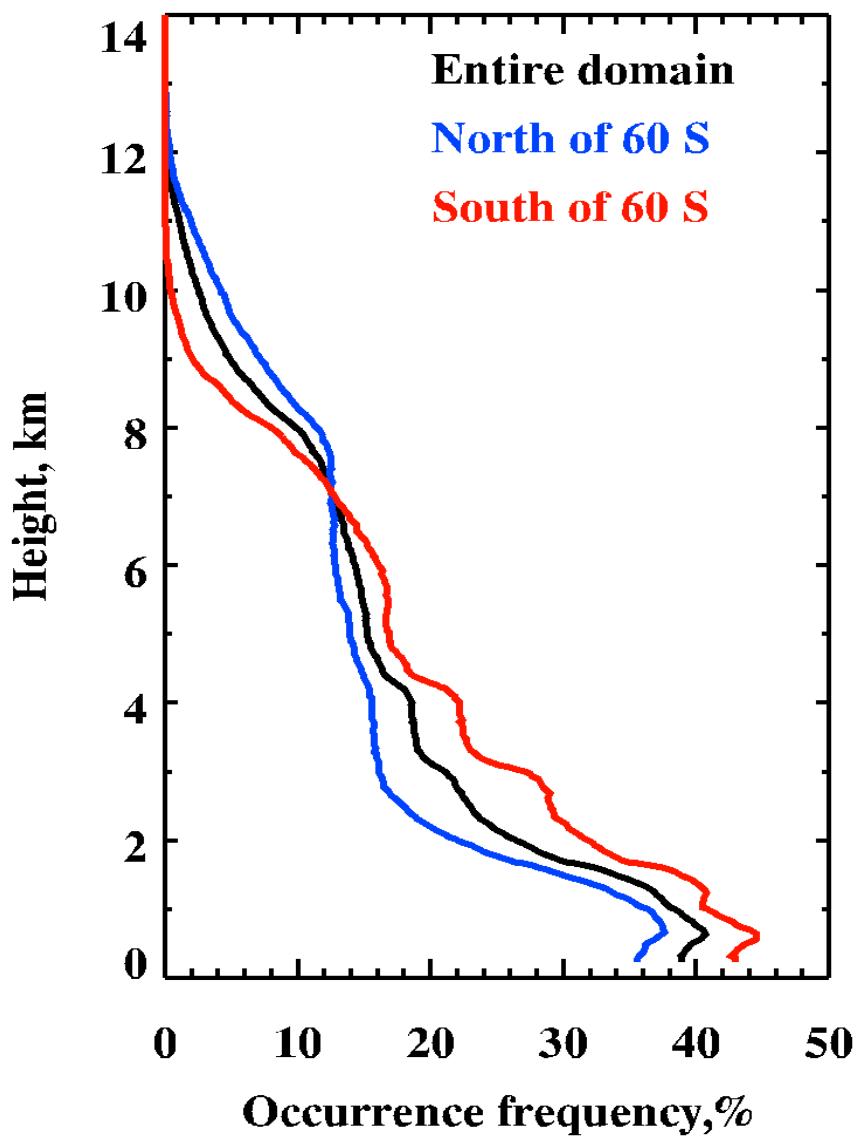

Note that Cloud Droplet Probe (CDP) measures particle size from 2 to 50  $\mu\text{m}$  in diameter; Two-Dimensional Stereo Probe (2DS) measures particle size from 50 to 5000  $\mu\text{m}$  in diameter.

**Table 4. Liquid, mixed, ice and OTHER phases of cloud properties within the single-layered low-level clouds**

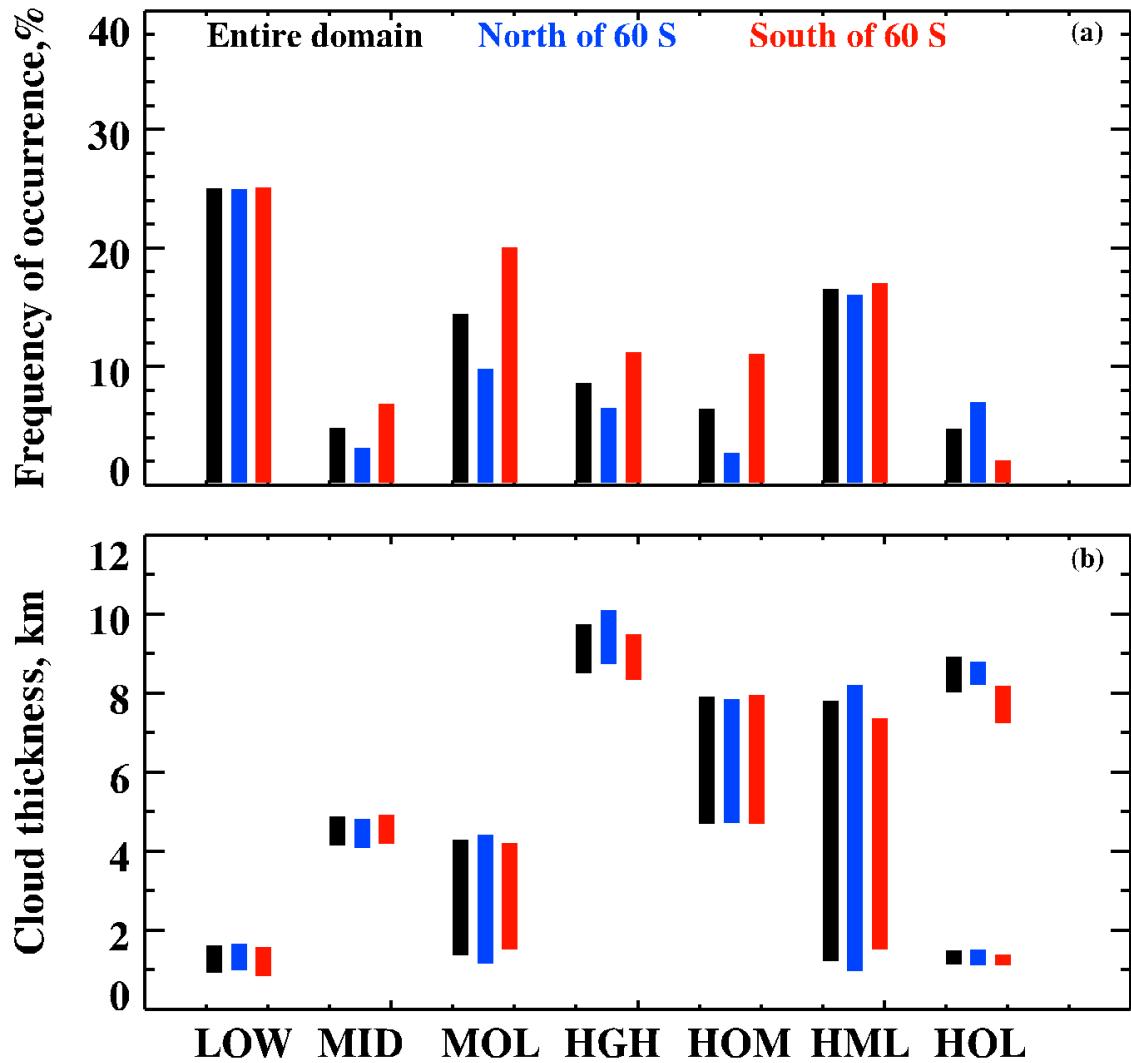

Phase	Samples	$H_{\text{base}}, \text{km}$	$H_{\text{top}}, \text{km}$	$\Delta H, \text{km}$	$LWP, \text{g m}^{-2}$	$PWV, \text{mm}$
<b>Liquid</b>	697	$0.424 \pm 0.204$	$1.327 \pm 0.242$	0.903	$113.6 \pm 90.1$	$15.7 \pm 3.5$
<b>Mixed</b>	3777	$0.834 \pm 0.465$	$1.434 \pm 0.617$	0.587	$119.7 \pm 136.6$	$8.9 \pm 5.0$
<b>Ice</b>	1205	$1.218 \pm 0.635$	$1.737 \pm 0.651$	0.519	0	$8.4 \pm 4.5$
<b>OTHER</b>	1255	$0.700 \pm 0.454$	$1.774 \pm 0.571$	1.074	$141.9 \pm 137.5$	$11.4 \pm 5.9$

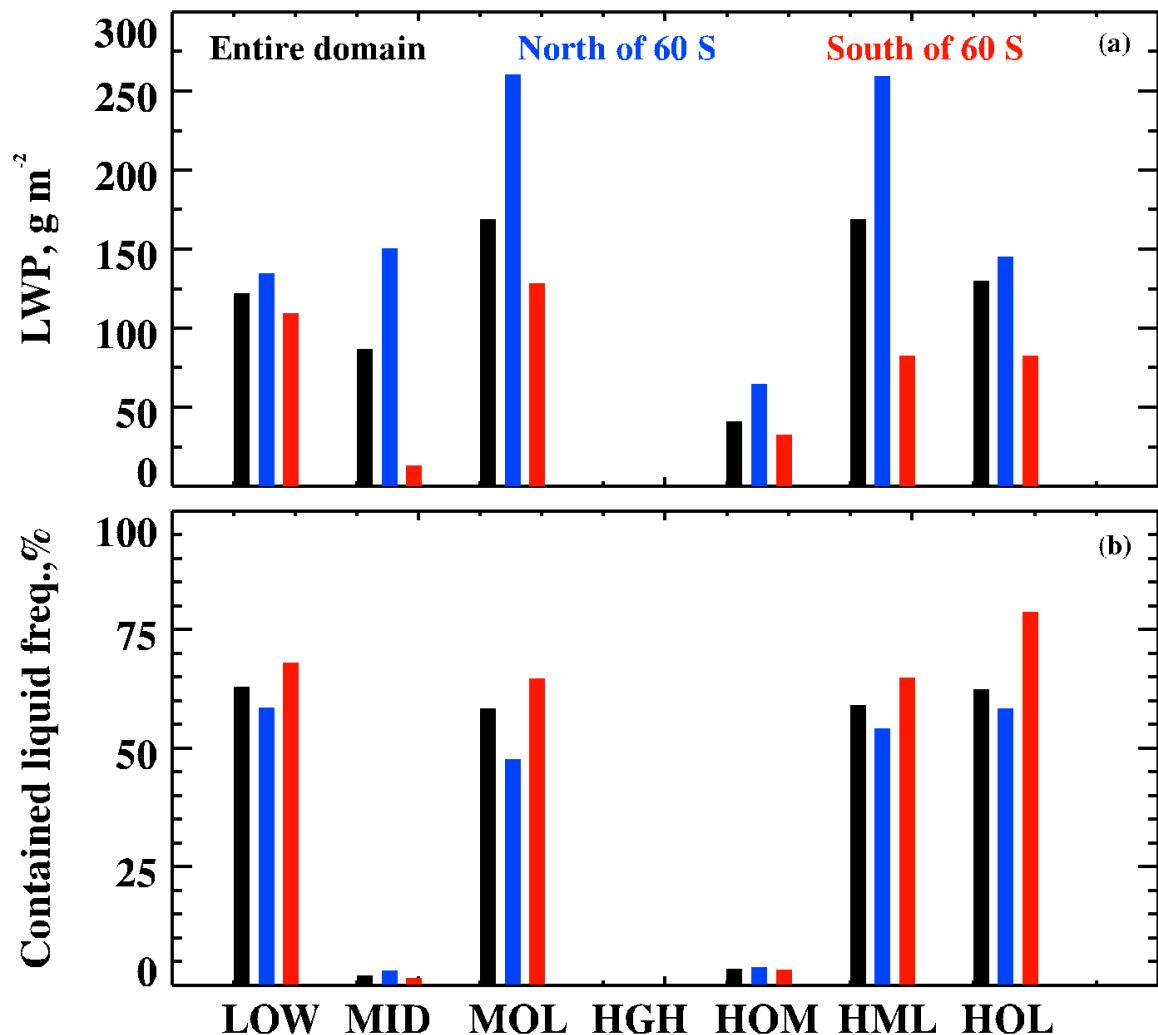

**Figure 1.** Shiptrack measurements between Hobart, Australia and Antarctica. Different colors represent different month's shiptracks from Oct. 29, 2017 to Mar. 23, 2018 during MARCUS. Along the shiptracks, the study domain is separated into northern (NSO) and southern (SSO) parts of the Southern Ocean with a demarcation line of 60 °S in order to study the clouds over the mid-latitudes (North of 60 °S) and Polar region (South of 60 °S). The black dotted rectangle represents the SOCRATES study domain. Some of the dates are labeled along the shiptracks, indicating the direction of the ship.

**Figure 2.** Mean vertical distributions of total clouds derived from ARM radar-lidar observations with a 5-min temporal resolution and a 30-m vertical resolution during MARCUS.

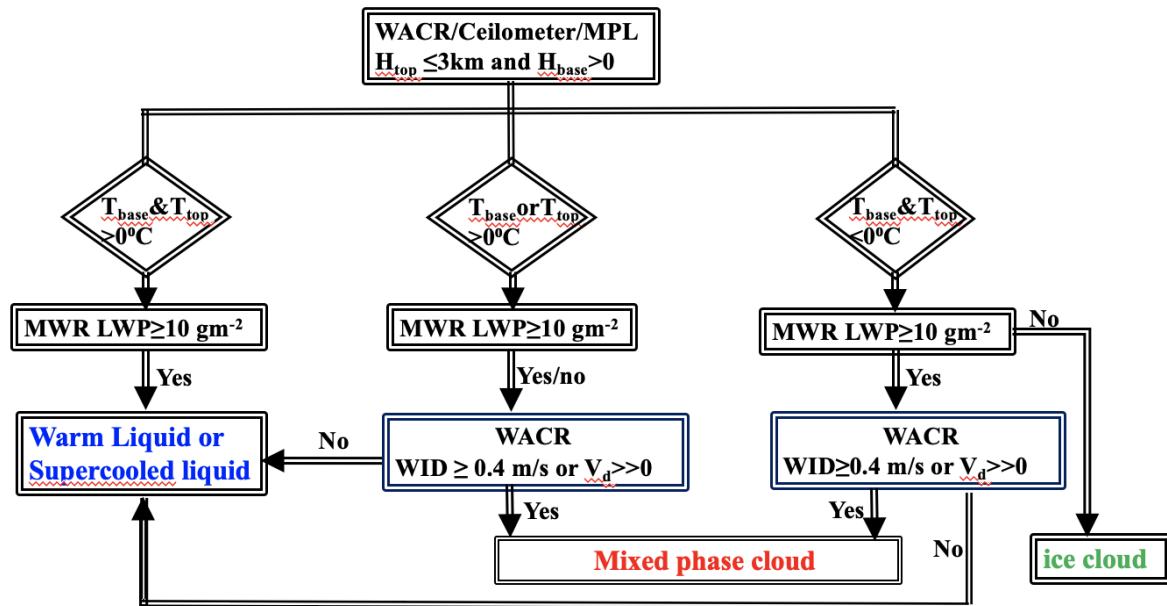

**Figure 3.** (a) Occurrence frequencies of categorized clouds by their vertical structures. LOW, single - layered low clouds ( $H_{\text{base}}$  and  $H_{\text{top}} \leq 3 \text{ km}$ ); MID, singlelayered middle clouds ( $H_{\text{base}} > 3 \text{ km}$  and  $H_{\text{top}} \leq 6 \text{ km}$ ); MOL, MID over LOW ( $H_{\text{base}} < 3 \text{ km}$  and  $H_{\text{top}} \leq 6 \text{ km}$ ); HGH, singlelayered high clouds ( $H_{\text{base}} > 6 \text{ km}$ ); HOM, HGH over MID ( $3 \text{ km} < H_{\text{base}} < 6 \text{ km}$  and  $H_{\text{top}} > 6 \text{ km}$ ); HML, HGH over MID and LOW ( $H_{\text{base}} < 3 \text{ km}$ ,  $H_{\text{top}} \geq 6 \text{ km}$  with a MID layer); and HOL, HGH over LOW (LOW and HGH appear at the same time). (b) Cloud thickness for each type of clouds (bar), the top and bottom of the bar represent the maximum cloud-top and minimum cloud-base heights, respectively. Black, blue, and red bars represent the entire domain (Lat:41-69 °S; Long: 60-160° E), north of 60 °S (NSO), and south of 60°S (SSO), respectively, during the MARCUS field campaign (10/2017-3/2018).

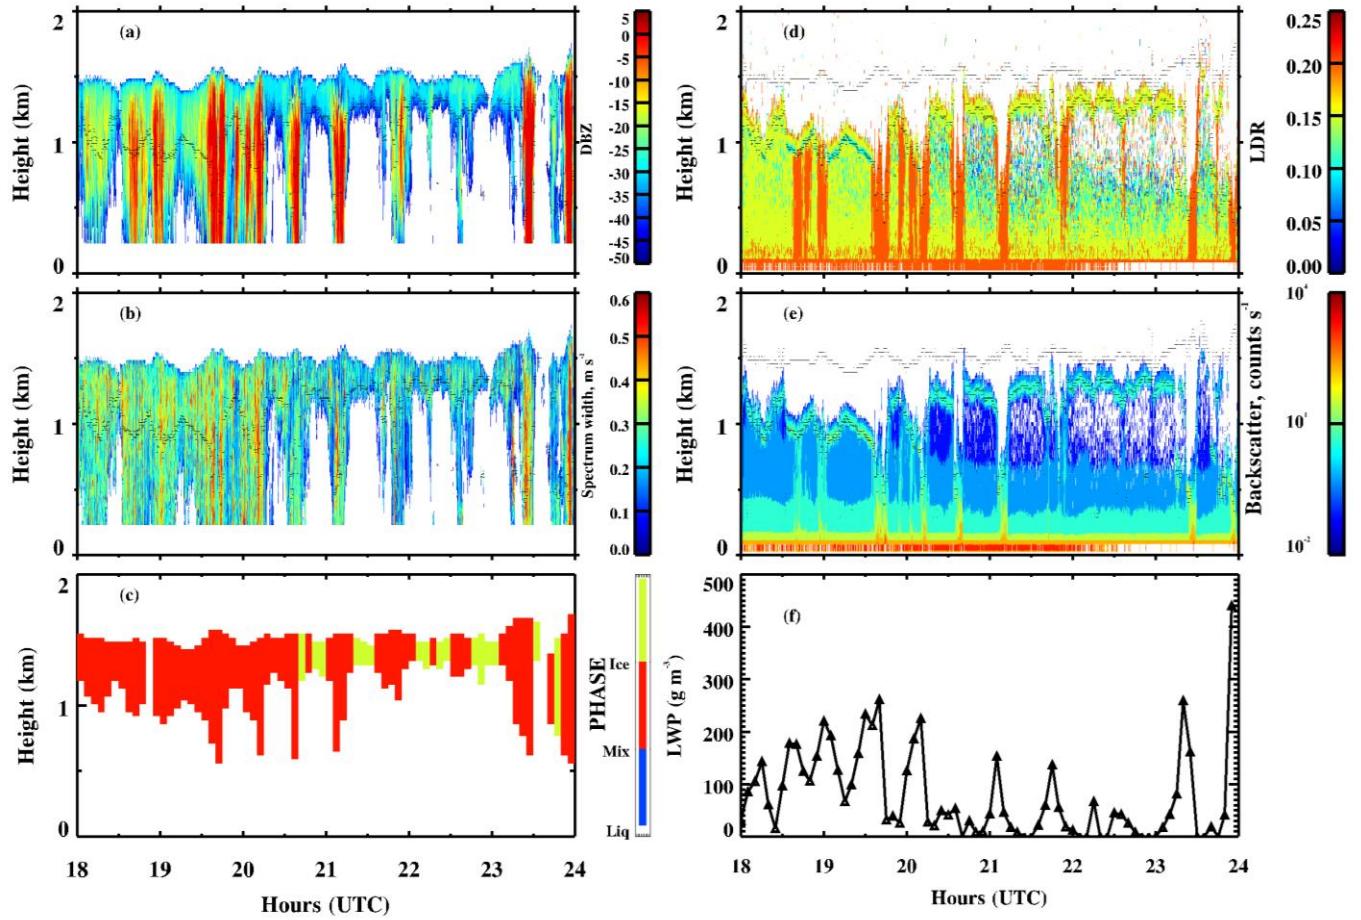

**Figure 4.** (a) Cloud liquid water paths (LWP) retrieved from microwave radiometer (MWR) measured brightness temperatures using a physical retrieval method for each type of cloud. (b) The occurrence frequencies of LWP > 10  $\text{g m}^{-2}$  for each type of clouds

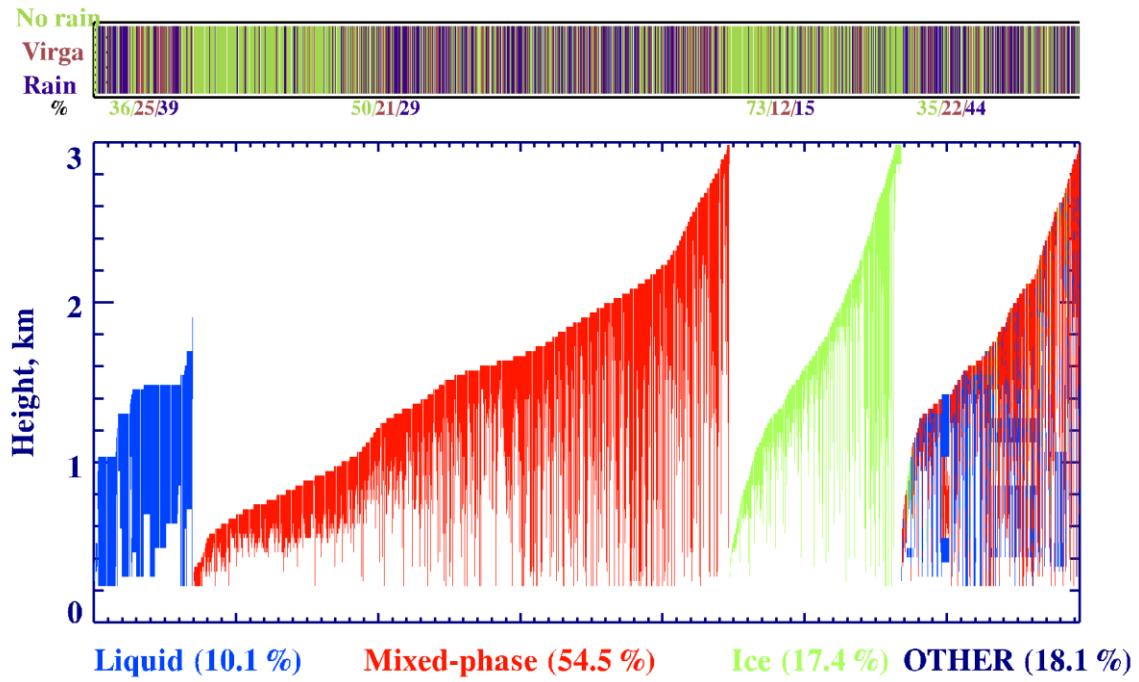

### Phase classification algorithm for single layered low level clouds

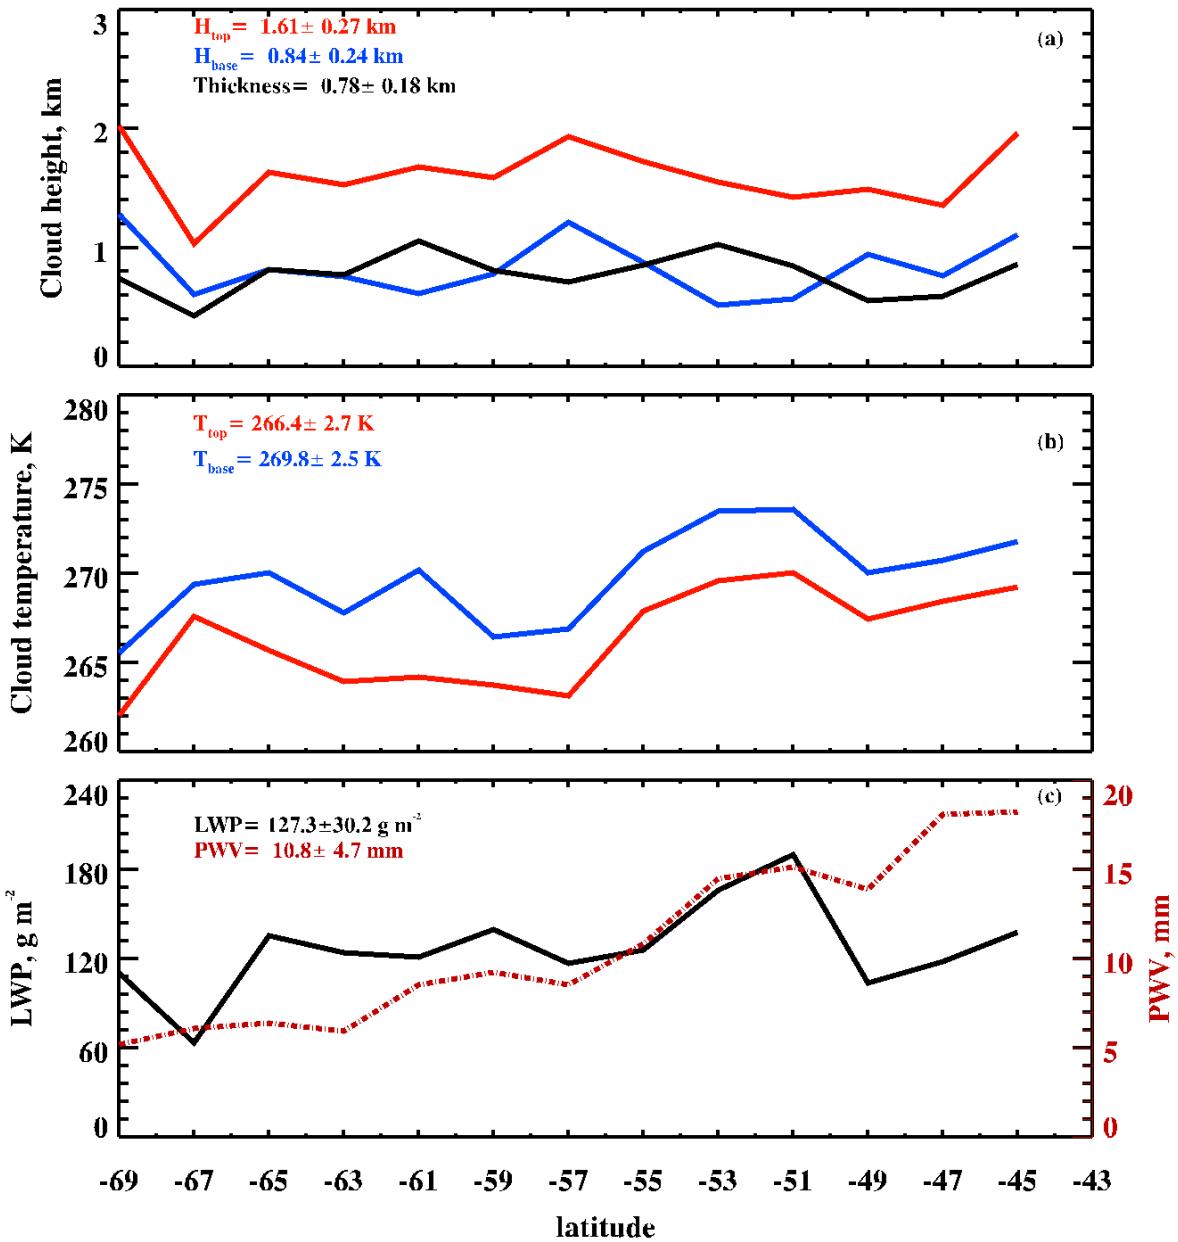

**Figure 5.** A flow chart for phase classification of single-layered low-level clouds. W-Band (95 GHz) ARM Cloud Radar (WACR) provides radar spectrum width (*WID*) and Doppler velocity ( $V_d$ ).

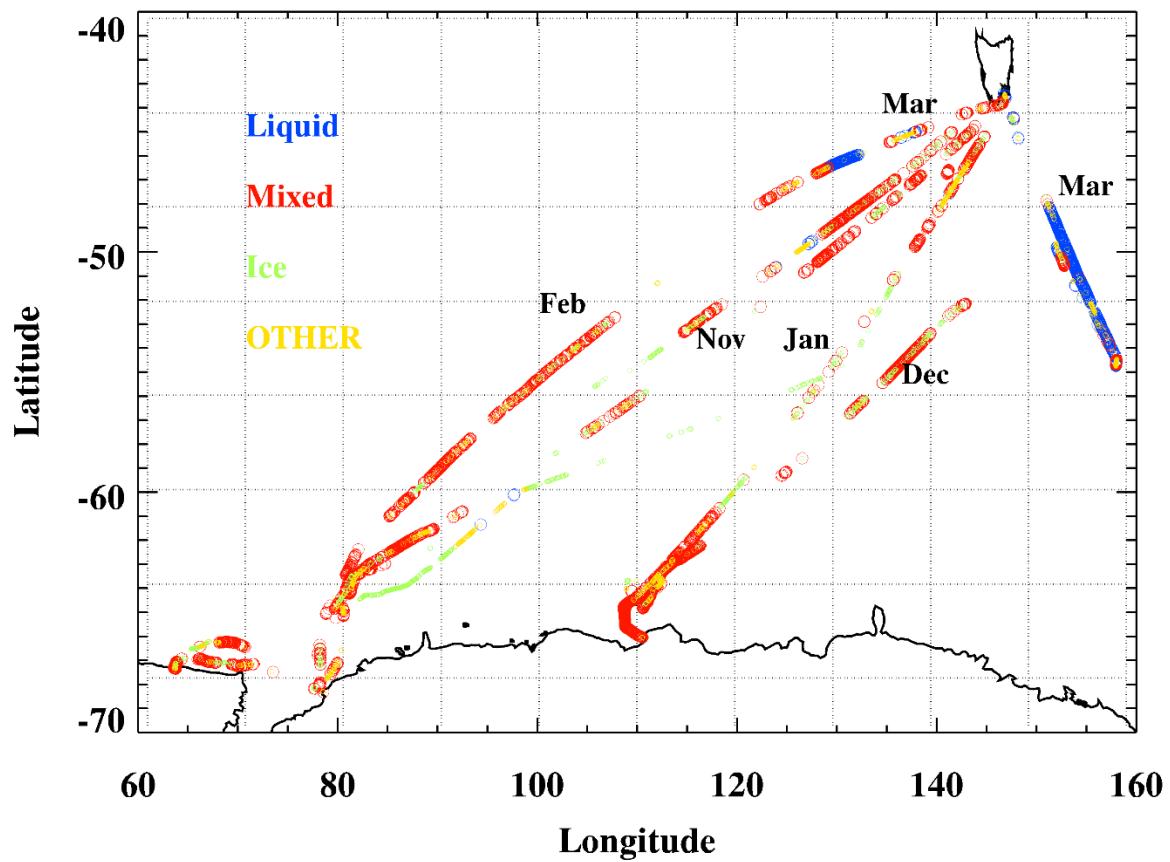

**Figure 6.** A case study that shows our phase classification (left column) and MicroPulse Lidar (MPL) linear depolarization ratios (*LDR*) and backscatter. W-Band (95 GHz) ARM Cloud Radar (WACR) reflectivity is shown in (a) and spectrum width is shown in (b). Correspondingly, the phase classification in (c); MPL *LDR* in (d) and backscatter in (e); and MWR-derived *LWP* in (f).

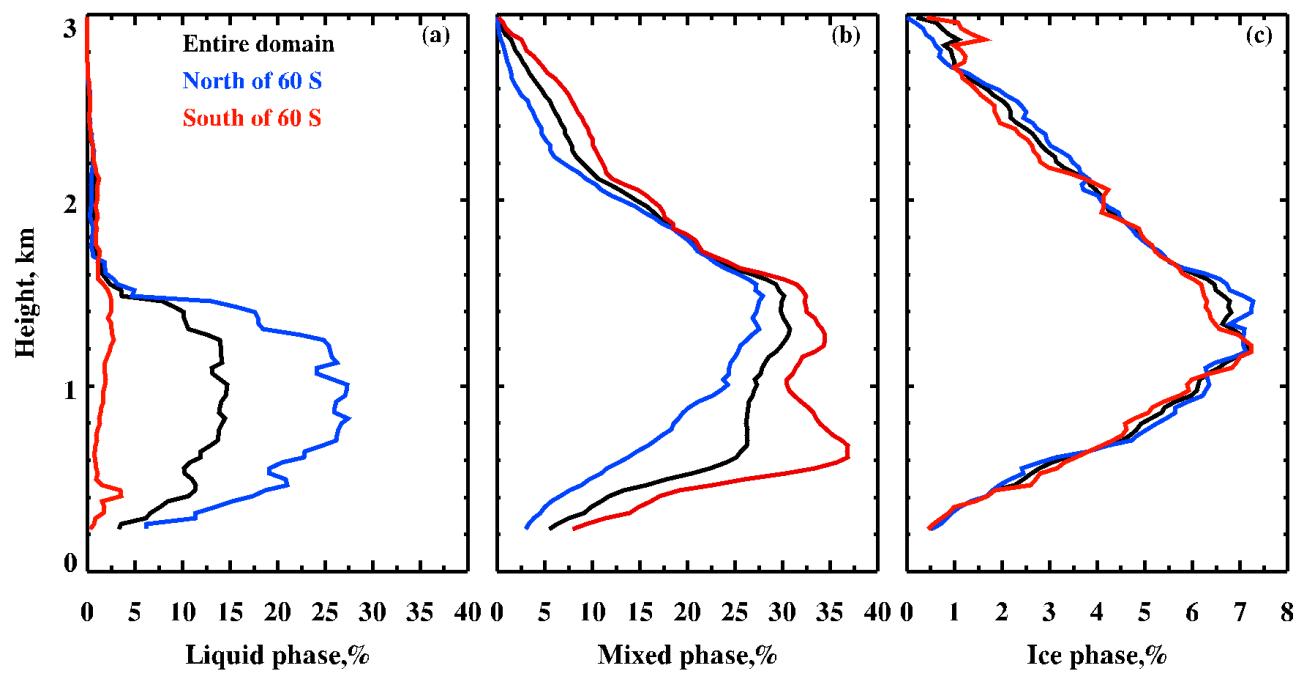

**Figure 7.** (Upper Panel) The drizzling status for each categorized cloud type, e.g., no rain (yellow-green), virga (brown) and rain (navy blue), the percentages shown below the x-axis represent the portion of drizzling in each type of clouds. (Bottom Panel) The percentages and vertical distributions of classified liquid, mixed-phase, ice, and 'OTHER' clouds for each column in the single-layered low-level clouds, represented by different colors, over the entire domain during MARCUS. Each line represents one 5-min sample. The definition of drizzle here is the radar reflectivity below the ceilometer-derived cloud base, which could be either liquid drizzle drops or ice crystals.

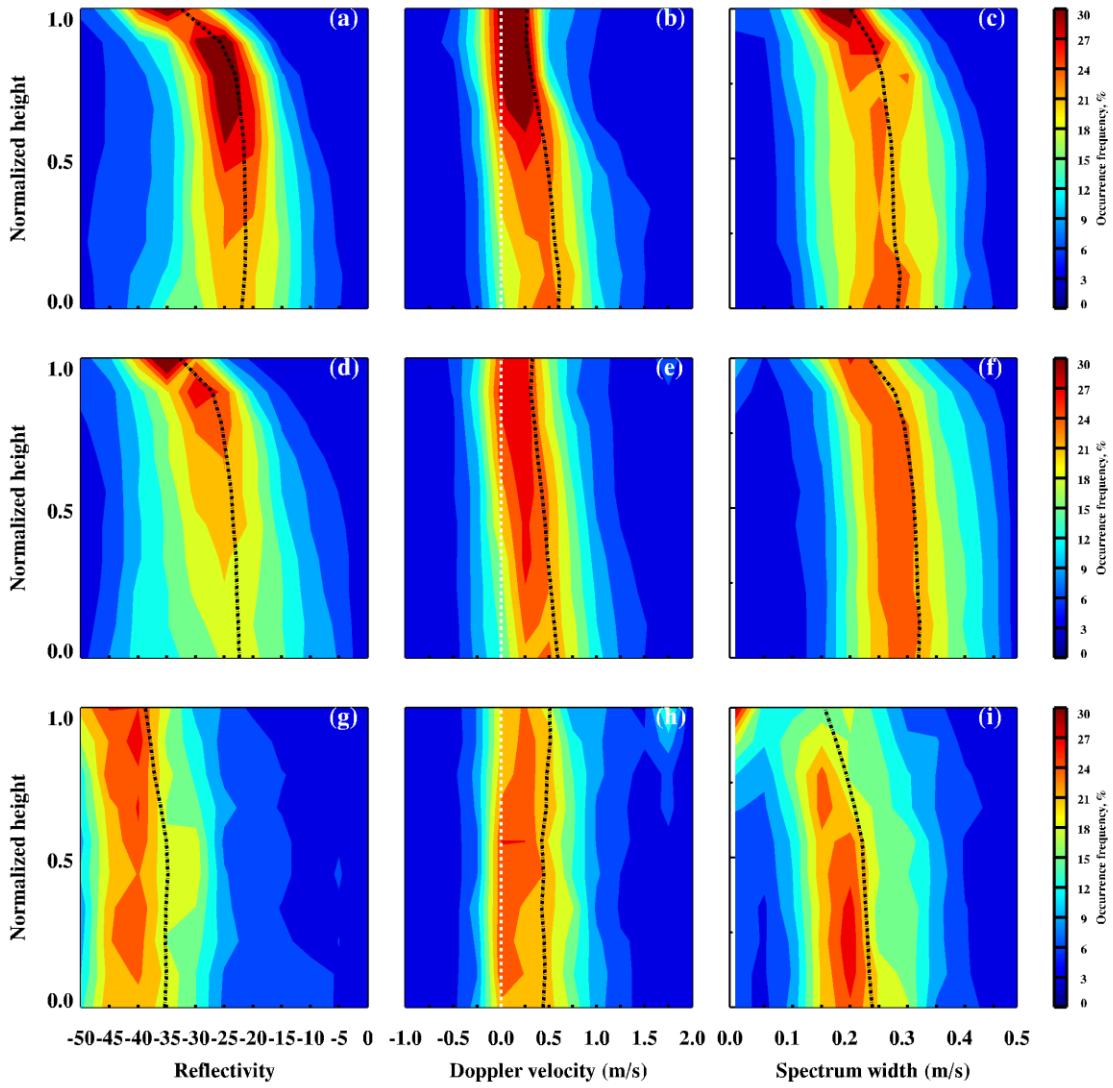

**Figure 8.** Meridional variations of single-layered low-level cloud properties: (a) cloud-base ( $H_{\text{base}}$ ) and -top ( $H_{\text{top}}$ ) heights, and cloud thickness ( $\Delta H$ ), (b) cloud-base ( $T_{\text{base}}$ ) and -top ( $T_{\text{top}}$ ) temperatures, and (c) cloud liquid water path ( $LWP$ ) and precipitable water vapor ( $PWV$ ) over the entire domain during MARCUS.

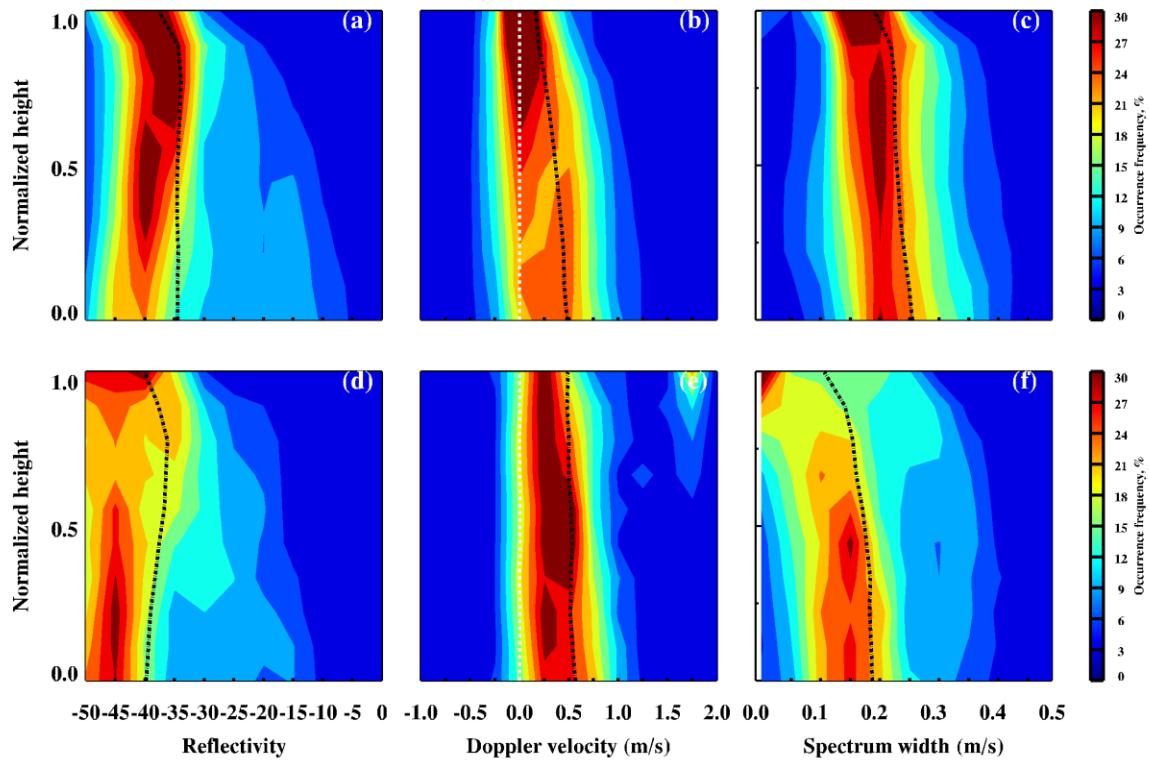

**Figure 9.** The latitudinal and longitudinal distributions of classified mixed-phase, liquid, and ice clouds in the single-layered low-level clouds. The liquid (blue), mixed (red), ice (light green), and OTHER (yellow) are shown along each shiptrack from October 2017 to March 2018 during MARCUS.

**Figure 10.** Occurrence frequencies of classified mixed-phase, liquid, and ice clouds over the entire domain (black), North of 60 °S (blue) and South of 60 °S (red) during MARCUS.

**Figure 11.** Normalized vertical distributions of radar reflectivity (a), Doppler velocity (b) and spectrum width (c) for the classified liquid (upper panel), mixed-phase (d to f, middle panel) and ice (g to i, bottom panel) clouds over the North of 60 °S during MARCUS Intensive observational period (IOP). Normalized height is defined as  $= \frac{H - H_{base}}{H_{top} - H_{base}}$  where cloud base is denoted as 0 and cloud top is 1. The black lines represent the median values and the white lines in Doppler velocity represent the reference of 0.0 m s<sup>-1</sup>.

**Figure 12.** Same as Fig. 11 but only for mixed-phase (a to c, upper panel) and ice (d to f, bottom panel) over the south of  $60^{\circ}$ S during MARCUS.
