**Abstract** Typhoon-related precipitation over land can result in severe disasters such as floods and landslides, and satellites are a valuable tool for estimating surface precipitation with high spatial-temporal resolutions. Accordingly, this study develops a surface precipitation integration framework to combine high-resolution observations from the radiometers of two geostationary satellites, Fengyun-4A (F4) and Himawari-8 (H8), with high-density rain-gauge observations or IMERG data and atmospheric reanalysis data based on a random forest (RF) algorithm. The RF algorithm integrates cloud and atmospheric features from radiometric observations and reanalysis information, and the intensity and spatial distribution of precipitation can be revealed by high-density rain-gauge or IMERG data. We take three typhoons that made landfall in South China during 2018 as examples. The F4-based and H8-based results using rain-gauge data as the predictand both show excellent results, yielding correlation coefficients (R) of ~0.75 and probabilities of detection (POD) of ~0.95. In contrast, when IMERG data are used as the predictand, the corresponding R and POD drop to ~0.5 and 0.93, respectively, due to the uncertainties related to IMERG retrievals. By carefully choosing the predictor, our RF algorithm successfully integrates the information from satellite observations, surface measurements and atmospheric reanalyses, resulting in precipitation estimates that are highly consistent with actual ground observations. Consequently, our proposed integration framework can reconstruct hourly surface precipitation estimates at high spatial-temporal resolutions for historical typhoon studies.

## 1 Introduction

Typhoons, also referred to as tropical cyclones, are high-impact atmospheric phenomena, that cause some of the most significant socioeconomic damage due to their intense winds, immense storm surges and flood-inducing rainfall [Negri et al., 2005; Rappaport et al., 2014; Wang et al., 2019]. Over eighty typhoons occur every year globally, and approximately one-third of them originate in the Northwest Pacific (NWPAC) [Chan et al., 2005]. Although the number of typhoons in the

NWPAC is exhibiting a decreasing trend with global warming, their average intensity is increasing, and as a result, coastal areas are suffering increasingly severe damage [Cai et al., 2004; Webster et al., 2005; Emanuel et al., 2013; Kang et al., 2016; Ho et al., 2021]. Unfortunately, because of its high spatial-temporal variability and complex physical processes, precipitation still accounts for one of the largest uncertainties in the forecasting of tropical cyclones [Su et al., 2012; Tu et al., 2013], and its high-quality observations of precipitation are also limited. Nevertheless, precipitation observations with a high spatial-temporal resolution during typhoon periods play an important role in research on not only the precipitation characteristics of tropical cyclones but also the prevention and mitigation of typhoon disasters.

Ground rain-gauges, weather radars and satellites are commonly used to acquire precipitation measurements [Villarini et al., 2008], and they all exhibit their unique advantages and disadvantages. Ground-based rain-gauges are direct and accurate at measure local surface precipitation, while is limited by the station locations and coverages, especially in oceanic, mountainous and polar regions. [Susana et al., 2013; Gires et al., 2012; Rodriguez et al., 2019; Looper et al., 2012]. In contrast, microwave radars can survey larger areas and can better capture the spatial variability of rainfall fields; however, the accuracy of radar-based measurements is strongly influenced by electromagnetic attenuation and the uncertainty in the relationship between the radar reflectivity factor and precipitation, particularly under extreme rainfall conditions [Marra et al., 2015; Bárdossy et al., 2017].

Satellite-based quantitative precipitation estimation (QPE) can be implemented on a large scale with a high spatial-temporal resolution, offering large scale capability with high spatial-temporal resolutions [Tang et al., 2016; Wang et al., 2018; Jozaghi et al., 2019], but quantitatively inferring the amount of surface precipitation from space is still a serious challenge, especially during typhoon periods. Nevertheless, with the continuous improvement of meteorological satellites, satellite-based QPE technologies have undergone considerable development [Boushaki et al., 2009; Nguyen et al., 2018]. Accordingly, various models have been developed to generate satellite-based QPE products by relying on the relationships between passive infrared/microwave observations and precipitation; typical products include the Tropical Rainfall Measuring Mission Multisatellite Precipitation Analysis (TRMM TMA) [Huffman et al., 2007; Liu et al., 2016], Integrated Multisatellite Retrievals for the Global Precipitation Measurement (GPM) Mission (IMERG) [Huffman et al., 2015; Wang et al., 2017], Climate Prediction Center morphing technique (CMORPH) [Joyce et al., 2004] and Global Satellite Mapping of Precipitation (GsMaP) [Aonashi et al., 2009; Ushio et al., 2009].

In addition, machine learning (ML) methods have been widely used to establish the relationship between precipitation and satellite passive spectral observations as well [Albawi et al., 2017; Sehad et al., 2017; Min et al. 2018; Ahmed et al., 2020; Wang et al., 2021; Zhang et al., 2021]. For instance, Min et al. used a random forest (RF) algorithm to establish the relationship between spectral imager observations and numerical weather prediction results, and quite reasonable rainfall area and intensity can be obtained [Min et al., 2018]. Wang et al. used a convolutional neural network (CNN) to establish a high-quality precipitation dataset based on Chinese FengYun geostationary satellite [Wang et al., 2017]. However, most of these studies intended to develop a general model for all kinds of precipitation across the globe or over large regions, and the variable responses of precipitation to different cloud properties and atmospheric conditions may limit their accuracy.

Furthermore, typhoons result in not only heavy and widespread precipitation but also thick clouds that significantly influence or even block satellite observations of surface processes. Thus, considering the complex and uncertain relationship between precipitation and clouds, the QPE product particularly designed for typhoon precipitation remains limited, leaving a gap in a the availability of accurate and high-resolution estimates of surface precipitation. Meanwhile, FengYun-4A (F4) and Himawari-8 (H8) are new-generation geosynchronous equatorial orbit (GEO) satellites launched by the Chinese and Japanese meteorological agencies, respectively [Min et al., 2017; Bessho et al., 2016]. These two satellites cover a similar observational region of the NWPAC and a large portion of East Asia, and their high temporal and spatial resolutions are favourable for the continuously monitoring of NWPAC typhoons [Ma et al., 2021; Honda et al., 2018]. Thus, in this study, we employ a ML technique to integrate F4/H8 radiometer observations with multi-source datasets to develop better surface precipitation integration algorithms, particularly for typhoon precipitation. More importantly, we investigate how multi-source (ground-based, satellite and reanalysis) data to improving the surface precipitation integration performance.

## 2 Data and study area

### 2 Data

In this work,to better estimate surface precipitation during the typhoon period, we aimed to take advantage of multi-source data for different atmospheric variables, while also include only popular and public-available ones for the generality of the method. Thus, in addition to the F4/H8 radiometer measurements, we would consider ground-based observations, atmospheric reanalysis and existing satellite-based surface precipitation estimations.

F4 and H8 can observe most of the NWPAC and East Asia; within this region, South China is frequently affected by the landfall of typhoons, resulting in serious disasters and casualties. The spectral radiometer onboard F4, namely, the Advanced Geosynchronous Radiation Imager (AGRI), has six visible and near-infrared channels and eight thermal infrared channels. The Advanced Himawari Imager (AHI) onboard H8 has a similar channel design but is equipped with two additional thermal infrared channels. To develop an integration algorithm capable of utilizing both daytime and nighttime measurements, we consider only the AGRI and AHI infrared channel radiances and their combinations. Specifically, to facilitate a fair comparison between the F4/AGRI- and H8/AHI-based algorithms, only the channels that are similarly equipped on both instruments are used, including the two water vapor channels (WV1 and WV2) and four longwave infrared channels (LW1–LW4). The central wavelengths of each channel considered in our integration algorithm are shown in Table 1, and it becomes interesting whether such small differences on the channel characteristics as well as those on channel spectral response functions and geolocation would influence the surface precipitation estimation.

Passive spectral observations can provide the spatial distributions of clouds and cloud top properties, whereas surface precipitation is highly related to the atmospheric conditions. Thus, our algorithm also adopts atmospheric variables such as the column water vapor content, cloud water content, atmospheric profiles and so on. These variables are obtained from the latest atmospheric reanalysis product developed by the European Center for Medium-Range Weather Forecasts (ECMWF), i.e., the

state-of-the-art Fifth-Generation ECMWF Reanalysis (ERA5) [Hersbach et al., 2020]. To infer the general atmospheric conditions within the integration region, we consider nine variables from ERA5 related to typhoon precipitation [Min et al., 2018]. For example, the convective available potential energy (CAPE) is an indicator of the instability (or stability) of the atmosphere and can be used to assess the potential for the development of convection, which can lead to heavy rainfall, thunderstorms and other severe weather. The K-index, calculated from the temperature and dew point temperature in the lower part of the atmosphere, is a measure of the potential for a thunderstorm to develop. The total column rain water (TCRW) is the total amount of water in droplets of raindrop size (which can fall to the surface as precipitation) in a column extending from the surface of the Earth to the top of the atmosphere. Total precipitation (TP) is the accumulated liquid and frozen water (comprising both rain and snow) that falls to the Earth's surface. The total column liquid water (TCLW) is the total amount of supercooled water in a column extending from the surface of the Earth to the top of the atmosphere. Furthermore, four basic atmospheric variables are considered, namely, the relative humidity at 850 hPa (R850) and 950 hPa (R950) and the temperature at 850 hPa (T850) and 950 hPa (T950), which describe the humidity and temperature states in the lower atmosphere.

## 2.2 Study area

Accurate precipitation observations are needed as the references to train ML-based models, and thus are essential for high-quality integration. Two kinds of data are considered: high-density ground rain-gauge data and IMERG estimates. Offering some of the most reliable and fundamental precipitation observations, rain-gauge data are obtained from the National Meteorological Information Center of the China Meteorological Administration (CMA). Due to the high frequency of rainfall and the dense distribution of urban areas in South China, a large number of automatic rain-gauge stations are distributed throughout this region, reaching a total of 5024 stations within the area of the study region ($79\times10^4$ km$^2$); the distribution of these stations is shown in Figure 1. However, such a high density of ground-based observations may not always be feasible, so another type of data that is more commonly used in ML-based precipitation estimation is also considered, i.e., the IMERG final run-calibrated precipitation data. IMERG provides gridded precipitation estimation from both passive microwave sensors on various satellites in the GPM constellation and infrared-based observations from GEO satellites [Liu et al., 2016, Tang et al., 2016] and therefore is one of the most reliable precipitation datasets available. IMERG has a half-hourly temporal interval with a maximum rain rate of 50 mm/h and covers the Earth's surface between the latitudes of 60°S and 60°N [Min et al., 2018]. This study investigates three typhoon events that made landfall in South China in 2018. Information on these three typhoon events is provided in Table 2, and the paths of the three typhoons are illustrated in Figure 1. We consider the area within the latitudes 15°–27°N and the longitudes 105°–125°E, including a large part of South China (15°–27°N; 105°–122.5°E) and the NWPAC, which are completely covered by the observation areas of F4 and H8. We consider the whole evolution of each of the three typhoons from landfall to dissipation, and the model performance over a total of ~120 hours is considered using approximately 600,000 hourly precipitation observations from the ground rain-gauge stations.

# 3 RF-based typhoon precipitation integration frameworks

130 ## 3.1 Establishment of a surface precipitation integration algorithm

The RF algorithm is an ML method widely used in the inversion of meteorological elements and has been proven to perform well in applications such as the estimation of precipitation, detection of clouds, and inversion of PM2.5 concentrations [Oscar et al., 2020; Tan et al., 2021; Liu et al., 2021; Guo et al., 2021]. Thus, this study used this simple but promising RF algorithm to establish the nonlinear relationships among surface precipitation, satellite observations and atmospheric characteristics.

135 In the framework of RF algorithms, two types of data are utilized for the integration model: the predictor and the predictand. To study the influences of different satellite observations (F4/AGRI vs. H8/AHI) as the predictor and different precipitation data (rain-gauges vs. IMERG) as the predictand on the surface precipitation integration algorithm, we established four independent surface precipitation integration models. These models are referred to hereinafter as F4-based and H8-based models according to the satellite data used in the predictor; similarly, the models using rain-gauge observations and IMERG data as the predictand are referred to as RG-based and IM-based models, respectively. Thus, a total of four models, i.e., F4-

140 RG, F4-IM, H8-RG and H8-IM, are developed. Table 3 differentiates these four models. It is worth noting that the only difference between the RG-based models and the IM-based models is the predictand used in the models, as will be described in more detail in the following.

The predictors for the surface precipitation integration algorithm include the geographic location, radiometer observations and

145 atmospheric reanalysis data. By testing the performance of the RF-based models with different combinations of variables, our final models consider a total of 21 variables, as listed in Table 4. The rain-gauge observations and IMERG estimates are used to provide the corresponding surface precipitation as the model predictand. It should be noted that only F4/AGRI observations are used in F4-RG and F4-IM, and only H8/AHI observations are used in H8-RG and H8-IM. Considering the uncertainties related to IMERG precipitation estimates, we use ground rain-gauge data to validate all four models.

150 Figure 2 illustrates the general flowchart of our surface precipitation integration algorithm, including the model development and surface precipitation estimation. During the model development, both ERA5 data and satellite data are collocated with high-density ground rain-gauge data to obtain RG-based training datasets. During the collocation processes, the satellite data have a high spatial resolution (4 km for F4/AGRI and 5 km for H8/AHI), and the average radiances values of the nine satellite pixels (3×3 pixels) closest to each ground station are collocated to represent the satellite data corresponding to that station. In

155 contrast, ERA5 has a much lower spatial resolution (0.25°), so the atmospheric variables from the single ERA5 grid point closest to each ground station are used. In other words, all the aforementioned data are collocated with the ground rain-gauge stations, and the resulting datasets are used for further training and model development. For a fair comparison, the IMERG precipitation estimates are also collocated with the rain-gauge observations, resulting in a dataset with the same spatial-temporal sampling interval as that of the RG-based models for model training. Thus, the F4-IM/H8-IM and F4-RG/H8-RG

160 models have completely the same predictor dataset, and differ only with regard to the predictand; i.e., rain-gauge observations are replaced with the corresponding IMERG estimates for F4-IM/H8-IM. With the training datasets obtained above, the RF

algorithm is used for the training phase, and the four surface precipitation integration models (F4-IM, H8-IM, F4-RG and H8-RG) are developed.

The right part of Figure 2 depicts the procedure for the pixel-level component of our surface precipitation integration algorithm. At this stage, linear interpolation is employed to obtain the ERA5 atmospheric variables at each F4/H8 grid point. Then, the surface precipitation integration results from the direct RF-based integration models are classified into two sets: pixels with precipitation and those without precipitation. Considering that the minimum precipitation resolution of a rain-gauge is 0.1 mm/h, pixels with a fused rainfall rate below 0.1 mm/h are defined as those without precipitation, while the integration results are retained for pixels with an estimated rainfall rate greater than 0.1 mm/h. This threshold of 0.1 mm/h ensures a high probability of distinguishing precipitation from non-precipitation.

To objectively evaluate the performance of our surface precipitation integration models, we consider the rain-gauge observations to be the "ground truth" and perform 10-fold cross-validation (10-cv) to ensure the independence between the training and testing datasets. In other words, the original training dataset is evenly divided into ten parts, one of which is taken as the testing dataset each time (without repetition), while the remaining nine are taken as the training dataset; this process is repeated ten times. We adopt four popular parameters to quantify the model performance: two categorical parameters (the probability of detection (POD) and false alarm ratio (FAR)) and two statistical parameters (the correlation coefficient (R) and root mean square error (RMSE)) between our results and the truth [Ebert et al., 2007; Mecikalski et al., 2008]. POD and FAR both range from 0 to 1, where larger POD and lower FAR values correspond to the better identification of precipitation events. Two important RF parameters must be considered: the number of trees to grow ($N_{tree}$) and the number of variables randomly sampled as candidates at each split ($M_{feature}$). Figure 3 quantifies the relationship between parameters $N_{tree}$ and max_features with the correlation coefficient (R), which is a measure of how well the RF models perform in the testing datasets created by 10-cv. Based on the results, the value of R increases with the increases in $N_{tree}$ and $M_{feature}$, and tends to be stable when $N_{tree}$ is greater than 500 and $M_{feature}$ is greater than 10. To ensure that the four models are comparable, the RF parameters are fixed to be the same. Considering the accuracy, computational efficiency and comparability of the models, the number of trees to grow ($N_{tree} = 1000$) and the number of variables randomly sampled as candidates at each split ($M_{feature} = 10$) are both fixed for the four models.

## 3.2 Testing and evaluation of the RF-based integration algorithm

Considering the distribution of precipitation throughout the year and the amount of damage caused by precipitation, the distribution of CMA ground rain-gauge stations is clearly uneven, with many more stations situated in eastern China than in western China. Because we employ ground rain-gauge observations for the integration, so the coverage of rain-gauge observations is crucial for representing the spatial distribution of precipitation. To explore the impact of station density on the integration of typhoon precipitation, we select data from different numbers of stations (increasing from 100 to 5000 with an interval of 100) to build training datasets of different sizes. Figure 4 shows the influence of the number of stations considered

on the model training results. The solid lines represent the RG-based model results, while the dashed lines represent the IM-based model results; the blue and red colors denote the F4-based and H8-based results, respectively. The evaluation parameters of all four models exhibit similar trends with an increasing number of stations; i.e., the integration results become more accurate due to both additional input data and a better representation on precipitation spatial distribution. The POD values of the four models are all close to 1, and vary only slightly with the number of stations, while the FAR values of the four models decreases with an increase in the number of stations. In contrast, the two statistical metrics (R and RMSE) fluctuate greatly when there are fewer than ~1000 stations, i.e., $1.26 \times 10^{-3}$ station per $km^2$; when observations from more than 1000 stations are considered, the R (RMSE) gradually increases (decreases) with an increasing number of stations. In general, in the estimation of typhoon precipitation, when the number of stations covering the region exceeds 1000, rain-gauge observations can generally reflect the spatial distribution of precipitation and thus can be used for surface precipitation integration. Of course, an increase in the number of stations does improve the integration performance, but only to a limited degree. Nevertheless, to ensure optimal model performance, this paper selects the data from all available stations.

The scatter plots in Figure 5 quantitatively compare the hourly precipitation estimated by our surface precipitation integration models with the 10-cv testing datasets, indicating only the generalization ability of the model. The two IM-based models (F4-IM and H8-IM) outperform the RG-based models (F4-RG and H8-RG) in the testing datasets according to the values of the POD (0.98 vs. 0.95, 0.97 vs. 0.95), FAR (0.25 vs. 0.46, 0.25 vs. 0.46), R (0.89 vs. 0.79, 0.89 vs. 0.79) and RMSE (1.25 mm/h vs. 2.19 mm/h, 1.25 mm/h vs. 2.17 mm/h). This may be using the satellite-based precipitation data of IMERG as the predictand may demonstrate better spatial consistency with the satellite observations than using the rain-gauge observations. In contrast, due to the similar satellite channels used as the predictors, the results based on different satellites are very similar in both the RG-based and the IM-based models. Noted that the "better performance" here only illustrates the better correlations between the predictors and predictands, but is not a high accuracy of the final model estimations, which also depend on the accuracy of the predictands compared to the truth (see Section 4).

To better understand the performance of the surface precipitation integration models, Figure 6 shows the importance of all the predictors considered in all four models. The importance of each variable is given in the form of the mean decrease in accuracy (%IncMSE), which can represent the relative contribution of each variable, and the sum of the importance of all variables is 100%. For F4-RG and H8-RG, the most important input variables are TCRW and TP, which represent the potential precipitable water in the atmosphere and the sum of large-scale precipitation and convective precipitation given by the atmospheric reanalysis. Geographical location data are also highly important, perhaps because the obvious spatial patterns of typhoon precipitation can be captured by RF-based training. The most important radiometer observations are certain brightness temperatures (BTs), such as BT12.0-BT10.7 for F4-RG and BT6.25-BT10.7 for H8-RG, both of which are related to the state of water vapor in the atmosphere. It is interesting that the most important variables in F4-IM/H8-IM differ significantly from those in F4-RG/H8-RG. Since the IMERG data comprise satellite-based precipitation estimates (Min et al., 2018), strong consistency is noted between the IMERG data and satellite observations, which is also reflected in the importance of variables. For F4-IM and H8-IM, the importance of variables such as BT8.5, BT6.2-BT10.7, BT6.2-BT11.2 and BT7.0-BT12.3 is

7

significantly high, while the importance of atmospheric reanalysis data and geographic data is relatively low; hence, the precipitation predicted by the F4-IM and H8-IM models is more dependent on the satellite observations. Meanwhile, the higher rankings of reanalysis-based variables in the RG-based models indicate their reasonable performance for distributing accurate atmospheric states (i.e., surface precipitation from rain gauges).

## 4 Typhoon precipitation integration performance

To evaluate the surface precipitation integration results, Figure 7 shows the ground rain-gauge observations and the results from the four integration models at three instants (from top to bottom) during Typhoon Mangkhut, which made landfall at 0900 UTC on 16 Sep. 2018. Three typical cases are illustrated at three distinct instants: before the typhoon made landfall (0100 UTC on 16 Sep. 2018), after the typhoon made landfall (1200 UTC on 16 Sep. 2018) and as the typhoon started to dissipate (2300 UTC on 17 Sep. 2018). Before the typhoon made landfall, the number of stations with precipitation on land was small, and heavy precipitations (e.g., stations with rain rates greater than 20 mm/h) was concentrated mainly over the coastline. After the typhoon made landfall, the precipitation area increased significantly, and both the extent of heavy precipitation area and the rain rates increased, with over 29 stations with recording rain rates exceeding 30 mm/h. Before the typhoon started to dissipate, the center of heavy rainfall disappeared, although there were still large regions of weak precipitation. At all instants steps, the four models consistently yield reasonable typhoon precipitation intensities and spatial distributions, especially the F4-RG and H8-RG, whereas F4-IM and H8-IM slightly overestimate the precipitation extent and cannot accurately represent the heavy precipitation centers. Figure 7 demonstrates that F4-RG and H8-RG predict similar spatial distributions, which is because the two models use similar predictors to predict the same predictand; the similar spatial distribution between F4-IM and H8-IM is also due to this reason. In addition, because the two RG-based models use rain-gauge data as the predictand during model development while the two IM-based models use IMERG data, the precipitation predicted by the RG-based models is closer to the rain-gauge precipitation, whereas that predicted by the IM-based models is closer to the IMERG precipitation, which further indicates that rain-gauge data are more suitable for the predictand than IMERG data when using ML to predict surface precipitation.

To quantitatively understand the abovementioned comparison, Figure 8 illustrates the differences in hourly precipitation between our integration results and the ground rain-gauge observations at the same instants steps in Figure 7. Warm colors indicate stations at which the surface precipitation integration results are overestimated (larger than the rain-gauge observations), while cold colors indicate those at which the surface precipitation integration results are underestimated. The differences between the F4-RG/H8-RG results and rain-gauge observations are mostly within 2 mm/h, significantly smaller than the differences between the F4-IM/H8-IM results and rain-gauge observations. However, all four models tend to underestimate the precipitation intensity in the area of heavy precipitation and overestimate the precipitation at the rain-gauge stations with relatively weak precipitation (rain rates below 5 mm/h). Ultimately, more than 70% of the surface precipitation is overestimated because many more stations experienced weak precipitation than heavy precipitation within the study region.

260    Table 5 summarizes the percentages of the precipitation that were overestimated by the four integration models at the three typhoon instants. The percentages in this table denote ratios of our integration results larger than the true values (i.e., rain-gauge observations) to the total amount of data at the particular rainfall rate. As our precipitation differences are strongly consistent with the rainfall rates, we divide the results into two groups: one group for stations with rainfall rates less than 5 mm/h and the other group for those with rainfall rates greater than 5 mm/h. For rain-gauge precipitation rates less than 5 mm/h,

265    more than ~85% of these data are overestimated. However, for rainfall rates greater than 5 mm/h, only approximately 20% of our results are larger than the true values, which means that the rate of underestimation is approximately 80%.

Figure 9 compares the daily precipitation of our four models during Typhoon Mangkhut on 16 Sep. 2018. The daily precipitation results of the RG-based models (F4-RG and H8-RG, top panels) exhibit close agreement, and similar consistency is noticed between the F4-IM and H8-IM results (bottom panels). However, the RG-based model results differ substantially

270    from the IM-based model results. The daily precipitation distributions of F4-RG and H8-RG indicate that during Typhoon Mangkhut, the precipitation over land was concentrated mainly in Guangdong Province, and the daily precipitation in some areas surpassed 200 mm/day. In contrast, F4-IM and H8-IM overestimate most of the daily precipitation on land but significantly underestimate the daily precipitation over 200 mm/day. It is worth noting that our models can yield the precipitation distribution over the ocean as well, but the performance could hardly be evaluated with any objectivity due to the

275    lack of ground-based observations at sea.

The spatial distributions of the above biases in our daily surface precipitation integration results are shown in Figure 10. In general, both the RG-based models and the IM-based models share considerable similarities in their spatial distribution of bias. For the two RG-based models, the average errors at most stations are between -20 mm/day and 20 mm/day, while the errors in the two IM-based models are significantly larger. Moreover, ~75% of the stations in all four models overestimate the rain

280    rate, which is consistent with the aforementioned analysis of the hourly results.

For further sample validation, Figure 11 shows the surface precipitation integration results from our integration models against the ground rain-gauge observations at both hourly (top panels) and daily (bottom panels) scales for all three instants during Typhoon Mangkhut, with the color bars indicating the occurrence frequency on a logarithmic scale at intervals of 0.5 mm/h at the hourly scale and 5 mm/day at the daily scale. In general, not only at the hourly scale but also at the daily scale, the surface

285    precipitation integration results from the RG-based models show better consistency with the rain-gauge observations than do those from the IM-based models.

To better explore the performance of the four surface precipitation integration models over time, Figure 12 illustrates time series plots of the four evaluation metrics at the hourly scale during the three typhoon events in 2018. The solid and dotted lines represent the RG-based and IM-based models, respectively, and the blue and red lines represent the F4-based and H8-

290    based models. Generally, the RG-based models (F4-RG and H8-RG) perform significantly better than the IM-based models (F4-IM and H8-IM) with relatively better classification metrics (i.e., without apparent fluctuations) and with better statistical metrics. Because the RG-based models use ground rain-gauge observations as the predictor while the IM-based models use IMERG estimates based on satellite observations as the predictor, the surface precipitation integration results differ greatly

9

between the RG- and IM-based models. In addition, because of the similar satellite observation channels adopted for the model development, the F4- based and H8-based models yield very similar surface precipitation integration results.

Note that all surface precipitation integration models perform better during Ewiniar and Mangkhut than during Bebinca, with the former two having higher POD and R values and lower FAR values; this is attributed to the uneven distribution of surface precipitation. As shown in Table 1, there was either light precipitation or no precipitation over most of the land area during Bebinca, accounting for 78% and 18%, respectively. Therefore, the surface precipitation integration results of all models are relatively poor for the precipitation process during Bebinca.

## 5 Summary

This paper proposes an RF-based surface precipitation integration framework for typhoons making landfall that combines geostationary spectral radiometer observations, atmospheric reanalysis data, high-density rain-gauge observations and IMERG estimates. To develop the model, we consider either F4 or H8 observations as the predictor and either rain-gauge observations or IMERG estimates as the predictand, and the performances of four models, i.e., F4-RG, H8-RG, F4-IM, and H8-IM, are systematically evaluated. All four models are capable of capturing precipitation events caused by typhoons making landfall. Regardless of whether hourly precipitation or daily precipitation is used, POD is greater than 0.9, and FAR is approximately 0.5; additionally, the RG-based models (F4-RG and H8-RG) can estimate surface precipitation well. For hourly precipitation, the R values between F4-RG and H8-RG and the ground rain-gauge observations are greater than 0.7, and the RMSE is approximately 2.5 mm/h. For daily precipitation, the R values between F4-RG and H8-RG and the ground rain-gauge observations are approximately 0.9, and the RMSE is approximately 25 mm/d. In contrast, while the two IM-based models achieve good success in model development, when the surface precipitation integration results of the two models are compared with the ground rain-gauge observations, the comparison results are obviously worse than those of the RG-based models, which indicates that the ground rain-gauge data are more suitable than IMERG data as ground truth for the development of the typhoon surface precipitation integration algorithm. Nevertheless, despite the excellent performance of our typhoon-only models, the surface precipitation estimates could be further improved by developing and using different models for different precipitation types.

Note that the input variables of the surface precipitation integration models include satellite observations, geographic locations and channel combinations. The key point to establishing surface precipitation integration models is how to accurately discerning the nonlinear relationship between the model input variables and precipitation. According to the importance of the variables shown by the RF algorithm used in the model development, TCRW, TP and geographic location rank much higher in importance, which is useful for confirming the accuracy of the surface precipitation integration results for typhoons. Furthermore, considering the complexity and variability of typhoon precipitating cloud systems, the vertical factors of clouds derived by passive microwave sensors (e.g., cloud water vapor profiles, cloud thickness) and the environmental conditions (e.g., wind shear, relative humidity) from a global forecast system should be introduced into the RF model to improve the QPE accuracy in the future.

## Code availability

The model in this paper is based on the random forest data package in the Python language, and our implementation and analysis code are available upon request to the corresponding author (chao_liu@nuist.edu.cn).

330 ## Data Availability

Fengyun-4A/AGRI data ([http://satellite.nsmc.org.cn/PortalSite/Data/Satellite.aspx](http://satellite.nsmc.org.cn/PortalSite/Data/Satellite.aspx)) and Himawari-8/AHI data ([http://www.eorc.jaxa.jp/ptree/](http://www.eorc.jaxa.jp/ptree/)) were used to establish the surface precipitation integration models. IMERG data ([https://gpm.nasa.gov/data/directory](https://gpm.nasa.gov/data/directory)) and surface precipitation observations collected from the China Meteorological Data Service Center ([http://data.cma.cn/en](http://data.cma.cn/en)) were used as predictands of the surface precipitation integration algorithm.
