Abstract. Measuring spectral aerosol absorption remains a challenging task in aerosol studies, especially in the UV region, where ~~the~~ ground and airborne measurements are sparse. In this research, we introduce an algorithm that synergizes ground measurements with satellite observations for the derivation of spectral single scattering albedo (SSA, ω_o) of aerosols in the UV to visible range (340-670 nm). The ~~approach~~ physical basis consists in explaining satellite measured near-UV radiances (340, 354 and 388 nm) by the Ozone Monitoring Instrument (OMI), and visible radiances (466 and 646 nm) by MODerate Imaging Spectrometer (MODIS), in terms of ground-based Aerosol Robotic Network (AERONET) measurements of total column extinction aerosol optical depth (AOD, τ), and retrieved total column wavelength dependent SSA using radiative transfer calculations. Required information on aerosol particle size distribution is taken from an AERONET-based seasonal climatology specifically developed for this project. ~~This~~ The inversion procedure is applied over 110 AERONET sites distributed worldwide, for which continuous, long-term AERONET measurements are available. Using the derived data set we present seasonal and regional climatology of $\omega_o(\lambda)$ for carbonaceous, dust and urban/industrial aerosol types. The UV-Visible spectral dependence of ω_o obtained for the three major aerosol types from the synergy algorithm is found to be consistent with the insitu measurements reported in the literature. A comparison to standard AERONET SSA product at ~~646~~ 440 nm shows absolute differences within 0.03 (0.05) for 40% (~~59~~65%) of the compared observations. The derived aerosol $\omega_o(\lambda)$ data set provides a valuable addition to the existing aerosol absorption record from AERONET by extending the absorption retrieval capability to the near-UV region. The combined UV-Visible data set, in addition to improving our understanding of spectral aerosol absorption properties, also offers wavelength-dependent dynamic aerosol absorption models for use in the satellite-based aerosol retrieval algorithms.

1 Introduction

Atmospheric aerosols play a significant role in the Earth's climate system through scattering and absorption of solar radiation, thus capable of perturbing radiation budget. The ratio of the amount of the light scattering to the total extinction referred to as single scattering albedo (SSA, ω_o) is a fundamental variable used to gauge the absorbing nature of aerosols. Mie-theory indicates ω_o equals to one for purely scattering aerosols and less than one towards zero for increasingly absorbing nature of aerosols. Studies show that the estimates of net aerosol radiative forcing is sensitive to the aerosol ω_o, and small changes to it could potentially alter the forcing on atmosphere (Chyacutelek and Coakley, 1974; Hansen et al., 1997). ~~Models~~ General circulation models are often fed with essential aerosol properties to estimate the forcing on the atmosphere. These properties include aerosol optical depth (AOD, τ), complex refractive index, and phase function. Here, the knowledge on spectral dependence of such properties is crucial in quantifying the overall effects of aerosols. For example, absorbing aerosols can lead up to a 50% ~~increase~~ decrease in the near-UV irradiance compared to the similar load of only scattering aerosols in the atmosphere (Bais et al., 2005). A report by Intergovernmental Panel on Climate Change suggests that the lack of spectral aerosol absorption is one of the major contributors leading to significant uncertainties in quantifying the net aerosol radiative effects on the Earth's climate (IPCC, 2013).

Developments in ground-based and satellite aerosol retrieval techniques have greatly improved our understanding of atmospheric aerosols over the last two decades. However, knowledge on spectral aerosol absorption properties is limited due to difficulties in measurements (e.g., Heintzenberg et al., 1997) and larger uncertainties in remote sensing retrievals (e.g,. Dubovik et al., 2000). Direct measurements of aerosol absorption can be obtained by using instruments that measure scattering and extinction coefficients. Such measurements are limited to discrete wavelengths and associated with few ground stations, laboratory measurements, or airborne field campaigns. In addition insitu techniques often require making corrections of measurements to overcome instrumental challenges (e.g., Weingartner et al., 2003; Virkkula et al., 2005; Collaud Coen et al., 2010). Aerosol absorption can also be inferred from the sky radiance and extinction measurements that rely on fitting ground observations to radiative transfer calculations (Nakajima et al., 1996; Dubovik et al., 1998; Cattrall et al., 2003). The accuracy (or uncertainty) of the aerosol absorption retrieval through ground-based techniques primarily relies on the calibration of measurements, while surface characterization has secondary effect on the overall accuracy of the retrievals. Detailed reviews of measurements and techniques to retrieve aerosol absorption are available in several papers (e.g., Clarke et al., 1967; Bond and Bergstrom, 2006; Moosmüller et al., 2009). Among the

ground-based sensors, currently, AERONET provides long-term aerosol absorption record at four discrete wavelengths from the visible (Vis) to near Infrared (NIR) spectrum over many sites distributed worldwide. Known limitation of the currently available AERONET inversion product (Version 3) is the lack of single scattering albedo at near-UV wavelengths, and the aerosol load threshold ($\tau_{440} > 0.4$) required to obtain reliable absorption in Vis-NIR spectrum. Like AERONET, a network of ground-based radiation measurement network with sites in Asia and Europe referred as SKYNET (sky radiometer network) provides aerosol optical depth and single scattering albedo in the near UV-NIR spectrum (Nakajima et al., 2007). However, the accuracy of the SKYNET aerosol absorption product is affected by temporally constant and spectrally invariant surface reflectance used in the inversion procedure (Jethva and Torres, 2019). These limitations incur knowledge gaps in the complete characterization of aerosol absorption as a function of both wavelength and aerosol load. ~~The known limitation of AERONET absorption product is the lack of near-UV wavelengths, besides higher aerosol load (τ_{440} > 0.4) and high solar elevation angle required to obtain reliable absorption in Vis-NIR spectrum. These limitations make it imperative to look for alternate data retrieval methods or sources to fill the knowledge gap.~~

For a few decades now, satellite remote sensing is used as an essential tool to gain a global perspective of aerosols distribution in the atmosphere. The physical basis of satellite aerosol retrievals is that under cloud-free conditions after accounting for Rayleigh (molecular) scattering and gaseous absorption effects, the upwelling top-of-the-atmosphere (TOA) reflectance is a function of aerosol optical depth, particle sizes and composition (i.e., complex refractive index). Mathematically for a cloud-free atmosphere overlying an Lambertian surface the upwelling TOA reflectance (L_{TOA}) received by a nadir viewing satellite can be expressed in normalized units as (Chandrasekhar, 1960):

$$L_{TOA}(\theta, \varphi, \lambda) = L_0(\theta, \varphi, \lambda) + \frac{\rho(\lambda) \cdot T(\tau, \theta, \lambda)}{(1 - s(\lambda) \cdot \rho(\lambda))} \tag{1}$$

where θ, φ, and λ are the zenith, azimuthal angles of the direction of propagation and wavelength of light, τ is the optical thickness of the atmosphere, ρ is the surface reflectivity, T is the total direct and diffuse transmittance of the light in the atmosphere, and $s(\lambda)$ is the spherical albedo of the atmosphere when it is illuminated from below. The first and second term on the right side of the equation represents the atmospheric path radiance and the amount of light that is reflected to the sensor after encountering the surface, respectively. The satellite measured TOA reflectances are sensitive to both τ and ω_o, in addition to the surface reflectance. Therefore, separating the contributions of atmosphere and surface is of utmost importance to retrieve aerosols from satellite measurements. For satellites with single-view measurements, aerosol retrieval algorithms rely on prior assumptions on particle

sizes (phase function) and ω_o to retrieve τ.~~Most satellite aerosol retrieval techniques require making assumptions on particle sizes (phase function) and ω_o to retrieve τ.~~ On the other hand, several efforts have been made to estimate aerosol ω_o from direct satellite measurements at visible wavelengths (e.g., Kaufman, 1987; Kaufman et al., 2002; Satheesh and Srinivasan, 2005; Zhu et al., 2011) and near-UV wavelengths (Torres et al., 1998, 2007, 2013~~Torres et al., 2007, 2013~~). However, the variety of natural surface types, choice of wavelengths, and aerosol models pose limitations on such techniques. In terms of wavelength, enhanced molecular scattering in the near-UV region acts as a strong attenuating background and helps identify absorbing aerosols. However, to retrieve aerosol absorption using near-UV measurements, quantitative information on aerosol layer height (ALH) is required. ~~The e~~Existing satellite aerosol retrieval techniques that rely on observations in the visible spectrum assume a temporally constant value of ω_o that varies regionally (Remer et al., 2005), and for a few algorithms, it is still assumed wavelength-independent (Hsu et al., 2013)~~value, and for a few sensors, it is still assumed wavelength independent.~~ A review on the commonly used satellite aerosol products singled out aerosol absorption as an inherent problem common to all sensors (Li et al., 2009). Studies using the evolving ground-based aerosol record provides evidence that satellite retrieved τ can lead to large biases if the assumed aerosol imaginary index, which derives ω_o is wavelength-independent (Jethva and Torres, 2011), and ~~constant~~ seasonally invariant (Lyapustin et al., 2011; Eck et al., 2013). These studies highlight the importance of using wavelength-dependent aerosol ω_o and account for its spatial and temporal variability in the assumptions made for satellite retrieval of aerosol products.

In the past, few studies used both ground and satellite measurements to retrieve aerosol absorption properties. Li et al., (1999) used visible band radiances from AVHRR and in situ measured τ during SCAR-B experiment to derive absorption from biomass burning aerosols. Sinyuk et al., (2003) used UV-radiances from TOMS and aerosol extinction from AERONET to derive the imaginary refractive index of dust particles over a few stations in the Sahara belt region. Lee et al., (2007) estimated the aerosol SSA across a few stations over China using combined ground and satellite (MODIS) measurements at visible wavelengths. Nonetheless, these studies are limited and do not provide a comprehensive characterization of absorbing aerosols from the UV-Visible spectrum.

The objectives of the present work are to derive columnar aerosol $\omega_o(\lambda)$, and its spectral dependence in the UV-Visible part of the spectrum. ~~This approach~~ The proposed inversion procedure makes use of ~~the~~ AERONET measured wavelength dependent τ, and ~~derived~~ retreived particle size distribution in conjunction with satellite

121 measured radiances at UV and visible wavelengths by A-train constellation sensors Aqua-MODIS and Aura-OMI

122 (Ozone Monitoring Instrument). ~~from AERONET in an inversion procedure. The A-train constellation of~~

123 ~~satellites that includes OMI and MODIS makes routine TOA measurements from the UV-Visible spectrum.~~ The

124 ~~n~~Near-simultaneous measurements from ~~A-train satellites~~these sensors provide an excellent opportunity to

125 combine satellite and ground measurements during the overpass times (local ~~noon~~time, ~13:30 hrs) over the

126 AERONET sites.

127

128 The organization of the remaining manuscript is as follows: section 2 describes the ground-based and satellite

129 measurements used in this work. Section 3 describes the methodology adopted to derive aerosol $\omega_o(\lambda)$. Section 4

130 provides the sensitivity analysis to estimate the expected accuracy of ~~tests conducted to estimate the error~~

131 ~~incurred in~~ the proposed aerosol absorption retrievals. Section 5 presents a comparison of retrieved SSA to the

132 AERONET aerosol absorption product. Section 6 presents the seasonal variability in regional aerosol $\omega_o(\lambda)$

133 derived for sites distributed across major aerosol environments worldwide. Section 7 provides a discussion of the

134 regional variability of the UV-Vis aerosol absorption product derived in this work.~~Section 5 presents the seasonal~~

135 ~~variability in aerosol $\omega_o(\lambda)$ derived for sites distributed across major aerosol environments worldwide. Section 6~~

136 ~~provides a discussion of the regional aerosol absorption models derived in this work. Section 7 presents a~~

137 ~~comparison of retrieved SSA with the AERONET absorption product.~~ Finally, section 8 provides a summary of

138 the work, along with the key findings and outlook for further studies.

139 **2 Data sets**

140 The details of ground-based and satellite data sets used in this work are provided in Table 1. Our usage of

141 satellite data is strictly limited to the TOA reflectances, the associate viewing ~~satellite-sun~~ geometry, and other

142 ancillary information such as ~~(~~quality flags, and aerosol index. ~~type) but not the aerosol retrievals (τ) themselves~~

143 ~~from OMI and MODIS.~~

144 **2.1 AERONET**

145 ~~Aerosol Robotic Network (~~AERONET~~)~~ employs an automatic sun-tracking photometer (CIMEL Electronique

146 CE-318) to measure sun and sky radiances (Holben et al., 1998). The direct sun measurements are made with a

147 1.2^o full field of view at nine nominal wavelengths of 340, 380, 440, 500, 675, 870, 940, 1020 and ~~1020~~ 1640 nm

148 typically for every ~5 to 15 minutes interval. Columnar extinction τ is computed from these measurements for all

149   wavelengths except for the 940 nm, which is used to retrieve water vapour amounts. The extinction τ obtained

150   from these measurements has an estimated uncertainty ±0.01 (±0.02) at the visible (near-UV) wavelengths,

151   primarily due to calibration uncertainty (Eck et al., 1999). The currently available AERONET Version 3 Level 2

152   AOD product uses improved cloud screening and quality checks to provide reliable data to the user community

153   (Giles et al., 2019). ~~The extinction τ obtained from these measurements are accurate within ±0.01 (±0.02) at the~~

154   ~~visible (near-UV) wavelengths (Dubovik and King, 2000).~~ In addition to the direct sun measurements, the

155   photometer also measures multi-angular diffuse sky radiances along the almucantar plane at four distinct

156   wavelengths from visible to the near-Infrared spectrum (440, 675, 870 and 1020 nm) with near-hourly frequency.

157   In recent years the newer model of instruments also include sky radiance measurements at 380, 500 and 1640 nm

158   (Sinyuk et al., 2020). An inversion procedure that uses both direct sun and angular sky radiances together is

159   implemented to derive aerosol particle size distribution and complex refractive indices (Dubovik and King, 2000;

160   Dubovik et al., 2006)~~Dubovik et al., 1998; Dubovik and King, 2000)~~. The uncertainty in the derived spectral

161   aerosol SSA provided by the AERONET inversion Level 2 product is estimated to be ±0.03 for $\tau_{440} > 0.4$

162   (Dubovik et al., 2000). Since 2018, the release of Version 3 inversion product implements several changes to the

163   traditional AERONET aerosol absorption retrievals. A complete description of the changes implemented in

164   Version 3 inversion products along with the updated uncertainty estimates are available in Sinyuk et al., (2020). It

165   should be noted here that in the currently available AERONET inversion products the shortest wavelength of

166   aerosol SSA is 440 nm. In this work, we use AERONET Version 2 inversion product for constructing a

167   representative aerosol model for the associated sites. For the AOD inputs to our retrieval algorithm and for the

168   comparison of SSA we use the latest Version 3 products. ~~For the locations, where aerosol loading is usually low,~~

169   ~~the derived aerosol absorption properties have much higher retrieval error (Level 1.5 inversion product). In this~~

170   ~~work, we use AERONET measured columnar τ as a constraint to derive aerosol absorption from satellite TOA~~

171   ~~measurements. The particle size distributions provided by AERONET products are used for constructing a~~

172   ~~representative aerosol model for the associated sites. Aerosol absorption properties from AERONET Level 2~~

173   ~~Version 3 product are used for comparison with our retrievals at visible wavelengths.~~ Figure 1 shows the location

174   of the total 110 AERONET sites used in this work for which long-term (> 7 years) quality assured ~~Level 2~~

175   ~~(version 3)~~ measurements are available.

176   **2.2 OMI**

177   Launched in July 2004, the ~~Ozone Monitoring Instrument (~~OMI~~)~~ on board NASA's EOS Aura satellite is a nadir-

178   viewing hyper-spectral imaging radiometer (Levelt et al., 2006). OMI measures the TOA radiances in the

179 wavelength range 270-500 nm with a ground pixel spatial resolution of 13 km x 24 km at nadir. OMI achieves

180 daily global coverage in 14-15 orbits with a swath of 2600 km scanning the entire earth's surface. In this work,

181 we use OMI radiances (340, 354, and 388 nm) provided in the in-house product OMLERWAVE and publicly

182 accessible OMI near UV OMAERUV Level 2 aerosol product (Version 1.8.9.1, Torres et al., 2018).~~OMAERUV~~

183 ~~Level 2 aerosol product (V1.8.9.1).~~ The OMLERWAVE product reports radiances and Lambertian equivalent

184 reflectivity (LER) at several discrete wavelengths in the near-UV and visible parts of the spectrum. Additionally,

185 we also use ancillary information on the quality of pixel (cloud contamination, land/sea mask, etc.), aerosol

186 ~~type~~index, LER, surface pressure and ALH data set used in the operational OMAERUV product. ~~The~~

187 ~~OMAERUV product primarily relies on the measured near-UV aerosol index and AIRS-retrieved carbon~~

188 ~~monoxide information to categorize aerosols into Carbonaceous, Dust, and Urban/Industrial types.~~ Since mid-

189 2007, OMI suffers from an external obstruction that affects the quality of radiance measurements in a few rows

190 (cross-track pixels). This is referred to as 'row anomaly' that restricts the current usage of OMI observations for

191 the scientific purpose to about half in a total of 60 cross-track rows (Schenkeveld et al., 2017). Extensive

192 documentation about how the row anomaly affects the OMAERUV aerosol product is available at Torres et al.,

193 (2018).

2.3 MODIS

195 The ~~MODerate resolution Imaging Spectro-radiometer (~~MODIS~~)~~ on board NASA's EOS Aqua and Terra

196 satellites are nadir-viewing, multi-spectral radiometer. MODIS measures the TOA radiances in 36 wavelength

197 bands ranging from 0.41-14.23 μm with a ground pixel spatial resolution between 250-1000 m (King et al.,

198 1992). MODIS scans the earth's surface with a 2300 km wide swath to provide near-global coverage on a daily

199 ~~basis~~. In this work, we use Aqua-MODIS radiances (at 466 and 646 nm) provided in the 10-km aerosol product

200 (MYD04_L2) from the Deep-Blue (DB) aerosol algorithm. This aerosol product provides cloud-free radiances

201 and ancillary information on the terrain height/pressure, quality of pixel and estimated cloud fraction (Hsu et al.,

202 2013). For surface characterization in visible wavelengths we use MODIS MAIAC (Multi-Angle Implementation

203 of Atmospheric Correction) MCD19A1 daily 1-km sinusoidal gridded spectral BRF (Bidirectional reflectance

204 function) or surface reflectance product (Lyapustin and Wang, 2018).~~quality of pixel and estimated cloud~~

205 ~~fraction.~~

3 Methodology

A schematic flowchart shown in Figure 2 illustrates the method adopted in this work to derive wavelength-dependent aerosol absorption.

~~A schematic flowchart of the method adopted in this work to derive wavelength-dependent aerosol absorption is shown in Figure 2.~~

3.1 Computation of site-specific Seasonal Look-up tables of TOA reflectances

To start, we compile a seasonal climatology of aerosol particle size distributions and real part of the refractive index (440 nm) for the entire τ range from the AERONET Level-2 Version-2 inversion product for each site considered in the study. Here, we assume that the spectral variability of the real part of the aerosol refractive index through UV-Visible is minimal and, therefore, values derived at 440 nm were assumed to be wavelength-independent across the UV-Visible spectrum range considered in this study. The resulting site-specific ~~climatology~~ climatologies of aerosol size distribution are fed to a radiative transfer model (RTM) to generate look up table (LUT's) of outgoing top of the atmosphere (TOA) reflectances at 340, 354, 388, 466, and 646 nm with varying nodal points of satellite-sun geometry (i.e., SZA–solar zenith angle at $0°$, $20°$, $40°$, $60°$, $66°$, $72°$ and $80°$; VZA–viewing zenith angle at $2°$ interval from $0–88°$; RAA–relative azimuth angle at $15°$ interval from $0–180°$). Reflectance LUTs are created for two values of surface pressure (1013.25 and 600 mb), seven values of τ (0.0, 0.1, 0.5, 1.0, 2.5, 4.0 and 6.0), five nodal points on ALH (0, 1.5, 3.0, 6.0 and 10.0 km) for the referenced surface pressure nodes, and eight values of imaginary component of the refractive index (0.000, 0.008, 0.016, 0.024, 0.032, 0.040, 0.048 and 0.056). The aerosol profiles used in the RTM follow a quasi-Gaussian distribution centred around the respective modes of ALH. We use a total column ozone of 275 Dobson unit in the RTM to account for ozone absorption. ~~, surface pressure, τ, ALH, and imaginary component of the refractive index.~~ The Gauss-Seidel radiative transfer code (Mie theory) used for this purpose accounts for gaseous absorption, molecular and aerosol multiple scattering (Herman and Browning, 1965). Thus, a database of AERONET site-specific seasonal LUT of reflectances for the aerosols observed over each site in the study is created. Figure 3 shows an example of the calculated net aerosol reflectance at the TOA for selected sun-satellite geometry (SZA=$20°$, VZA=$40°$, RAA=$130°$) and varying values of τ and ω_o from our LUT developed for the GSFC site ($38.92°$ N, $76.84°$ W). These results illustrate that for a given satellite-sun geometry, observed radiance, and assumed LUT, multiple combinations of τ and ω_o can explain the satellite measurements. In addition, it is noted that the net reflectances are mostly invariant at low optical depths (~0.1) regardless of variations in SSA for all

wavelengths. This is a typical scenario for the LUT approach to derive aerosol properties, suggesting retrieval of absorption is likely not reliable at low optical depths. These results also illustrate the *critical reflectance concept* (Kaufman, 1987), as a particular upwelling reflectance value (also associated with a particular value of surface reflectance) at which there is no sensitivity to aerosol optical depth and, therefore, theoretically suitable for the retrieval of aerosol absorption from satellite observations. Nonetheless, to derive the best-fit or unique solution of ω_o from satellite measurements, an accurate characterization of τ, cloud-free radiances, and surface reflectances are required.Figure 3 shows the calculated net aerosol reflectance at the TOA over the GSFC site (38.92° N, 76.84° W) using particle sizes derived from the AERONET product and varying values of τ and ω_o. These results illustrate that for a given satellite-sun geometry and observed radiance, multiple combinations of τ and ω_o can explain the satellite measurements. This simulation demonstrates that in order to derive ω_o from satellite measurements, an accurate characterization of τ, cloud-free radiances, and surface reflectances are required.

The site-specific LUTs developed here assume spherical particle shapes (Mie theory) for carbonaceous and urban aerosols. However, mineral dust particles are assumed non-spherical and modeled as randomly oriented spheroid (Dubovik et al., 2006; Torres et al., 2018). To account for the non-spherical sphericity behavior of dust particles, a unified dust model LUT is created using particle sizes from selected AERONET sites over Sahara and Arabian Middle East region that include: Saada, SEDE_BOKER, Solar_Village, and Tamanrasset_INM. These sites were selected based on the observed prevailing dust aerosol type. The particle sizes and real refractive index obtained at these sites are used with a pre-computed set of kernels that assume a spheroidal shape with a fixed distribution of axis ratio to produce phase function (Dubovik et al., 2006). The obtained phase matrix elements are input to the RTM to create reflectance LUT's. The process of acquiring a non-spherical unified dust model LUT is necessary to account for the non-spherical shape of particles and save a considerable computational time, which otherwise would require to create another set of site-specific LUTs.

3.2 Collocation of satellite and ground measurements

We use satellite measurements (ground pixels) located within the 50 km radius of each AERONET site. In essence, we treat the overlying atmospheric aerosols within a 50 km radius of the site as a representative of the AERONET measured τ. We look for valid AERONET τ measurements within ±2 hours of satellite overpass and assign the τ closest in time to all the ground pixels. It should be noted here that for OMI sensor, the OMAERUV product provides cloud-free radiances (340, 354 and 388 nm) in the native pixel resolution of 13 km x 24 km, while the MODIS sensor DB-product provides cloud-free radiances (466 and 646 nm) at 10 km x 10 km

resolution. ~~To allow for more sampling, we associate the AERONET observations within ±2 hours of satellite overpass to the measured TOA radiances. Here, we do not employ any averaging scheme for the AERONET data and keep it intact. While with satellite measurements, we use native pixel resolution of 13 km x 24 km for the OMI wavelengths (340, 354 and 388 nm) and 10 km x 10 km resolution radiances for the MODIS wavelengths (466 and 646 nm).~~

3.3 Retrieval of aerosol $\omega_o(\lambda)$

The proposed technique to derive aerosol absorption follows the procedure of obtaining (a) the AERONET AOD at desired wavelengths for OMI and MODIS, (b) aerosol type, (c) optimal layer height, (d) surface pressure, (e) surface reflectance, and (f) best quality assured cloud free-TOA reflectances.

~~the best quality assured cloud free TOA reflectances, identifying the aerosol type, optimal layer height, and characterize surface reflectance. We select over land pixels from both sensors with the best quality flags ('0' OMI, '3' MODIS DB) and cloud fraction < 0.2 in the retrieval procedure. Aerosol type information for the OMI wavelengths is directly adopted from the OMAERUV product. While for the MODIS wavelengths, our algorithm looks for the nearest OMI footprint to obtain and assign the corresponding aerosol type. Once an absorbing aerosol type i.e., carbonaceous smoke or mineral dust is identified, we choose the best estimate of ALH from the joint OMI-CALIOP climatology derived from a 30-month long record of collocated observations (Torres et al., 2013). While for a weakly absorbing aerosol (Urban), ALH is characterized with a Gaussian distribution of aerosols with a peak at the surface. This is similar to the procedure adopted in the OMAERUV aerosol retrieval (Torres et al., 2013). For the surface characterization at OMI wavelengths, we use a near-UV surface albedo database used in the OMAERUV algorithm. At MODIS wavelengths, surface reflectance provided by MAIAC products (Lyapustin and Wang, 2018) is used. Our retrieval technique gathers all above mentioned information for each pixel along with the associated AERONET τ to perform an inversion for each wavelength independently. The inversion procedure solves for the best fit of radiances and τ with the prior computed site-specific seasonal LUT radiances to derive aerosol $\omega_o(\lambda)$.~~

3.3.1 AERONET AOD at sensor wavelengths

The AODs at the nominal wavelengths measured by AERONET along with the Extinction Ångström Exponent (EAE, α) for several wavelength pairs (340-440, 380-500, 440-675, 440-875, etc.) are provided in the AOD product. We derive the τ at our interest of satellite wavelengths using the closest available measurement and α through the power-law approximation (Ångström, 1929) as shown in equation 2. For OMI wavelengths, the

295 AERONET 340 and 380 nm measurements are readily available while τ_{354} is obtained with $\lambda_{Ref} = 380$ nm and

296 $\alpha_{\lambda\_Ref} = \alpha_{340-440}$. For the few sites with older models of AERONET sunphotometer that does not have direct sun

297 measurements at 340, and 380 nm (for example Banizoumbou, Avignon, etc.), we use $\lambda_{Ref} = 440$ nm and $\alpha_{\lambda\_Ref} =$

298 $\alpha_{440-675}$. Similarly, for MODIS wavelengths the τ at 466 and 646 nm are obtained using $\lambda_{Ref} = 440$ nm and $\alpha_{\lambda\_Ref} =$

299 $\alpha_{440-675}$.

300
$$\tau_\lambda = \tau_{\lambda_{Ref}} \left(\frac{\lambda}{\lambda_{Ref}} \right)^{-\alpha_{\lambda\_\lambda Ref}} \hspace{3cm} (2)$$

301

302 ### 3.3.2 Aerosol type and ALH

303 Aerosol type information is essential to derive absorption properties. We use a combination of Extinction

304 Ångström Exponent ($\alpha_{440-870}$) derived from AERONET and near UV Aerosol Index (UVAI) from OMAERUV

305 product to categorize the observed aerosols into three basic types – dust, carbonaceous, and urban/industrial.

306 Initially, our algorithm uses $\alpha_{440-870}$ to identify the aerosols as coarse ($\alpha_{440-870} \leq 0.2$) and fine ($\alpha_{440-870} \geq 1.2$) mode

307 dominated particles. Threshold $\alpha_{440-870}$ of 0.2 chosen for coarse mode particles unambiguously identifies dust

308 aerosols. However, the sample of fine mode particles consists of both absorbing carbonaceous and weakly

309 absorbing urban type aerosols. The near-UV aerosol index is an excellent indicator to identify the presence of

310 absorbing aerosols. Threshold UVAI value adopted from OMAERUV algorithm is used to separate carbonaceous

311 (UVAI ≥ 0.8) and urban (UVAI < 0.8) aerosols, respectively. Based on extensive tests on the OMI signal strength

312 on all surface types it is determined that a minimum UVAI of 0.8 is required to identify absorbing aerosols

313 (Torres et al., 2007, 2013). Although UVAI is an excellent indicator to identify the presence of absorbing

314 aerosols, the large OMI footprint (13 km x 24 km) and sub-pixel contamination of signal strength might at times

315 underestimate UVAI categorizing the observed aerosols as urban type. To derive aerosol absorption for dust,

316 non-spherical LUT is selected while for carbonaceous and urban aerosols site-specific LUTs are used. In

317 addition, for the absorbing types of aerosols i.e., carbonaceous and dust, we choose the best estimate of ALH

318 from the joint OMI-CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization) product. The joint OMI-

319 CALIOP product was developed using 30-month long record of collocated observations to gather absorbing

320 aerosol backscattering profiles at 1064 nm that were gridded on 1° x 1° resolution to produce global monthly

321 average ALH. Prescribed uncertainty in the ALH derived from joint OMI-CALIOP product primarily due to

322 limited sampling of the CALIOP lidar overpasses is expected to be within ±1 km (Torres et al., 2013). For urban

323 aerosols, an exponential aerosol profile peaking at the surface is employed to perform the inversion procedure.

324

3.3.3 Surface reflectance and pressure

For the surface characterization at OMI wavelengths, we use a near-UV surface albedo database at quarter degree grid resolution provided in the OMAERUV product (Torres et al., 2007). The near-UV surface albedo employed by OMAERUV is derived from minimum Lambertian equivalent reflectance obtained from available long-term measurements. The uncertainty in the near-UV surface albedo from these measurements is expected to be within ± 0.01 (Torres et al., 2018). At MODIS wavelengths, surface reflectance or BRF provided by MAIAC MCD19A1 product is used. The MAIAC MCD19A1 provides spectral surface BRF over cloud-free and clear-to-moderately turbid atmospheric conditions ($\tau_{466} \leq 1.5$) for solar zenith angles below 80°. The measurement-based uncertainty in MCD19A1 BRF at visible wavelengths is reported to be in the range of 0.002–0.003 for the combined sources of errors including uncertainties from gridding, cloud detection, and aerosol model properties (Lyapustin et al., 2018). Additionally, the surface or terrain pressure reported in the OMAERUV, and terrain height (converted to pressure) reported in the MODIS aerosol products are used in our SSA retrievals.

Our retrieval technique gathers all the above-mentioned required inputs including the best quality assured cloud-free radiances reported in OMAERUV (Quality flag = 0) and MODIS-DB (Quality flag = 3) products to perform an inversion for each wavelength independently. The inversion procedure interpolates the LUT radiances linearly for the prescribed satellite-sun geometry, ALH, τ, and logarithmically over the surface pressure nodes. The obtained LUT radiances as a function imaginary refractive index are then fitted with the satellite measured radiances to derive aerosol $\omega_o(\lambda)$.

3.3.4 Illustration of retrieved SSA

Figure 4 shows the retrieved aerosol SSA over the GSFC site as a function of AERONET measured τ. Located in the vicinity of a metropolitan area, the prevailing aerosols over the GSFC site are the urban or industrial types that are relatively more scattering in nature. In general, retrieved SSA increases with aerosol loading, except for a small decrease at large AOD's at 466 and 646 nm. The mean aerosol SSA retrieved at the GSFC site for all τ observations at 340, 354, 388, 466 and 646 nm are 0.91, 0.93, 0.93, 0.90 and 0.85, respectively. The variability of the retrieved SSA is high at lower aerosol loading for all wavelengths. Particularly notable is the high variability of retrieved SSA in most τ bins for the visible wavelengths (i.e., MODIS bands). This is due to the weaker diminishing aerosol signal strength for weakly absorbing urban type aerosols at lower aerosol loading in the visible spectrum, where the measured TOA radiances are dominantly contributed by the underlying surface, notably at 646 nm. The mean aerosol SSA retrieved at the GSFC site for observations with $\tau_{440} > 0.4$ at 340, 354,

388, 466 and 646 nm are 0.94, 0.95, 0.95, 0.94 and 0.93, respectively. These results agrees well with the values reported for GSFC site using AERONET products at 440 and 675 nm as 0.96 and 0.95, respectively (Giles et al., 2012). Also shown in figure 4 is the number of collocated observations that were used in the inversion and the percent of observations for which SSA is retrieved. For about 12 years of the satellite and ground collocated observations used here, it is clearly evident that the number of observations from OMI is less than MODIS observations. The difference in the number of collocated observations stems partly from the OMI row-anomaly, cloud contamination, and the coarser pixel resolution. The percent of SSA retrieved observations varies widely even within the corresponding sensor wavelengths (OMI: 340, 354, 388 nm and MODIS: 466, 646 nm). At times depending on the surface albedo usedreflectance, the computed net aerosol reflectance might exceed the LUT limits and produce SSA values above one or less than the maximum absorption in the LUT, typically referred to as out-of-bounds retreival. We avoid this by constraining our inversion procedure within the LUT limits and do not allow for any extrapolation of the inputsradiances. However, this leads to the unequal number of retrieved observations within the sensor wavelengths. In other words, for a given observation within the OMI or MODIS sensor, it is possible to have aerosol SSA retrieved at one wavelength and no retrieval (out-of-bounds) at other wavelengths. Also, it is worth mentioning that for few sites located along the coasts or in the islands (e.g., Mauna_Lao, Ascension_Island, Nauru), we were either unable to retrieve aerosol SSA or the number of days with retrieval is quite low. This is a consequence of OMI's large pixel size, where the satellite measured radiances are often contaminated by clouds and mixed signal from the surface that are challenging to resolve and lead to out-of-bounds in the inversion.

To examine the seasonal variation of aerosol SSA and its spectral dependence of aerosol absorption, we created a subset of the data that includes observations for which aerosol SSA is retrieved for all the corresponding sensor wavelengths simultaneously (OMI: 340, 354, 388 nm and MODIS: 466, 646 nm) on any given day. This step reduces the sample size drastically but eliminates the need for making prior assumptions on the wavelength dependence of aerosol absorption angstrom exponent to fill those gaps. Instead, tThe obtained subset of aerosol SSA in the UV-Visible range is used to compute the resulting spectral dependence of aerosol absorption of the prevailing aerosols over the corresponding AERONET sites in terms of the Aerosol Absorption Ångström Exponent (AAE), a measure of the spectral dependence of aerosol absorption absorption optical depth (Bond, 2001) using a power-law approximation, analogous to the Angstrom Extinction Ångström Exponent (van de Hulst, 1957). The spectral dependence of aerosol absorption AAE, is reported as Absorption Angstrom Exponent

386 (AAE) defined as the slope of aerosol absorption optical depth with wavelengths on a log-log scale. The aerosol

387 absorption optical depth $\tau_{abs}(\lambda)$ is derived as shown in equation (~~1~~3):

388
$$\tau_{abs}(\lambda) = \left(1 - \omega_0(\lambda)\right).\tau_{ext}(\lambda) \tag{~~1~~3}$$

389 from which the AAE for wavelength range λ_1, λ_2 is calculated as shown in equation (~~4~~2).

390
$$AAE(\lambda_1, \lambda_2) = -\frac{\ln(\tau_{abs}(\lambda_1)/\tau_{abs}(\lambda_2))}{\ln(\lambda_1/\lambda_2)}$$

391 (~~2~~4)

392 The results presented hereafter include only a data subset that meets the following three conditions: (a) SSA

393 retrievals are available for all five wavelengths on a given day, (b) $\tau_{440} > 0.4$, to ensure reliable accuracy spanning

394 through UV-Visible wavelengths, and (c) there are at least 5 days of observations available per season per aerosol

395 type. ~~In addition, we make use of the AERONET extinction angstrom exponent (α) at 440-870 nm to distinguish~~

396 ~~the particles as coarse (α < 0.2), fine (α > 1.2), and in between as intermediate or mixed-mode. Since our aerosol~~

397 ~~identification strictly uses three primary types, the use of qualitative indicator α helps delineate the mixture of~~

398 ~~aerosols when applicable.~~

399 **4 SSA retrieval sensitivity analysis**

400 The ~~inversion procedure employed here~~proposed inversion procedure to derive spectral aerosol absorption from

401 the combined ground and satellite measurements is susceptible to several systematic and random errors. These

402 error sources include uncertainties in the following input parameters: (a) aerosol extinction measurements, (b)

403 estimation of particle size distribution, (c) real part of refractive index, (d) calibration of satellite measured TOA

404 radiances, (e) sub-pixel cloud contamination, (f) any unaccounted trace gaseous absorption in the RTM, (g)

405 surface reflectance, (h) ALH, and (i) surface pressure.~~(e) surface reflectance, (f) aerosol layer height, and (g) sub-~~

406 ~~pixel cloud contamination.~~ The retrieved aerosol absorption from our inversion procedure could be affected by all

407 these sources of uncertainties. ~~Among these, error sources from (a-d) are inevitable for which we do not have any~~

408 ~~direct control over them. However, we do have control only for the sources from (e-g) in our retrieval.~~ Errors

409 associated with surface reflectance, aerosol layer height, and cloud contaminations on the satellite retrieved

410 optical depths are well documented in the literature (e.g., Fraser and Kaufman, 1985; Torres et al., 1998; Jethva et

411 al., 2014). In summary it is known that an: (i) overestimation (underestimation) of surface reflectance leads to

412 lower (higher) aerosol SSA, (ii) overestimation (underestimation) of τ leads to lower (higher) aerosol SSA, (iii)

413 overestimation (underestimation) of ALH produces higher (lower) aerosol SSA ~~—~~(significantly more pronounced

414 in the UV than in visible wavelengths), and (iv) an increase in TOA reflectance due to sub-pixel cloud

415 contamination produces higher aerosol SSA. ~~We use sensitivity tests for these key input variables to derive a~~
416 ~~quantitative estimate of the error percolated in the aerosol SSA retrieval due to changes in these variables.~~
417

4.1 Estimation of theoretical errors in the retrieved aerosol $\omega_o(\lambda)$

419 Here, we conduct sensitivity tests for all sources of errors in the input variables to derive a theoretical estimate of
420 the error percolated in the aerosol SSA retrieval due to uncertainties in the assumed values of these variables. To
421 have a controlled setup, we performed tests for a representative fixed satellite-sun geometry (SZA=20°,
422 VZA=20°, RAA=130°) over the GSFC, Mongu, and Tamanrasset_INM. These sites were selected to represent
423 three distinct aerosol types as well as surface conditions. We assume a fixed value of $\omega_o = 0.9$ at 388 nm and
424 aerosol load $\tau_{440} = 0.2$, 0.3, and 0.4 as our references to estimate errors in the retrieved SSA. To derive
425 corresponding spectral AODs at remaining wavelengths, we assume an $EAE_{340-646}$ of 1.9, 0.2, and 1.9 for
426 carbonaceous, dust and urban aerosols, respectively. Similarly, spectral SSA at other wavelengths is estimated
427 assuming an $AAE_{340-646}$ of 1.7, 2.5 and 0.9 for carbonaceous, dust and urban aerosols, respectively. We calculate
428 the uncertainty of the derived spectral SSA for each aerosol type by perturbing, one at a time, the nominal values
429 of the nine inputs parameters by an assumed or observationally known uncertainty. The absolute error is
430 computed as the SSA obtained with altered input minus the assumed SSA. The combined uncertainty of the
431 derived spectral SSA is given by square root of the summation of the squares of the errors associated with each
432 parameter.
433

434 Figure 5 shows the error analysis of the retrieved SSA as a function of wavelength and optical depth given a
435 change in the input (a) $\tau_{ext}(\lambda)$, (b) particle sizes, and (c) real part of refractive index. We perturb the input τ with
436 an absolute value of ±0.02 for $\lambda < 400$ nm and ±0.01 for $\lambda > 400$ nm as prescribed by the AERONET AOD
437 product. As shown in Fig 5a, AOD over-estimations result in SSA under-estimations whereas AOD
438 underestimations yields SSA overestimations for all aerosol types over the considered spectral range. The
439 magnitude of the SSA error ($\Delta\omega_o$) decreases with increasing AOD. It is noted that for all aerosol types an
440 underestimation (overestimation) of AOD, the magnitude of $\Delta\omega_o$ is positive (negative) and increases with
441 wavelength (340 nm to 388 nm, and 466 nm to 646 nm). The higher magnitudes of $\Delta\omega_o$ noted for visible
442 wavelengths are attributed to lower spectral AODs where the aerosol absorption signal is diminished for a stable
443 retrieval, particularly notable for weakly absorbing urban aerosols. For the reference $\tau_{440} = 0.4$, perturbation of

±0.02+τ at 340 nm yields an error $\Delta\omega_o$ within ±0.002, while a perturbation of ±0.01+τ at 646 nm yields an error within ±0.011.

Uncertainties in assumed particle sizes are also expected to affect the retrieval of aerosol absorption. To estimate the error incurred in our SSA retrieval, we perturb the particles size (volume mean radius, VMR) derived from all AOD observations by 20%. We chose $\Delta VMR = 20\%$ based on examination of seasonal climatology of particle sizes as a function of τ_{440} and the most frequently occurring τ_{440} bin. It is noted that an overestimation of particle radii produces higher aerosol SSA leading to positive $\Delta\omega_o$ and vice-versa. However, the $\Delta\omega_o$ noted for dust aerosols are quite small/negligible in UV wavelengths while the $\Delta\omega_o$ remains invariant at visible spectral range. This owes to the size of dust particles that are much higher than the considered spectral range where extinction of radiation reaches maximum efficiency and remains less variant with additional increase in particle sizes. It should be noted that at the AODs considered, particle size assumptions here have only a small effect on the retrieved SSA. Spectrally the magnitude of $\Delta\omega_o$ is minimum in the UV and increases towards the visible wavelengths. The magnitude and spectral behavior of $\Delta\omega_o$ noted here suggests aerosol scattering primarily drives the particle size effect. For the reference $\tau_{440} = 0.4$, perturbation of ±20% VMR to all aerosol types yields an error $\Delta\omega_o$ within ±0.018, and ±0.044 at 340 nm and 646 nm, respectively.

Another aerosol intrinsic property input for our SSA retrieval algorithm obtained from AERONET inversion product is the real part of refractive index (RRI) – which primarily contributes to the magnitude of scattering. The prescribed uncertainty in aerosol RRI is estimated to be ±0.04 (Dubovik et al., 2000). Our results indicate that an overestimation of RRI produces lower aerosol SSA and vice-versa. The effect of aerosol RRI perturbation on retrieved SSA is noted to be higher in the UV-spectrum than in the visible. This is likely a result of strong competing effects from molecular scattering and aerosol absorption, while aerosol load adds an additional weak dependence. For the reference $\tau_{440} = 0.4$, perturbation of ±0.04+RRI yields an error $\Delta\omega_o$ within ±0.009 and ±0.002 at 340 nm and 646 nm, respectively.

Figure 6 shows the error analysis of the retrieved SSA as a function of wavelength and optical depth given a change in the (a) TOA radiances due to sensor calibration, (b) sub-pixel cloud contamination, and (c) trace gaseous absorption. The prescribed uncertainty in the TOA radiance measurements for OMI and MODIS sensors are expected to be ±1.8% (Schenkeveld et al., 2017) and ±1.9% (Guenther et al., 2002), respectively. As expected, an overestimation of TOA radiances due to sensor calibration produces lower aerosol SSA and vice-

475 versa. Errors in the retrieved SSA due to uncertainties in the sensor calibration increase with decreasing aerosol
476 optical depth. For the reference $\tau_{440} = 0.4$, perturbation of $\pm1.8\%$ in TOA radiances at 340 nm yields an error $\Delta\omega_o$
477 within ±0.027, while a perturbation of $\pm1.9\%$ in TOA radiances at 646 nm yields an error within ±0.037.
478 However, an overestimation in TOA radiances due to assumed optically thin cloud ($\tau_{cloud} = 0.5$) produces higher
479 aerosol SSA. The effect of cloud contamination in TOA radiances is more pronounced in the visible than in UV
480 spectrum. For observations with $\tau_{440} = 0.4$, the sub-pixel cloud contamination yields an error $\Delta\omega_o$ within ±0.020
481 and ±0.056 at 340 nm and 646 nm, respectively.
482
483 As described in section 1, for the retrieval of aerosol properties from satellite measured radiances it is important
484 to separate the TOA radiance signal from the underlying surface and atmospheric constituents including trace
485 gases. It should be noted that the RTM used in this work accounts only for the H_2O and O_3 gaseous absorption.
486 For the UV channels from OMI, specific wavelengths at 340, 354 and 388 nm are chosen for aerosol retrieval
487 that has minimal absorption due to trace gases (Torres et al., 2007). However, for the visible channels at 466 and
488 646 nm from MODIS the absorption trace gases such as NO_2 could be significant. To account for the remaining
489 trace gases (for example O_2, NO_2, etc.), we use an estimate of the optical depth due to all trace gases in the
490 atmosphere to derive the error incurred in our SSA retrievals. The combined optical depth of all traces gases that
491 has absorption lines in visible wavelengths are estimated to be 0.0042 and 0.0344 for the MODIS wavelengths at
492 466 nm and 646 nm, respectively (Patadia et al., 2018). To estimate an error in our aerosol SSA retrieval due to
493 unaccounted trace gases we initially derive the LUT radiances for the prescribed τ_{gases} and retrieve SSA by
494 perturbing the TOA radiance by that amount. Since our LUT radiances are developed by not accounting for all
495 trace gases, the retrieval of SSA matches higher radiances than the actual, producing lower aerosol SSA than the
496 actual. Our analysis shows that for the prescribed τ_{gases} the error in the retrieved aerosol SSA for observations
497 with $\tau_{440} = 0.4$ are negligible at 466 nm and within 0.024 at 646 nm.
498
499 Figure 7 shows the error analysis of the retrieved SSA as a function of wavelength and optical depth given a
500 change in the (a) surface reflectance, (b) ALH, and (c) surface pressure. We perturb the surface reflectance by an
501 absolute ±0.01 for all wavelengths to derive an estimate of error incurred in the SSA retrieval. Our results
502 indicate that $\Delta\omega_o$ increases with increasing wavelength and decreasing τ due to changes in surface reflectance for
503 all aerosol types. For less-absorbing (urban) aerosols, the surface reflectance becomes increasingly important at
504 the visible wavelengths than compared to absorbing (carbonaceous or dust) aerosols. For the observations with
505 $\tau_{440} = 0.4$, it is noted that $\Delta\omega_o$ are within ±0.011 and ±0.050 at 340 nm and 646 nm, respectively. In contrast to the

surface reflectance, the effect of ALH becomes prominent at near-UV wavelengths under the prescribed uncertainty of ±1 km. The $\Delta\omega_o$ due to changes in ALH decreases with wavelength because of the gradually diminishing the intensity of Rayleigh scattering (proportional to λ^{-4}) and its radiative interactions with aerosols. For the observations with $\tau_{440} = 0.4$, it is noted that $\Delta\omega_o$ due to ±1 km ALH are within ±0.028 and ±0.001 at 340 nm and 646 nm respectively for both absorbing and non-absorbing aerosols.

Another essential input in our SSA retrieval algorithm employed here is the terrain or surface pressure that determines the contribution of molecular scattering in the simulated TOA radiances through pre-computed LUT. We assume an uncertainty of ±100 m in the terrain height equivalent to ±12 mb or hPa pressure to derive an estimate of error incurred in aerosol SSA. Our analysis indicates that an overestimation of surface pressure produces lower aerosol SSA to compensate the higher radiances reaching the TOA. For absorbing (carbonaceous or dust) aerosols, the effect of surface pressure on the retrieved SSA is high in the UV spectrum than in visible, while for less-absorbing (urban) aerosols the error is retrieved SSA is spectrally invariant. Colarco et al., (2017) provides detailed examination of the effect of terrain pressure on OMI measurements and reported these effects are prominent at sites over mountainous regions owing to the coarser OMI footprint. In addition to the surface elevation uncertainty, the atmospheric effects also alter surface pressure. For the observations with $\tau_{440} = 0.4$, it is noted that $\Delta\omega_o$ due to ±12 hPa surface pressure is within ±0.011 and ±0.006 at 340 nm and 646 nm, respectively. Sensitivity tests are performed on observations that were reported with best accuracy (minimal cloud contamination in both OMI and MODIS data sets) for a few selected sites that include GSFC, Avignon, Tamanrasset_INM, Saada, Alta_Floresta, and Mongu. These sites were selected to include different types of aerosols observed over these sites. Figure 5 shows the error analysis of the retrieved SSA as a function of wavelength and optical depth given a change in the surface reflectance and ALH by an absolute change of ±0.01 and ±1 km ALH. The absolute error is computed as the SSA obtained with altered input minus the actual SSA. As expected, the error in retrieved SSA increases with increasing wavelength and decreasing τ due to changes in surface reflectance for all aerosol types. For less-absorbing (Urban) aerosols, the surface reflectance becomes increasingly important at the visible wavelengths than compared to absorbing aerosols. Our analysis shows that for small τ_{440} (~0.2), the error in retrieved SSA is much higher (> ±0.05) for visible wavelengths, while that in the near-UV region reaches up to ±0.03. However, for observations with τ_{440} ~0.4, a reliable accuracy of within ±0.05 is achieved even for the non absorbing aerosols at 646 nm. In contrast to the surface reflectivity, the effect of ALH becomes prominent at near UV wavelengths. The error in retrieved SSA due to changes in ALH decreases with wavelength because of the gradually diminishing the intensity of Rayleigh scattering and its

537 ~~radiative interactions with aerosols. The errors in the retrieved SSA are estimated to be better than ±0.03 in the~~
538 ~~near-UV and negligible at visible wavelengths for both absorbing and non-absorbing aerosols.~~

539

540 Table 2 summarizes the SSA error analysis 340 nm and 646 nm due to uncertainties in most relevant input
541 variables. Among the nine input variables used in our algorithm, the $\Delta\omega_o$ at 340 nm arises mostly from (in
542 descending order) the uncertainties in calibration of TOA radiances, sub-pixel cloud contamination, ALH,
543 particle sizes and so on. While for the visible wavelength at 646 nm the $\Delta\omega_o$ arises mostly from (in descending
544 order) cloud contamination, surface reflectance, calibration of TOA radiances, particle sizes, trace gases, and so
545 on. These sensitivity tests clearly indicate that $\Delta\omega_o$ is (a) spectrally dependent due to multiple variables, (b)
546 decreases with increasing τ, and (c) varies with absorbing nature of aerosols. The combined error in retrieved
547 SSA can be now estimated as the square root of the sum of individual error squares (RMSE). Overall, for the
548 observations with $\tau_{440} = 0.4$, the combined error in the retrieved SSA for absorbing (less-absorbing) aerosols are
549 within ±0.043 (±0.038) and ±0.073 (±0.086) at 340 nm and 646 nm, respectively. However, it should be noted
550 that depending on the reliability of the input variables, the errors stemming from individual sources could be in
551 opposite direction resulting in cancellation of errors. Under such scenario, the combined error in the retrieved
552 spectral SSA is expected to be much lesser than the combined value reported here with our sensitivity tests.
553 ~~presents the achievable accuracy in our SSA retrievals at 340 nm and 646 nm. Overall, for the observations with~~
554 ~~τ_{440} equals to 0.4, the estimated accuracy in our retrieved SSA is within ±0.03 (±0.05) for absorbing (non-~~
555 ~~absorbing) aerosols through 340-646 nm. While for the observations with τ_{440} up to 0.2, the achievable accuracy~~
556 ~~in SSA reaches up to ±0.05 (> ±0.05) for absorbing (non-absorbing) aerosols.~~

557

558 **4.2 Estimation of theoretical errors in the derived AAE**

559 Similar to the estimation of errors in the retrieval of SSA, we conduct sensitivity tests to determine the errors in
560 the computed AAE due to certainties in the retrieved SSA. We assume a fixed $\omega_o(388) = 0.9$, aerosol load $\tau_{440} =$
561 0.4, $EAE_{340-646}$ of 1.9, 0.2, and 1.9 for carbonaceous, dust and urban aerosols, respectively to derive the nominal
562 AAE values at three wavelength pairs 354-388, 466-646, and 340-646. By using fixed $\tau(\lambda)$, we perturb the $\omega_o(\lambda)$
563 by ±0.01 intervals to compute the AAE. The errors are reported as difference in AAE from perturbed SSA minus
564 the AAE derived from nominal SSA.

565

Table 3 presents the theoretical uncertainty in computed AAE due to uncertainties in the SSA. As expected, the ΔAAE noted for all wavelength pairs increases with increasing $\Delta\omega_o$ for all aerosol types. It is noted that for fine mode particles (carbonaceous and urban), an overestimation of ω_o produces lower AAE (negative errors) and underestimation of ω_o produces higher AAE (positive errors). In contrary for coarse mode particles, an overestimation of ω_o produces higher AAE (positive errors) and underestimation of ω_o produces lower AAE (negative errors). This is due to the fact that large particle size drives the scattering effect producing low aerosol absorption optical depths and, therefore, further overestimation of ω_o yields lower single scattering co-albedo ($1 - \omega_o$). The magnitude of ΔAAE is higher for overestimation than those noted for underestimation of SSA. In addition, it is noted that for fine mode particles the errors in $\Delta AAE_{354-388}$ (UV spectral range) are higher, while for coarse mode particles the errors in $\Delta AAE_{466-646}$ (visible spectral range) are higher than the other two wavelength pairs. For the assumed carbonaceous aerosols, perturbation of $\Delta\omega_o = \pm 0.04$ yields a ΔAAE within ± 0.13 for all wavelength pairs. For the urban aerosols, perturbation of $\Delta\omega_o = \pm 0.04$ yields a ΔAAE within ± 0.70 for all wavelength pairs. However, for dust a perturbation of $\Delta\omega_o = \pm 0.04$ yields a ΔAAE up to ± 1.3 for 354-388 wavelength pair and much higher in the 466-646, and 340-646 wavelength pairs. Additional tests were performed by perturbing only one of the SSA while deriving AAE for any wavelength pair. The resulting ΔAAE is much higher than for the tests where SSA is perturbed for all wavelengths. It is noted that for even a small perturbation of $\Delta\omega_o = \pm 0.01$ at one of the wavelengths in a pair, the ΔAAE is ± 1.2, ± 0.2, and ± 0.4 for the wavelength pairs at 354-388, 466-646, and 340-646 respectively for all aerosol types. Overall, the errors noted for AAE are consistent with the wavelength dependence of ω_o that is function of both size and absorbing nature of the particles.

5 Results

The results presented hereafter include only a data subset that meets the following three conditions: (a) SSA retrievals are available for all five wavelengths on a given day, (b) $\tau_{440} > 0.4$, to ensure reliable accuracy spanning through UV-Visible wavelengths, and (c) there are at least 5 days of observations available per season per aerosol type. We include results of retrieved SSA for cases when $\tau_{440} \leq 0.2$ as supplementary materials. Table 3 presents seasonal averages of aerosol SSA and AAE for all sites considered in this work. The spectral dependence of absorption quantified as AAE is reported for three different wavelength pairs covering the near-UV (354, 388), Vis (466, 646) and UV-Vis (340, 646) spectra.

5.1 Biomass Burning

5.1.1 South America

The AERONET sites located in South America include Alta_Floresta, Arica, CEILAP-BA, CUIABA Miranda, Rio_Branco, Ji_Parana_SE, SANTA_CRUZ_UTEPSA, Sao_Paulo and Campo_Grande_SONDA. In general, carbonaceous aerosols over South America are dominantly emitted from biomass burning during southern hemisphere spring (JJA) and summer (SON), with distinct peaks in August and September. Most aerosol emissions are associated with biomass burning for land and agricultural management practices. Further, densely populated places like Sao Paulo and CEILAP-BA are also affected by vehicular and industrial emissions. Aerosols from northern parts of the Amazon Basin advecting south or southeast, and long-range transport of aged smoke from Southern Africa are not uncommon over few locations in South America. Figure 6a shows regional average SSA for carbonaceous particles at 466 nm is noted to be 0.92 (0.93) during JJA (SON) months. Average τ_{440} and $\alpha_{440-870}$ are about 1 and 1.8 respectively for both seasons, indicating dominantly fine mode nature of these particles. Spectral SSA increases from 340 nm (0.90) to 388 nm (0.93) followed by a decrease toward the visible wavelengths. For urban aerosols, the average τ_{440} (0.57) and $\alpha_{440-870}$ (1.70) are lower than those of carbonaceous particles. The average SSA at 466 nm for urban aerosols is 0.88 (0.92) for JJA (SON) months. We also find that the urban aerosols in South America are more absorbing during JJA than in SON. Examining individual sites (Table 3) reveals high absorption during JJA at CUIABA and Sao Paulo. It is likely that the urban aerosol samples shown here attribute to a mixture of aerosols.

5.1.2 Southern Africa

The AERONET sites located in the Southern Africa are Mongu, Pretoria, and Skukuza. In addition to the natural forest fires and emissions from crop residue burning, heavy industrial facilities and episodic dust commonly dictate the aerosol amounts over Southern Africa. Figure 6b shows the regional average SSA derived for aerosols over the Southern Africa. For the carbonaceous and urban aerosols observed over the region, maximum absorption is found in JJA period. The average SSA for carbonaceous particles increases from 340 nm to 466 nm and then decreases at longer wavelengths. Distinct seasonality in absorption for carbonaceous particles is observed with maximum (minimum) value of 0.87 (0.90) at 466 nm for JJA (SON) months. The range of regional average values of τ_{440} and $\alpha_{440-870}$ for carbonaceous particles are about 0.76 to 1.02 and 1.76 to 1.84 ranges respectively, while for urban aerosols the variability ranges are 0.55 to 0.73 and 1.68 to 1.74, respectively. As noted, τ_{440} and $\alpha_{440-870}$ are higher for carbonaceous particulate than for urban aerosols. For the latter, the average

SSA shows similar spectral behavior as carbonaceous particles. However, the AAE of carbonaceous aerosols in the UV-Vis range is noted to be ~1.73, while for urban aerosols it is ~2.2. Notable seasonality for urban aerosols is observed for DJF where the average SSA is almost flat from 340 nm to 466 nm with a slight increase thereafter. Aerosols organic components are likely the cause of such absorption spectral feature.

5.1.3 Australia

In general, inland Australia is categorized as arid region vastly covered with deserts. However, Northern and Western parts of the continent are covered with savanna grasslands, where biomass burning due to natural forest fires and land management practices are known to produce high aerosol emissions during the dry season (May-October). The regional average SSA for the aerosols observed over Northern Australia at the sites Jabiru and Lake_Argyle is shown in figure 6c. For the sample obtained in this work, carbonaceous and urban aerosols are found during spring (SON). The average τ_{440} and $\alpha_{440-870}$ for carbonaceous particles is 0.65 and 1.62, respectively. Average SSA increases with wavelength from 0.87 (340 nm) to 0.89 (388 nm) and then decreases to 0.87 (646 nm). Such behavior of fine-mode particles is likely a result of a mixture of black carbon and organic carbon amounts in the atmosphere, producing stronger (weaker) absorption in the UV (Vis) wavelengths. Although the mean $\alpha_{440-870}$ for both carbonaceous and urban aerosols is similar, the mean τ_{440} for urban particles is relatively low. The UV-Vis spectral dependence of urban aerosols (1.57) follows similar behavior as carbonaceous aerosols (1.42). Unlike the typical urban aerosol absorption, the spectral SSA observed here indicates a mixture of urban and carbonaceous particles.

5.2 Dust

5.2.1 Sahara

The seasonal average SSA of aerosols over the sites Saada and Tamanrasset is shown in figure 7a. As one would expect from the region, dominantly dust aerosols are observed with average τ_{440} and $\alpha_{440-870}$ ranging from 0.63 to 0.85 and 0.11 to 0.16, respectively. Regional average aerosol SSA obtained at 466 nm is ~0.94. The spectral dependence of dust aerosols shows increase in SSA with wavelength, i.e., 0.86 at 340 nm to 0.97 at 646 nm. The UV-Vis AAE obtained for dust aerosols range from 2.8 to 3.3 with no distinct seasonality in the average spectral SSA. As noted, in addition to the coarse dust both sites constitute intermediate range of aerosols with average $\alpha_{440-870}$ up to 0.3. Compared to coarse particles the intermediate sizes exhibit typical 'dust' absorption curve but has relatively low SSA (0.95) at 646 nm and therefore low UV-Vis AAE (2.1 to 2.5). This is consistent with the known dependence of scattering effects at longer wavelength for the dust particles.

5.2.2 Sahel

The AERONET sites located in the Sahel region are Agoufou, Banizoumbou, Dakar, IER_Cinzana, Ilorin, Ouagauodu, and Zinder_Airport. Regional average SSA for the aerosols over Sahel region is shown in figure 7b. For dust aerosols, the average spectral SSA resembles typical dust absorption curve (increase in SSA with wavelength). No distinct seasonality in regional average absorption is observed. However, during SON months relatively low τ_{440} (0.64) and UV-Vis AAE (1.57) is noted compared to other seasons. Aerosols with intermediate size category ($0.2 < \alpha_{440-870} < 1.2$) are observed for all sites in the Sahel region. The spectral SSA obtained for these aerosols clearly indicate mixture of dust and carbonaceous particles. Eck et al. (2003) reported smoke particles found toward southern parts of the West Africa are relatively coarse (α ranges 0.3 to 0.5) than those found elsewhere – likely a result of mixing with other aerosol types, coagulation, humidification or combination of such processes. Typical carbonaceous absorption curve noted here for the wet season (JJA and SON) is consistent with those reports. The average SSA for these (coarse-) carbonaceous particles is ~0.93 at 466 nm and exhibit a UV-Vis AAE range 0.5 to 1.2. The average SSA observed for DJF and MAM (dry season) indicates a mixture of prevailing dust and carbonaceous particles. For the sample obtained over Sahel region, fine mode carbonaceous and urban aerosols are observed at Ilorin during DJF and SON. Both these aerosol types show significant absorption with the average SSA at 340 nm and 646 nm is ~0.86 and 0.87, respectively, with nearly no spectral dependence. This likely indicates the presence of black carbon amounts over the Ilorin site during DJF and SON. In addition to the biomass burning, fossil fuel combustion, and vehicular emissions, the vast number of gas flaring stations (> 300) around the Niger Delta produces high emissions (Onyeuwaoma et al., 2015). Highly absorbing black carbon amounts observed at Ilorin is possibly a result of such emissions.

5.2.3 Arabian Peninsula

The AERONET sites located in the Middle East/Arabian Peninsula region include Solar_Village, SEDE_BOKER, Nes_Ziona, and Cairo_EMA_2. The regional average SSA of aerosols observed for these sites is shown in figure 7c. For dust aerosols, as expected, the average SSA increases with increasing wavelength. The regional average SSA ranges from 0.89 to 0.98 at 340 nm to 646 nm, with UV-Vis AAE in the range of 2.7 to 3.8. No distinct seasonality in SSA is found from our sample of observations. However, a slight increase in SSA at UV wavelengths is noted during winter (DJF). Examining individual sites reveal this feature corresponds to the aerosols over Solar_Village. The increase in SSA and high AAE_{354_388} noted for Solar_Village during DJF likely indicates transport of aerosols from neighboring regions. Intermediate range of particles with $0.2 < \alpha_{440-870} < 1.2$

are observed over all sites. The regional average SSA observed for these particles clearly indicate mixture of aerosols. Carbonaceous aerosols found over Cairo from our sample have average SSA ranging from 0.89 to 0.91 at 340 nm to 646 nm. The UV-Vis AAE (1.91) obtained for these aerosols likely indicate mixture of black and organic carbon amounts. For the urban aerosols observed over Cairo and Nes Ziona the regional average SSA is found to be 0.89 at both 340 nm and 646 nm indicative of mixture of aerosols. While urban aerosols and pollution prevail over Nes Ziona, emissions from crop residue burning (rice straws) over the Nile delta region during winter (DJF) and heavy pollution dictate the aerosol absorption noted over Cairo.

5.3 Urban/Industrial

5.3.1 Western North America

Dominantly urban type aerosols are observed in Western North America primarily produced from industrial activities and vehicle emissions. In addition, owing to the general meteorological and geographical setting of the western North America, the region experiences drier months in the summer and fall that initiates natural forest fires. The regional average aerosol SSA derived from our sample over the western North America is shown in figure 8a. The average aerosol absorption for urban aerosols decreases in the wavelength range 340-388 nm followed by an increase at longer wavelengths. Carbonaceous aerosols are observed in our sample over the Missoula site located in the State of Montana. The average SSA retrieved for carbonaceous particles increases with wavelengths from 340 nm to 466 nm (0.89 at 0.94) and then decreases towards 646 nm (0.88). The average τ_{440}, $\alpha_{440-870}$ and UV-Vis AAE obtained for the carbonaceous particles are 1.74, 1.8 and 1.72 respectively.

5.3.2 Eastern North America

Similar to the western part, atmospheric aerosols found over the eastern North America primarily originated from the industrial activities and secondary aerosol processes (Malm, 1992). Biomass burning generated carbonaceous particles and dust or mixture of aerosols over the eastern parts of the continent is a rare occurrence, except in the events of long-range transport of smoke from the west. Thus, the average aerosol SSA retrieved over the AERONET sites in this region follows a typical 'Urban' spectral absorption curve, as shown in figure 8b. It is observed that aerosol SSA increases from the 340 nm to 388 nm or 466 nm and then decreases attaining a maximum absorption (~0.90) at 646 nm. The regional average SSA for the MAM and JJA months at 466 nm is 0.89 and 0.87 respectively. It should be noted that for urban aerosols the retrieval error at visible wavelength is high (up to 0.05). Since there are no notable changes in the aerosol sources, the observed decrease absorption at 646 nm for JJA period is likely attributed from the retrieval uncertainty.

5.3.3 Europe

For the AERONET sites located in the Europe, dominantly urban aerosols are observed (figure 8c). The regional average SSA increases from 340 nm to 388 nm and then decreases reaching a minimum value (0.83) at 646 nm for most seasons. The observed aerosol absorption is similar for spring (MAM) and summer (JJA). However, there is an increase in absorption at wavelengths other than 646 nm for fall (SON) that reaches a maximum absorption 0.86 and 0.89 at 340 nm and 466 nm respectively. This likely suggests the presence of organic carbon amounts emitted from local fuel combustion sources. This feature is consistent with Ilias et al., (2019), that reports annual cycle of aerosol absorption over Thessaloniki site. Individual site observations reveal this increase in absorption is prominent for most locations in Europe during fall (Table 3) and winter (Table S1). While the aerosol loading is similar throughout the seasons, the average UV-Vis AAE for urban aerosols range from 1.0 to 1.26. In addition to the urban/industrial aerosols, long-range transport of dust from Sahara is not uncommon over central Europe and Mediterranean Basin. Although our sample over European sites do not constitute any coarse mode particles, intermediate range ($0.2 < \alpha_{440-870} < 1.2$) of aerosols are observed for most sites. The average SSA curve noted here indicates mixture of aerosols.

5.4 Mixed aerosol types

5.4.1 Mid-Atlantic North America

The seasonal average aerosol SSA obtained over the Mexico City is shown in figure 9a. Unlike typical urban aerosol absorption, the SSA curve obtained here shows steep decrease from 388 nm to 466 nm and remains flat or slightly decreases till the 646 nm. Seasonality in aerosol absorption is observed at UV wavelengths (< 400 nm) with maximum (DJF, SON) and minimum (MAM) absorption of 0.86 and 0.91 at 354 nm. It is clearly evident that such absorption curve and seasonal variation is a result of prevailing mixture of aerosols. Seasonal average $\alpha_{440-870}$ indicates the prevalence of fine mode particles over the Mexico City. The average SSA at 466 nm for DJF, MAM and SON months are 0.85, 0.86 and 0.84 respectively. Although the seasonal average UV-Vis AAE of aerosols over Mexico City ranges from 0.94-1.27, the AAE_{354_388} is higher for (5.13) MAM than compared to (2.2) DJF and (0.6) SON months. In general, Mexico City is a densely populated urban location that is well known for its high pollution levels among the other megacities worldwide. In addition to the high concentration of aerosols from fossil fuel combustion throughout the year, Mexico City also experiences biomass burning aerosols during the relatively dry months of March-May from local sources (Eck et al., 1998).

5.4.2 North-Eastern Asia

The AERONET sites located in the Northeastern Asia include: Beijing, Osaka, Shirahama and XiangHe. Figure 9b shows the regional average SSA derived over Northeastern China. For the samples obtained, dust aerosols possibly mixed with regional pollution are observed over Beijing and XiangHe during spring (MAM). The spectral curve of regional average SSA shows an increase from 0.87 at 340 nm to 0.95 at 646 nm. The UV-Vis AAE obtained for the dust aerosols is 1.56. Among sites considered here, carbonaceous aerosols are observed throughout the year at Beijing and XiangHe. The spectral behavior of carbonaceous aerosols shows increase in SSA from 340 nm to 466 nm and thereafter remains near constant or slightly decreases with an UV-Vis dependence ranging from 1.84 to 2.14. However, significant seasonality is noted with minimum (0.95 at 466 nm) and maximum (0.90 at 466 nm) absorption during JJA and DJF respectively. The increase in SSA likely caused the humidification and secondary aerosol processes during JJA. Carbonaceous and urban aerosols over the region show high absorption in winter (DJF), likely due to high amounts of local fossil fuel combustion and agricultural waste burning. The spectral behavior of urban aerosols is similar to carbonaceous aerosols with decrease in magnitude of average SSA, AOD, and UV-Vis AAE. As expected from the local sources, mixture of aerosols categorized by particle sizes ($0.2 < \alpha_{440-870} < 1.2$) is observed at all sites in the region with widely varying spectral dependence.

5.4.3 Northern India

The AERONET sites located in Northern India include Jaipur, Gandhi College and Kanpur. Major source of aerosols over the region includes industrial and vehicular emissions, combustion of biomass and fossil fuels. In addition, desert dust passage from arid and semiarid regions of northwestern India, Pakistan, and Arabian Peninsula is commonly observed during spring and summer months. Figure 9c shows the regional average aerosol absorption observed at Kanpur. As expected from the source regions, dust aerosols are observed during spring (MAM) and summer (JJA) months over Jaipur and Kanpur. The average SSA shows a steep increase from 340 nm (0.88) to 466 nm (0.95), and a relatively smaller increase from 466 nm to 646 nm (0.97). The dust aerosols noted here has average τ_{440} 0.73 to 0.77 and exhibit UV-Vis AAE between from 2.9 to 3.4. For our sample, carbonaceous aerosols are observed over Kanpur and Gandhi College with similar regional average absorption during SON and DJF. The spectral behavior of carbonaceous aerosols shows increase in average SSA from 340 nm (0.91) to 466 nm (0.93) and slight decrease till 646 nm (0.91). The regional average UV-Vis AAE for carbonaceous aerosols range 1.2 to 1.5. Emissions from crop residue burning during SON and biomass

~~burning for residential heating in DJF prevail over the entire Indo-Gangetic plain and likely result in such absorption. In addition the vehicular and industrial emissions add an extra burden of aerosols to the atmosphere. In other words, urban aerosols over the Northern India can be categorized as carbonaceous aerosols resulting from various carbon emitting, both black and organic carbon, sources such as crop residue burning, local biomass burning for house-hold heating purposes in DJF months, vehicular and industrial emissions. These urban aerosols are relatively more absorbing (ω_o(466) ~0.89) than the carbonaceous aerosols (ω_o(466) ~0.93) from industrial/vehicular activities observed over Northern India. Throughout the seasons, influence of pollution aerosols is clearly evident in the observed urban aerosol absorption. Although the UV-Vis AAE is found to be in the similar range, the AAE_{354_388} values are low for urban than carbonaceous aerosols indicative of high organic amounts in crop residue/biomass burning emissions. For the group of aerosols in between the fine and coarse mode the spectral variation of SSA varies widely.~~

6 Spectral Aerosol Absorption in Major Aerosol Environments

In this section, we describe regional average aerosol absorption and AAE derived from our subset of results over worldwide regions dominated by carbonaceous, dust, and urban aerosols. The AERONET sites selected for this analysis are based on the dominant samples observed here and well-known aerosol sources from the literature.

The average of aerosol SSA and AAE derived for all sites considered in this work are presented in Table S1 as supplementary materials. In addition, the corresponding particle size distributions used for developing the LUT radiances for these sites are presented in supplementary materials as well.

6.1 Biomass Burning

Emissions from biomass burning are one of the major contributors of carbonaceous aerosols found in the atmosphere. These carbonaceous aerosols are primarily composed of black carbon and organic carbon components in addition to minor fractions of inorganic components (Andreae and Merlet, 2001). Studies show that black carbon amounts in the atmosphere are high absorbers of solar radiation and have near unity AAE due to invariant imaginary part of refractive index in the UV-Visible spectrum (Bergstrom, 1973; Bohren and Huffman, 1983; Bergstrom et al., 2002). The typical spectral behavior for carbonaceous aerosols has decreasing SSA with increasing wavelength in the visible spectrum (Eck et al., 1998; Reid and Hobbs, 1998). Additionally,

the presence of organic carbon amounts shows enhanced absorption in the UV region (Kirchstetter et al., 2004). Our observations for the carbonaceous aerosols from worldwide biomass burning regions depict these characteristics very well. The seasonal average of spectral SSA for carbonaceous aerosols found over major aerosol environments are shown in Figure 11.

For the Missoula site located in Northwestern United States (US), carbonaceous aerosols are observed during JJA. Aerosols observed over Missoula are primarily emitted from natural forest fires of the northwestern US in the dry season (JJA). The spectral SSA of these aerosols is noted to increase from 340 nm (0.89±0.02) to 466 nm (0.94±0.03) followed by a decrease toward the 646 nm (0.90±0.06). Average τ_{440} and $\alpha_{440-870}$ are about 1.2 and 1.8 respectively, while the average $AAE_{340-646}$ is noted as 1.8. Our results are consistent with the insitu measurements of wildfire smoke at the Missoula ground station for 2017 and 2018 summer, that reports an average SSA of 0.93-0.94 at 401 nm and AAE 1.7-1.9 over the spectral range 401-870 nm (Selimovic et al., 2020).

Over South America, our subset of carbonaceous aerosols is observed for sites at the Alta Floresta, Cuiaba, Ji Parana, and Santa Cruz. In general, carbonaceous aerosols over South America are dominantly emitted from biomass burning during southern hemisphere spring (JJA) and summer (SON), with distinct peaks in August and September. Most aerosol emissions are associated with biomass burning for land and agricultural management practices. The regional average SSA of these aerosols at 466 nm is noted to be 0.92±0.03 (0.93±0.02) during JJA (SON) months. Spectral SSA increases from 340 nm (0.90±0.02) to 388 nm (0.93±0.03) followed by a decrease toward the visible wavelengths. Average τ_{440} and $\alpha_{440-870}$ are about 1 and 1.8 respectively with mean $AAE_{340-646}$ ranging between 1.5-1.8 for both JJA and SON months. Among the sites considered here, Cuiaba located in the cerrado ecosystem exhibit highest aerosol absorption (ω_o ~0.89±0.03 at 466 nm), while the remaining sites are surrounded by tropical rainforest exhibit relatively less absorption (ω_o ~0.93±0.03 at 466 nm). Burning of cerrado (wooded savanna) and rainforest dominantly happens through flaming and smoldering phase combustion respectively, resulting in the noted variation of aerosol absorption over these sites (Schafer et al., 2008).

Over Southern Africa, our subset of carbonaceous aerosols is observed for sites at the Mongu, and Skukuza. Emissions from biomass burning primarily for agricultural and land management practices are major source of aerosols over Southern Africa (Eck et al., 2001, 2003). In addition, crop residue burning, heavy industrial facilities and episodic dust commonly dictate the aerosol amounts over Southern Africa. Fine mode carbonaceous

aerosols noted over these sites shows high average absorption during JJA period. The average SSA for these aerosols increases from 340 nm to 466 nm and then decreases at longer wavelengths. Distinct seasonality in absorption for carbonaceous particles is observed with maximum (minimum) value of 0.87 ± 0.02 (0.90 ± 0.03) at 466 nm for JJA (SON) months. The range of regional average values of τ_{440} and $\alpha_{440-870}$ for these aerosols are about 0.76 to 1.02 and 1.76 to 1.84 ranges, respectively. Average $AAE_{340-646}$ of these carbonaceous aerosols is noted to be ~1.73 and 1.58 for JJA and SON months.

For the sample obtained over Sahel region, carbonaceous aerosols are observed at Ilorin during DJF. Fine mode aerosols observed over Ilorin are primarily emitted from the biomass burning of the grasslands and savanna in Sahelian and Sudanian zones during the dry season (November through March). Our results show these aerosols exhibit significant absorption with the average SSA ~0.86 ± 0.02 and 0.87 ± 0.03 at 340 nm and 646 nm, respectively. Average τ_{440} and $\alpha_{440-870}$ are about 1 and 1.3 respectively with mean $AAE_{340-646}$ 1.38 for DJF period. The high aerosol absorption noted here is consistent with the AERONET data analysis that reports high aerosol absorption with increasing fine-mode fraction (FMF) of particles (SSA ~0.80-0.87 and 0.81-0.85 at 440 nm and 675 nm for observations with FMF of 0.75-0.54 at 675 nm) over Ilorin during the dry season (Eck et al., 2010). Spectrally the SSA is noted to be nearly invariant, suggesting high fractions of black carbon amounts in the aerosols over Ilorin during DJF. Emissions from burning of grasslands and savanna in the Sahelian and Sudanian zones dominantly happens through flaming phase combustion producing high amounts of soot (Eck et al., 2010). In addition to the biomass burning, fossil fuel combustion, and vehicular emissions, the vast number of gas flaring stations (> 300) around the Niger Delta produces high emissions (Onyeuwaoma et al., 2015). Highly absorbing black carbon amounts observed at Ilorin is likely a result of such emissions.

For the Cairo site in the Middle East, carbonaceous aerosols are noted in our sample. Cairo in the Middle East is one of the highly polluted places among the megacities worldwide. Carbonaceous aerosols over Cairo are primarily emitted from burning of the agricultural waste in the Nile delta during the burning season from September through December (El-Metwally et al., 2008). The average SSA for these aerosols ranges from 0.89 ± 0.03 to 0.91 ± 0.05 exhibiting weak spectral dependence from 340 nm to 646 nm. Average τ_{440} and $\alpha_{440-870}$ are about 0.6 and 1.4 respectively with $AAE_{340-646}$ about 1.9 during DJF. The spectral dependence noted for these aerosols likely indicate mixture of black and organic carbon amounts.

Over Northeastern China, carbonaceous aerosols are observed throughout the year at the sites Beijing and XiangHe. The spectral behavior of carbonaceous aerosols at these sites shows increase in SSA from 340 nm to 466 nm and thereafter remains near constant or slightly decreases with an UV-Vis dependence ranging from 1.84 to 2.14. However, significant seasonality is noted with minimum (0.95 ± 0.03 at 466 nm) and maximum (0.90 ± 0.04 at 466 nm) absorption during JJA and DJF, respectively. The increase in SSA is likely result of humidification and secondary aerosol processes during JJA. The high aerosol absorption noted during winter (DJF) is likely contributed from high amounts of local fossil fuel combustion and agricultural waste burning.

For the sample obtained over Northern India, carbonaceous aerosols are observed over Kanpur and Gandhi College during SON and DJF. Emissions from crop residue burning during SON and biomass burning for residential heating in DJF prevail over the entire Indo-Gangetic plain and likely result in such absorption. In addition, industrial activities and vehicular emissions are observed throughout the seasons. The spectral behavior of these aerosols shows increase in average SSA from 340 nm (0.91 ± 0.02) to 466 nm (0.93 ± 0.03) and slight decrease till 646 nm (0.91 ± 0.04). The regional average $AAE_{340-646}$ for carbonaceous aerosols ranges 1.2 to 1.5. The weak spectral dependence of SSA noted here is consistent with AERONET SSA analysis. For the aerosols observed over the Kanpur site, spectral dependence of aerosols becomes nearly invariant (SSA ~0.89 at 440 and 675 nm) for high fine mode fraction (FMF ~0.85) of aerosols (Eck et al., 2010).

Over Northern Australia, carbonaceous aerosols are observed at the sites Jabiru and Lake_Argyle during SON. In general, Northern and Western parts of the Australia are covered with savanna grasslands, woodlands, and forests, where biomass burning due to natural fires and land management practices are known to produce high aerosol emissions during the dry season (Scott et al., 1992; Mitchell et al., 2013). Our results indicate the average SSA for carbonaceous aerosols over Northern Australia increases with wavelength from 0.87 ± 0.02 (340 nm) to 0.89 ± 0.03 (388 nm) and then decreases to 0.87 ± 0.06 (646 nm). Average τ_{440} and $\alpha_{440-870}$ for these aerosols is 0.65 and 1.62, respectively, while the UV-Vis spectral dependence ($AAE_{340-646}$) is noted to be ~1.42. Such behavior of fine-mode particles is likely a result of a mixture of black carbon and organic carbon amounts in the atmosphere, producing stronger (weaker) absorption in the UV (Vis) wavelengths.

6.2 Dust

For dust aerosols, minerals such as hematite and other form of oxides play role in scattering/absorption of particles. The absorbing nature of pure dust aerosols close to the source is sensitive to the presence of hematite

than other minerals at shorter wavelengths (Sokolik and Toon, 1999). In addition to the sedimentation of coarse aggregates, the dust aerosols observed away from the source are sometimes found to have mixed (internally or externally) with anthropogenic aerosols altering its absorbing nature. Studies show that the typical spectral behavior of dust absorption decreases with increasing wavelength primarily due to attributed to the larger size of the particles (Sokolik and Toon, 1996, 1999). However, the absorption of dust from different sources is known to vary depending on the mineral composition of the soil origin (Di Biagio et al., 2019). The seasonal average of spectral SSA for coarse-mode dust aerosols found over major aerosol environments are shown in Figure 12.

For the dust aerosols sample obtained at Saharan region at the sites Tamanrasset and Saada, the average SSA is ~0.94 at 466 nm. The average SSA for these dust aerosols increase with wavelength from about 0.86±0.03 at 340 nm to 0.97±0.02 at 646 nm. The seasonal average $AAE_{340-646}$ for dust aerosols derived at these sites range from 2.8 to 3.3 with no distinct seasonality in the average spectral SSA. Dust aerosols over the Middle East are observed for the sites Cairo, Solar Village and SEDE BOKER with an average SSA ~0.95±0.02 at 466 nm. From UV (340 nm) to visible (646 nm), the regional average SSA for dust over the Middle East sites ranges from 0.89±0.03 to 0.98±0.02, while the $AAE_{340-646}$ ranges from 2.7 to 3.8. No distinct seasonality in SSA is found from our sample for the dust aerosols over Middle East. However, a slight increase in SSA at UV wavelengths is noted during winter (DJF). Examining individual sites reveal this feature corresponds to the aerosols over Solar_Village (Table S1). The increase in SSA and high $AAE_{354-388}$ noted for Solar_Village during DJF likely indicates transport of aerosols from neighbouring regions.

Over Sahel, dust aerosols are observed for several sites that include Agoufou, Banizoumbou, Dakar, IER_Cinzana, Ilorin, Ouagauodu, and Zinder_Airport. Located in the middle of Sahelian region through the west Africa, these sites are influenced by both dust and biomass burning emissions (Basart et al., 2009). It should be noted that for the identifying dust in this work, we use $\alpha_{440-870} \leq 0.2$ derived from AERONET. The regional average spectral SSA for dust aerosols derived here resembles typical dust absorption curve (increase in SSA with wavelength, ~0.87-0.91±0.03 at 340 nm to 0.95-0.97±0.02 at 646 nm) with absorption ranging ~0.93-0.94±0.02 at 466 nm. No distinct seasonality in absorption of dust aerosols is noted over Sahel. Average $AAE_{340-646}$ for dust over Sahel ranges 2.0-2.3 for all seasons with an exception during SON where $AAE_{340-646}$ is noted to be relatively less 1.57.

Over Northern India, dust aerosols are observed during spring (MAM) and summer (JJA) months for the sites at Jaipur and Kanpur, where the former site is in proximity to the Thar desert and the later site is influenced by the dust transport. The average SSA shows a steep increase from 340 nm (0.88±0.02) to 466 nm (0.95±0.03), and a relatively smaller increase from 466 nm to 646 nm (0.97±0.02). The dust aerosols noted here has average τ_{440} 0.73 to 0.77 and exhibit $AAE_{340-646}$ between 2.9 to 3.4. Compared to AERONET the absorption for dust aerosols derived here agrees well. Eck et al (2010) reports the coarse mode particles noted over Kanpur during pre-monsoon (MAM) months exhibit climatological average SSA ~0.89 and 0.95 at 440 and 675 nm, respectively.

For the samples obtained over northeastern China, dust aerosols are observed over Beijing and XiangHe during spring (MAM). The spectral curve of regional average SSA shows an increase from 0.87±0.03 at 340 nm to 0.95±0.03 at 646 nm. The average $AAE_{340-646}$ obtained for the dust aerosols at these sites is 1.56. Among the regional dust observations presented here (Figure 12), northeastern China exhibit high absorption in visible wavelengths (ω_o ~0.93±0.03 and 0.95±0.03 at 466 and 646 nm) and low $AAE_{340-646}$. It is likely that these coarse particles are influenced by black carbon components over such highly polluted environments and exhibit anomalously low AAE than dust particles noted for other regions. However, due to large particle size ($\alpha_{440-870}$ ~0.09) the spectral SSA noted still shows increasing SSA with wavelength. Chaudhry et al., (2007) reported insitu measurements of coarse mode particles over XiangHe during March-2005 that exhibits high absorption in visible wavelengths (ω_o ~0.70-0.94 at 450, 550 and 700 nm). Li et al., (2007) explained the variation in SSA for coarse particles during March-2005 over XiangHe is a result of synoptic fluctuation – passage of cold fronts that uplifted ground-level pollution to higher altitudes influencing the aerosol absorption. Similar low $AAE_{340-646}$ values for coarse mode ($\alpha_{440-870} \leq 0.2$, dust) are noted for few sites over the Sahelian region during DJF (burning season). It is likely that these coarse particles are influenced by black carbon amounts emitted from biomass burning.

6.3 Urban aerosols

Urban aerosols dominantly constitute sulfates and other forms of nitrate particles. Additionally, industrial emissions and fossil fuel combustion produces various forms of carbon that contribute to the overall optical properties of urban aerosols. Further the aerosol size growth due to increase in relative humidity in the atmosphere and coagulation processes are known to alter the absorbing nature of aerosols. The typical spectral SSA of urban aerosols decreases with increase in wavelength from UV-Vis spectrum (Bergstrom, 1972). The

946 seasonal average of spectral SSA for carbonaceous aerosols found over major aerosol environments are shown in

947 Figure 13.

948

949 Aerosols observed over the Central United States (US) at the sites Sioux Falls and Bondville are primarily

950 produced from industrial activities and vehicle emissions. The average aerosol SSA for these urban aerosols

951 shows increase (0.93-0.95±0.03) in the wavelength range 340-388 nm followed by a decrease (0.89±0.06 at 646

952 nm) towards the visible wavelengths. Average τ_{440} and $\alpha_{440-870}$ are about 0.48 and 1.7 respectively, while the

953 average $AAE_{340-646}$ noted as 1.1. Urban aerosols over the Mid-East US are noted for the sites at GSFC,

954 MD_Science_Center, and SERC. The average aerosol SSA noted for these sites increases from (0.93±0.02) 340

955 nm to (0.95±0.03) 388 nm and then decreases attaining a maximum absorption (~0.87±0.06) at 646 nm. The

956 regional average SSA for the MAM and JJA months at 466 nm is 0.94±0.03 and 0.92±0.03, respectively.

957 Seasonally, the average SSA noted for JJA follows typical 'urban' absorption curve, while the spectral SSA

958 shows decrease in aerosol absorption in the visible wavelengths for MAM. Since there are no significant changes

959 in aerosol sources during MAM and JJA over Mid-East US, the seasonal variation in SSA noted for visible

960 wavelengths are likely stemming from weak absorption signal insufficient for a robust retrieval. Recall, for

961 weakly absorbing aerosols the error in SSA retrievals at visible wavelengths are high due to identified factors

962 from our analysis such as cloud contamination, surface reflectance, particle size, etc.

963

964 For the site at the Mexico City, Central America urban aerosols are noted in our sample. In general, Mexico City

965 is a densely populated urban location that is well known for its high pollution levels among the other megacities

966 worldwide. In addition to the high concentration of aerosols from fossil fuel combustion throughout the year,

967 Mexico City also experiences biomass-burning aerosols during the relatively dry months of March-May from

968 local sources. The seasonal average aerosol SSA over Mexico City shows decrease in absorption (0.90±0.03 and

969 0.91±0.05 at 340 and 388 nm) and increases towards the visible wavelengths during MAM. However, the spectral

970 SSA noted for DJF (0.88±0.04 and 0.87±0.05 at 340 and 388 nm) and SON (0.88±0.04 and 0.85±0.05 at 340 and

971 388 nm) deviates from known pattern and exhibit high absorption in the UV spectral range with nearly constant

972 or slight increase in the visible spectral range. The average SSA at 466 nm for DJF, MAM and SON months are

973 0.85±0.06, 0.86±0.06 and 0.84±0.06, respectively with average $\alpha_{440-870}$ about 1.7 throughout the seasons.

974 Although the seasonal average $AAE_{340-646}$ of aerosols over Mexico City ranges from 0.94-1.27, the $AAE_{354-388}$ is

975 higher for (5.13) MAM than compared to (2.2) DJF and (0.6) SON months. It is likely that our aerosol samples

976 obtained during MAM are influenced by biomass burning emissions from local neighbour sources exhibiting high

AAE$_{354-388}$ values suggesting the absorption is driven by organic components (Barnard et al., 2008). While for the samples noted during SON and DJF the aerosol absorption is primarily driven by the black carbon components emitted from the heavy industrial and vehicular fleet over the region.

Our subset of samples noted urban aerosols at the site Sao Paulo, South America. Sao Paulo is the largest South American megacity with population exceeding 21 million inhabitants. Heavy industrial and vehicular emissions are the dominant source of aerosols observed over Sao Paulo. In addition, aerosols from northern parts of the Amazon Basin advecting south or southeast over Sao Paulo is not uncommon during the peak burning season (August through September). Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.57 and 1.5, respectively during JJA and SON months. Spectral SSA noted here resembles typical urban absorption curve during SON. However, during JJA spectral SSA shows steep decrease from 340 nm to 388 nm (0.87±0.03 to 0.85±0.03) and remains nearly invariant towards the visible spectral range from 466 to 646 nm (0.85±0.05 to 0.84±0.07). The average SSA noted at 466 nm is 0.88±0.06 (0.92±0.06) for JJA (SON) months. It is noted that the urban aerosols at Sao Paulo are more absorbing during JJA than in SON.

For the urban aerosols observed over Cairo and Nes Ziona in the Middle East, the average SSA is noted to be 0.89±0.03 at both 340 nm and 646 nm. While urban aerosols and pollution prevail over Nes Ziona, emissions from crop residue burning (rice straws) over the Nile delta region during winter (DJF) and heavy pollution dictate the aerosol absorption noted over Cairo. Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.60 and 1.3, respectively throughout the seasons, with mean AAE$_{340-646}$ ranging between 1.5-2.0. Unlike typical urban aerosol absorption curve, the spectral SSA noted for these aerosols do not exhibit steep decrease from 388 to 646 nm indicating mixture of black carbon and organic carbon amounts.

Over Europe, dominantly urban aerosols are observed at the sites Avignon, Carpentras, Ispra, IMS-METU-ERI, Lille, Lecce_University, Minsk, Modena, Moldova, Moscow_MSU, Palaiseau, Rome, and Thessaloniki. Primarily industrial activities, vehicular emissions are dominant sources of aerosols over Europe. In addition, fuel combustion for residential heating during winter and outbreak of episodic dust aerosols during spring-summer over Iberian Peninsula and Mediterranean basin are known to influence the aerosol loading (Basart et al., 2009; Mallet et al., 2013). The regional average SSA increases from 340 nm (0.91±0.02) to 388 nm (0.93±0.03) and then decreases reaching a minimum value (0.87±0.07) at 646 nm for most seasons. The observed aerosol absorption is similar for spring (MAM) and summer (JJA). However, there is an increase in absorption at

wavelengths other than 646 nm for fall (SON) that reaches a maximum absorption 0.86±0.03 and 0.90±0.04 at 340 nm and 466 nm, respectively. These highly observing aerosols in our sample are noted over polluted urban sites at Ispra, Modena, and Rome indicating the mixture of organic and black carbon amounts. Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.50 and 1.5, respectively throughout the seasons, with mean $AAE_{340-646}$ ranging between 1.0-1.3.

Over Northeastern China urban aerosols are noted for the sites Beijing, and XiangHe. Significant seasonality in aerosol SSA is noted with minimum (0.93±0.04 at 466 nm) and maximum (0.88±0.05 at 466 nm) absorption during JJA and DJF, respectively. Seasonal variability in aerosol absorption noted here is likely caused by the humidification and secondary aerosol processes. In addition to the high industrial and vehicular emissions throughout the year, fuel combustion for residential heating purposes and agricultural waste burning during DJF adds additional aerosol burden over the Northeastern China. High aerosol absorption noted during DJF is likely a result of such emissions. Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.65 and 1.4, respectively throughout the seasons, with mean $AAE_{340-646}$ ranging between 1.2-1.7. For the urban aerosols noted at the sites Shirahama, and Osaka in Japan during MAM, the spectral aerosol SSA noted follows typical urban absorption curve with slight increase in SSA from (0.90±0.02) 340 nm to (0.92±0.02) 388 nm and then a steep decrease towards (0.87±0.07) 646 nm. Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.5 and 1.5, respectively with mean $AAE_{340-646}$ about 1.2.

Over Northern India urban aerosols are noted for the sites at Jaipur, Kanpur, and Gandhi College. Major source of aerosols over the region includes industrial and vehicular emissions, combustion of biomass and fossil fuels. The average aerosol SSA increases from (0.88±0.02) 340 nm to (0.90±0.04) 466 nm and decreases towards 646 nm (0.87±0.07) 646 nm. These aerosols are noted to exhibit relatively high absorption ω_o ~0.89±0.04 at 466 nm. Average τ_{440} and $\alpha_{440-870}$ noted for these aerosols are ~0.60 and 1.4, respectively throughout the seasons, with mean $AAE_{340-646}$ about 1.3. Throughout the seasons, influence of pollution aerosols is clearly evident in the observed aerosol absorption.

6 7 Discussion

Through extensive studies in the literature, it is known that optical properties of biomass burning aerosols depend on fuel/vegetation type, combustion processes, available moisture content (e.g., Ward, 1992; Reid and Hobbs,

1998; Reid et al., 1998; Eck et al., 2001). Such studies reported varying properties of aerosols emitted from two phases of vegetation burning: flaming and smoldering. While flaming phase rapidly oxidizes the available volatile hydrocarbons in the biomass, smoldering phase mostly requires a surface where slow diffuse oxygen converts the biomass through exothermic reaction. In general, burning of grasslands happens dominantly through flaming phase combustion process that emits high amounts of sootblack carbon, while smoldering combustion prevail the burning of woodlands/deciduous forest that emits less sootblack carbon and more organic carbon. The observed aerosol absorption at the biomass burning sites (figure Figure 611) clearly makes this distinction. Over South America, in addition to the emissions from burning rainforest (near–by Alta Floresta and Ji Parana), Cerrado (wooded grasslands) type vegetation dominates at most sites considered here (Schafer et al., 2008). Biomass burning of tropical forests occur through smoldering combustion exhibiting aerosol ω_o (0.93±0.03 at 466 nm). Such biomass burning occurs through smoldering combustion exhibiting relatively high aerosol ω_o (0.93 at 466 nm). Compared to South America, the aerosols over Southern Africa have distinct seasonality and high absorption (ω_o ~0.88±0.02 at 466 nmfigure 6b). Eck et al (2013) demonstrated that this seasonality in aerosol absorption is likely a result of shift in fuel type and combustion process. At the beginning of dry season (starting June), the central region is prone to undergo a rapid burning through flaming process, while in the late dry season (ends November) the wooded lands located southeastern parts begins to burn through dominantly smoldering processphase. For the savanna with open grasslands in the northern Australia, biomass burning happens dominantly through flaming phase combustion producing high amounts of soot, as also noted in our retrievals. Figure 140 shows the regional averagerange of AAE obtained for carbonaceous aerosols at three wavelength pairs. Overall, the average slope of absorption in visible (AAE_{466_646}) and UV-Vis (AAE_{340_646}) for carbonaceous aerosols is found to be within 2. This is consistent with the studies that report AAE of biomass burning aerosols from several field campaigns in the range 1 to 3 (Kirchstetter et al., 2004; Schnaiter et al., 2005; Bergstrom et al., 2007; Clarke et al., 2007). However, the average AAE_{354_388} obtained is high up to 4 for most regions. This is likely a result of higher organic matter in the regional biomass types and highlights the importance of UV spectral region in delineating such group of aerosols. Studies show that spectral dependence of aerosol absorption in the UV-visible range can be high up to 6 for aerosols with organic compounds (Kirchstetter et al., 2004; Bergstrom et al., 2007 and references therein). Among the biomass burning regions, for the emissions where contribution of flaming phase combustion is high, the mean $AAE_{354-388}$ noted is relatively low– Northern Australia (2.1) and Sahel (1.6). For the savanna grasslands in Australia where flaming combustion prevails the mean AAE_{354_388} is relatively low (2.2 or less) compared to other biomass burning regions. Further, it is noted that carbonaceous aerosols observed over Northern India, Northeastern China, Sahel, and the Middle

East For the sample obtained at Ilorin in Sahel and Cairo in the Arabian Peninsula, the mean AAE was found up to 2 for all wavelength pairs. Further, it is noted that carbonaceous aerosols observed over Northern India, Northeastern China, Sahel, and Arabian Peninsula has an average $\alpha_{440-870}$ ~1.4 (i.e, at the lower end of the fine-mode range), while in South America, South Africa and Australia has average ~1.8. This indicates the role of aerosol mixing and secondary processes in emanating the observed variability in aerosol absorption other than its composition alone.

Figure 15 shows the range of AAE obtained for dust aerosols at three wavelength pairs. Regional average of the UV-Vis spectral dependence ($AAE_{340-646}$) is found to be close to or greater than 3 for all regions, except for the Sahel and Northeastern China, where average value ranges 1.5 to 2.5. Although no distinct seasonal variation in spectral absorption of dust is noted, the variability in spectral dependence over the regions is quite evident. The regional average of SSA for dust aerosols from 340 nm to 646 nm are 0.87±0.02 to 0.98±0.02, 0.89±0.03 to 0.96±0.02, 0.89±0.02 to 0.98±0.01, 0.87±0.02 to 0.97±0.02, and 0.87±0.03 to 0.95±0.03 over Sahara, Sahel, Middle East, Northern India, Northeastern China, respectively. While the average SSA ranges 0.87-0.89±0.03 at 340 nm, differences in retrieved SSA are evident with increasing wavelength. The regional average spectral SSA noted at 466 nm are 0.94±0.02, 0.93±0.02, 0.96±0.02, 0.95±0.02 and 0.93±0.02 for Sahara, Sahel, MiddleEast, Northern India, and Northeastern China, respectively. A recent study uses soil samples collected from over different arid regions worldwide to characterize the mineral composition of dust and estimate the spectral SSA using the measured scattering absorption coefficients through aethalometer operating at seven discrete wavelengths from 370–950 nm (Di Biagio et al., 2019). Their study reports high absorption (~ 0.70-0.75 at 370 nm) for dust samples obtained over Niger, Mali, Southern Namibia, and Australia due to the presence of higher amounts of iron oxides. While for the samples collected over Bodélé, Northern Namibia, Arizona the estimated absorption (~ 0.91-0.96 at 370 nm) and amounts of iron oxides are relatively low. In comparison, our retrievals indicate the dust aerosols noted at Sahel and northeastern China are highly absorbing, while those noted over MiddleEast, and Northern India are less absorbing and dust over Sahara shows intermediate absorption. These results can be explained by combination of varying mineral composition (iron oxide amounts) and mixing of dust with other sources along the transport pathway. However, the magnitude of SSA and AAE reported by Di Biagio et al., (2019) are lower than those retrieved here for all regions. The reason for the differences noted in SSA is unknown and needs further investigation. In contrary, our retrieved SSA for coarse mode particles agrees well with AERONET SSA (59% and 87% observations within ±0.05 envelope at 466 nm and 646 nm respectively). For dust aerosols, minerals such as hematite and other form of oxides play role in scattering/absorption of

1099 ~~particles. The absorbing nature of pure dust aerosols close to the source is sensitive to the presence of hematite~~
1100 ~~than other minerals at shorter wavelengths (Sokolik and Toon, 1999). In addition to the sedimentation of coarse~~
1101 ~~aggregates, the dust aerosols observed away from the source are often found to have mixed (internally or~~
1102 ~~externally) with anthropogenic aerosols altering its absorbing nature. For example, ω_o of dust aerosols were~~
1103 ~~reported as 0.83 to 0.87 near the source and ~0.9 far away from the source over the tropical North Atlantic Ocean~~
1104 ~~using satellite measurements at 331 nm (Torres et al., 2002). For the dust aerosol samples obtained in this work,~~
1105 ~~high absorption at 340 nm with a regional average of ~0.86 is noted for Sahara, while relatively lower absorption~~
1106 ~~~0.90 is noted for the Sahel region. The mixing of dust with biomass burning emissions and local pollutants over~~
1107 ~~the Sahel likely attributed to the observed low absorption. Similar low absorption (0.90) of dust at 340 nm is~~
1108 ~~observed for the Arabian Peninsula region. However, the UV-Vis spectral dependence noted at the Sahel, and~~
1109 ~~Arabian Peninsula varies significantly. Figure 11 shows the regional average AAE obtained for dust aerosols at~~
1110 ~~three wavelength pairs. Among the dust prone regions considered here, the regional average of the UV-Vis~~
1111 ~~spectral dependence (AAE_{340_646}) is found to be close to or greater than 3 for all, except the Sahel and Eastern~~
1112 ~~China, where average value ranges 1.5 to 2.5. Although no distinct seasonal variation in spectral absorption of~~
1113 ~~dust is noted, the variability in spectral dependence over the regions is quite evident.~~ Overall the regional average
1114 of AAE for dust aerosols observed here is consistent with insitu measurements that report values ranging ~~1.5~~ 2.0
1115 to 3.5 (Bergstrom et al., 2004, 2007; Müller et al., 2009; Petzold et al., 2009). However, observations at
1116 individual sites (Table 3) show that the spectral dependence of the observed dust for few sites is relatively high
1117 than those reported by insitu measurements. Considering our retrieval method where aerosol absorption is
1118 derived independently for each wavelength and have computed the dependence, our results agree reasonably well
1119 with the insitu measurements reported in the literature.

1120

1121 Figure 16 shows the regional average AAE obtained for urban aerosols at three-wavelength pairs. Urban aerosols
1122 in highly polluted environments such as over the Mexico City have near unity spectral dependence. While the
1123 passage of biomass burning emissions over such environment show unusual decrease in absorption at the UV
1124 region attributing to high $AAE_{354-388}$. ~~While urban aerosols constitute dominantly sulfates and other forms of~~
1125 ~~nitrate particles, industrial emissions and fossil fuel combustion produces various forms of carbon that contribute~~
1126 ~~to the overall optical properties. Further the aerosol size growth due to increase in relative humidity in the~~
1127 ~~atmosphere and coagulation processes are known to alter the absorbing nature of aerosols. Figure 12 shows the~~
1128 ~~regional average AAE obtained for urban aerosols at three-wavelength pairs.~~ Urban aerosols in highly polluted
1129 environments such as over the Mexico City have near unity spectral dependence. While the passage of biomass

burning emissions over such environment show unusual decrease in absorption at the UV region attributing to high AAE_{354_388}. This is consistent with studies that report relatively high AAE in UV region and near unity in visible region for the aerosol mixture consisting of organic matter and black carbon amounts (Barnard et al., 2008; Vanderlei Martins et al., 2009; Bergstrom et al., 2010; Jethva and Torres, 2011). The urban aerosols found in our sample over Northern Indian and ~~Eastern~~ Northeastern China are highly absorbing exhibiting AAE_{340_646} ~1.5 than the carbonaceous aerosols with AAE_{340_646} ~2. These results suggest the combination of magnitude of aerosol absorption and its spectral dependence in UV, visible and UV-Visible spectrum could be used to partition mixture of aerosol types found in such environments. ~~Overall~~Overall, the regional average UV-Visible AAE for the urban aerosols is found to be near 2.

5~~7~~ Comparison with AERONET SSA product

We compare of our aerosol SSA retrievals at the visible wavelengths with ~~that available~~those from the AERONET data set. The comparison ~~of SSA retrievals~~ is limited AERONET Level 2 reliable retrievals as determined the aerosol load at 440 nm (τ_{440} > 0.4)~~to τ_{440} > 0.4 and where AERONET Level-2 inversion is available~~. ~~It should be noted~~We emphasize here that since AERONET SSA is a derived quantity and cannot be considered as 'ground truth', this comparison serves as a consistency check rather than a strict validation exercise. The nearest AERONET wavelength available for comparison with OMI wavelength (388 nm) retrievals is at 440 nm. To facilitate the comparison, we use the AAE computed from our retrievals at 388-466 wavelength pair to transform the retrieved SSA at 388 nm to 440 nm (440_{OMI}). While at the MODIS wavelengths 466 and 646 nm, the AERONET SSA were computed by linear interpolation of the values reported at 440 and 675 nm. ~~For ease in comparison, we transform the AERONET SSA at 440 and 675 nm to MODIS wavelengths of 466 and 646 nm respectively following interpolation.~~ This conversion will unlikely introduce any notable bias in our comparison as the difference in the nearest wavelengths of both data sets is very low (< 30 nm).

First, we investigate the consistency of retrieved SSA for selected sites for which the prevailing aerosol types and local source environment are well known as documented in several studies in the literature. We use the AERONET SSA from time period 2005-2016 for the comparison. Figure ~~13~~ 8 shows the comparison of ~~average~~ spectral SSA (box plots showing lower and upper quartile of observations with white line representing its mean value) for three distinct aerosol types sampled from the selected sites. The mean AAE derived for the visible wavelength pair at 466-646 nm agrees within 0.5 or less with the AERONET values for all aerosol types and sites

considered. However, it should be noted that AAE is highly susceptible to small changes in the retrieved SSA for both data sets. ~~The vertical bars shown in the figure corresponds to the uncertainty estimate provided by AERONET (±0.03) and the estimate due to change in ±0.01 surface reflectance for our retrieved SSA (±0.05).~~ For dust aerosols, the retrieved average SSA show good agreement with AERONET SSA obtained at Dakar and Ouagadougou (within ±0.008), while the differences in SSA (retrieved minus AERONET) at Tamanrasset and Solar Village are +0.02 and +0.05, respectively at 466 nm. Although our sample is limited for few days that met our criteria for subset, the observed differences in SSA are within the overall uncertainty estimates ~~as also noted from the overlapping error bars~~presented in the previous section. For carbonaceous particles, the retrieved and AERONET SSA agree well with differences of less than 0.015 for Alta_Floresta, CUIABA and Mongu. However, notable difference in SSA (0.045) is observed at the Lake_Argyle with high absorption for AERONET than our retrieved value at both 466 nm and 646 nm. ~~It should be noted that, while AERONET version 3 employs surface reflectance following BRDF parameters from MODIS BRDF/Albedo CMG Gap Filled Snow Free Product MCD43GF (Sinyuk et al., 2020), we use MODIS MCD19A1 surface reflectance product. For absorbing aerosols, the SSA differences observed here is likely a result of different surface reflectances data employed by the two data sets.~~ For urban/industrial aerosols at GSFC, Avignon, Moldova and Cairo the retrieved SSA agrees within the uncertainty estimates. Particularly notable difference (–0.05) is found for Avignon at 646 nm. It should be noted that, while AERONET Version 3 employs surface reflectance using BRDF parameters from MODIS BRDF/Albedo CMG Gap-Filled Snow-Free Product MCD43GF (Sinyuk et al., 2020), we use MODIS MCD19A1 BRF/surface reflectance product. The use of different surface reflectances data in the two retrieval algorithms likely contributes to some of the observed SSA differences. As discussed in the sensitivity analysis, surface reflectance is the second higher source of errors in the retrieved SSA at visible wavelengths after cloud contamination. Additionally, for our retrievals as well as with AERONET, uncertainties in SSA increases with wavelength for fine mode particles (carbonaceous and urban) with high EAE, notably for weakly absorbing aerosols. For example, the ±0.03 uncertainty in AERONET SSA at 440 nm for τ_{440} ~0.4 is achieved for the NIR wavelength (1020 nm) at τ_{440} ~0.6 for the fine mode particles observed over the GSFC site (Sinyuk et al., 2020).

Figure ~~14~~ 9 shows the absolute difference in retrieved SSA ~~comparison of retrieved SSA~~ with AERONET as a function of τ_{440} for all collocated observations. For the SSA at 440 nm$_{OMI}$, the observations within ±0.03 (±0.05) envelopes are 38% (62%), 42% (66%) and 39% (66%) for dust, carbonaceous, and urban aerosol types, respectively. As expected, the SSA difference is highest for lower AOD's and decreases with increasing aerosol load for all aerosol types. For the SSA at 466 nm, the observations within ±0.03 (±0.05) envelopes are 25%

(59%), 38% (63%) and 34% (56%) for dust, carbonaceous, and urban aerosol types, respectively. In terms of particle sizes, the difference in SSA for fine-mode ($\alpha_{440\text{-}870} > 1.2$) are noted to be more scattered than the difference in SSA noted for coarse mode particles. For the SSA at 646 nm, the observations within ±0.03 (±0.05) envelopes are 73% (87%), 39% (60%) and 28% (45%) for dust, carbonaceous, and urban aerosol types, respectively. Spectrally, there is significantly more scatter at 646 nm with SSA differences in the range -0.3 to 0.2 for urban aerosols. The RMSE of the SSA ranges from 0.04 to 0.09 with lowest error for dust particles at 646 nm and highest error for urban aerosols at the same wavelength. This owes to the high spectral AODs for coarse mode particles through UV-Visible where sufficient absorption signal is available for the retrieval of SSA. While for fine mode particles with the decreasing spectral AODs from UV-Visible the absorption signal becomes weak, particularly notable for the less absorbing (urban) aerosols. ~~For the SSA at 466 nm, the observations within ±0.03 (±0.05) envelopes are 26% (59%), 38% (63%) and 34% (56%) for dust, carbonaceous, and urban aerosol types, respectively. It is observed that for dust aerosols, the observations are well concentrated in a narrow range of SSA (retrieved values range from 0.92 to 0.99 at 466 nm), while for carbonaceous (0.86 to 0.95 at 466nm) and urban types (0.84 to 0.98 at 466 nm) the observations become increasingly scattered through wide range of SSA. In terms of wavelength, the observations at 646 nm are more widely scattered than for the SSA at 466 nm for all aerosol types. For the SSA at 646 nm, the observations within ±0.03 (±0.05) envelopes are 73% (87%), 39% (60%) and 28% (45%) for dust, carbonaceous, and urban aerosol types, respectively. The root mean square error (RMSE) of the SSA ranges from 0.04 to 0.09 with lowest error for dust particles at 646 nm and highest error for urban aerosols at 646 nm. Among the aerosol types, it is noted that our retrieved SSA for dust at 466 nm has relatively high scattering than AERONET, while for other types the results are found to be consistent.~~

Figure 10a shows the absolute difference in retrieved and AERONET SSA as a function of optical depth by combining all aerosol types together. The differences in SSA for all wavelengths at 440_{OMI}, 466 and 646 nm are higher for lower τ and become negligible for higher τ. It is observed that at 440_{OMI} and 466 nm the observations with positive differences are relatively more than that at 646 nm. Comparison of the retrieved SSA with AERONET SSA for all aerosol types is shown in Figure 10b. Our retrieved SSA at 440_{OMI}, 466 and 646 nm agree within ±0.03 of AERONET SSA for 39% (0.05), 34% (0.06) and 34% (0.08) of observations (RMSE) respectively. ~~Figure 15a shows the comparison of retrieved SSA with AERONET by combining all aerosol types together. Our retrieved SSA at 466 and 646 nm agree with AERONET SSA for 34% (0.06) and 40% (0.07) of observations (RMSE) respectively. The absolute difference in retrieved and AERONET SSA as a function of optical depth is~~

shown in figure 15b. The differences in SSA for both wavelengths at 466 nm and 646 nm are higher for lower τ and become negligible for higher τ. It is observed that at 466 nm, the observations with positive differences are relatively more than that at 646 nm.

It is important to note here that our retrieval method and that used in the AERONET inversion differ fundamentally in several aspects. (i) different source of surface reflectance data used, (ii) instantaneous particle sizes derived from sky radiances measurements by AERONET and climatological average particle sizes used in our retrievals, (iii) the use multi-spectral sky radiance measurements by AERONET along the almucantar plane (multi-angular) and the single-view TOA radiance measurements by the satellites in our retrievals, and (iv) the use of weak constraint on spectral variation of imaginary refractive index for the fine mode particles in AERONET SSA retrievals, while our retrievals of SSA are carried for each wavelength independently. The use of weak constraint on spectral variation of imaginary refractive index for the fine mode particles with high $\alpha_{440-870}$ for AERONET inversion owes to the lower spectral AODs and diminished absorption signal strength at higher wavelengths insufficient for a robust absorption retrieval (Dubovik et al., 2006). The differences noted between our SSA retrievals and that from AERONET at different wavelengths could stem from one or more sources of the differences listed above. It is important to note here that our retrieval method and that used in the AERONET inversion differ fundamentally in several aspects. Other than the different source of surface reflectance data used, one major distinction between the two methods is that the present inversion algorithm retrieves SSA at different UV and Vis wavelengths independently, whereas the AERONET algorithm internally applies a condition ensuring the spectral shape of SSA follows an expected pattern for the observed aerosol type (private communication with Thomas Eck, NASA GSFC). The differences noted between our SSA retrievals and that from AERONET at different wavelengths could be attributed, at least partially, to this treatment of reported values of SSA.

8 Summary

Ground-based measurements of direct and diffuse solar radiation under cloud-free conditions over worldwide sites are providing valuable insights into regional aerosol characteristics. Long-term measurements obtained from such network, such as from AERONET, are widely used to develop regional aerosol climatology and investigate seasonal/annual variability, in addition to providing validation data set for the satellite-based AOD retrievals. Satellite measurements of TOA radiances are able to provide global distribution of columnar aerosol amounts. However, deriving aerosol optical properties from satellite measurements require constraints on particle sizes and

1250 optical properties. Reliable aerosol measurements from ground-networks and airborne/field campaigns are

1251 traditionally used to validate and improve the constraints in satellite aerosol retrievals.

1252

1253 In this work, we use AERONET measured extinction τ as constraint in a robust inversion technique that uses

1254 satellite measured TOA radiances from OMI and MODIS to derive spectral aerosol absorption in the UV-Vis part

1255 of the spectrum. Other than cloud contamination of the TOA radiances, major sources of error in our retrieved

1256 SSA come from surface reflectance, and aerosol layer height. We use TOA radiance observations with minimal

1257 or no cloud-contamination reported by both OMI and MODIS products. Sensitivity tests show that our retrieved

1258 aerosol SSA has reliable accuracy up to ±0.04~~3~~ from UV-Visible wavelengths for absorbing aerosols

1259 (carbonaceous and dust) with $\tau_{440} > 0.4$. ~~However~~However, for less-absorbing aerosols the error in SSA retrieval

1260 reaches up to ±0.07~~5~~. ~~For the sites with low aerosol loading (i.e, τ_{440} up to 0.2) the accuracy of retrieved SSA~~

1261 ~~reaches up to ±0.05 at the UV wavelengths, while in the visible it exceeds ±0.05.~~Using a subset of results where

1262 SSA is retrieved independently for 340, 354, 388, 466 and 646 nm wavelengths for the same day with

1263 observations $\tau_{440} > 0.4$, we examine the seasonal variability in aerosol SSA and derive spectral dependence

1264 (AAE) at three wavelength pairs in the UV-Vis spectrum.

1265

1266 Key observations noted from the spectral aerosol absorption data set derived here are highlighted below:

1267 **Biomass burning aerosols**

1268 a) Among sites dominated by biomass burning aerosols, Mongu in Southern Africa has high absorption ω_o

1269   ~0.85±0.02 and 0.84±0.05 at 340 nm and 646 nm, respectively.

1270 ~~a) ~0.85 to 0.84 from 340 nm to 646 nm.~~

1271 b) Strong seasonality in absorption of carbonaceous aerosols is evident in Southern Africa indicating the

1272   role of biomass types and combustion process. The average ω_o from 340 nm to 646 nm during JJA and

1273   SON are ~0.85±0.02 (0.88±0.02) and 0.83±0.05 (0.87±0.05), respectively.~~~0.85 to 0.84, and ~0.88 to~~

1274   ~~0.89, respectively.~~

1275 c) Carbonaceous aerosols found over Northern Australia are as strongly absorbing (ω_o ~0.87±0.03 and

1276   0.86±0.06 at 340 nm and ~~~0.87 to 0.86 from 340 nm to~~ 646 nm) as smoke over Southern Africa but has

1277   relatively constant absorption from UV-Vis spectra.

1278 d) Carbonaceous aerosols found over Alta_Floresta in the Amazon Basin have similar absorption (ω_o

1279   ~0.89±0.02 and 0.91±0.06 at 340 nm and 646 nm ~~~0.89 to 0.91 from 340 nm to 646 nm)~~ and AAE_{340-}

1280 $_{646}$~~UV-Vis AAE~~ (1.8) to those found over Missoula in North~~estern US~~ ~~America~~.

e) Highly absorbing carbonaceous aerosols ~~(ω$_o$ ~0.86 to 0.87 from 340 nm to 646 nm)~~ with weak spectral dependence are found in Cairo (ω$_o$ ~0.89±0.02 and 0.91±0.06 at 340 nm and 646 nm) and Ilorin (ω$_o$ ~0.86±0.02 and 0.87±0.03 at 340 nm and 646 nm) in the Middle East and Sahel ~~region~~ during winter (DJF). ~~These carbonaceous particles exhibit mean α$_{440-870}$ < 1.4, indicating possible mixture of fine and coarse modes.~~

f) Carbonaceous aerosols found over Northern India (ω$_o$ ~0.91±0.02 and 0.92±0.04 at 340 nm and 646 nm), ~~Eastern~~ Northeastern China (ω$_o$ ~0.87-0.90±0.03 and 0.90-0.94±0.05 at 340 nm and 646 nm), Sahel (ω$_o$ ~0.86±0.02 and 0.87±0.03 at 340 nm and 646 nm), and ~~Arabian Peninsula exhibiting~~Middle East (ω$_o$ ~0.89±0.03 and 0.92±0.05 at 340 nm and 646 nm~~0.86 to 0.89 at 340 nm~~) has low average α$_{440-870}$ (< 1.4) than over other prominent biomass burning regions, suggesting mixture of fine and coarse modes.

g) Distinct seasonality in spectral absorption of carbonaceous and urban aerosols is noted for Eastern China. ~~For carbonaceous aerosols, t~~The maximum ~~and~~ (minimum) absorption is noted during DJF (JJA) exhibiting ω$_o$ ~0.87±0.02 and 0.90±0.05 at 340 nm and 646 nm (ω$_o$ ~0.91±0.02 and 0.94±0.04 at 340 nm and 646 nm), respectively.~~at 466 nm are found during DJF ~0.90, and JJA ~0.95, respectively.~~

Dust aerosols

a) For desert dust aerosols, the SSA is known to increase with wavelength from UV to Visible spectrum. No distinct seasonality in SSA is noted. The regional average of SSA for dust aerosols from 340 nm to 646 nm are 0.87±0.02 to 0.98±0.02, 0.89±0.03 to 0.96±0.02, 0.89±0.02 to 0.98±0.01, 0.87±0.02 to 0.97±0.02, and 0.87±0.03 to 0.95±0.03 over Sahara, Sahel, Middle East, Northern India, Northeastern China, respectively.~~The regional averages of SSA for dust aerosols from 340 nm to 646 nm are 0.86 to 0.98, 0.88 to 0.96, and 0.90 to 0.99 over Sahara, Sahel and Arabian Peninsula respectively.~~

b) Among the dust dominated regions considered here, our retrievals indicate relatively high absorption (ω$_o$ ~0.93±0.03 at 466 nm) for aerosols noted at Sahel and northeastern China, while those noted over MiddleEast, and Northern India (ω$_o$ ~0.97±0.03 at 466 nm) are less absorbing and dust over Sahara (ω$_o$ ~0.95±0.02 at 466 nm) shows intermediate absorption. These results can be explained by combination of varying mineral composition (iron oxide amounts) and mixing of dust with other sources along the transport pathway.

~~b) For regions where sources are nearby the sites (Sahara, Middle East/Arabian Peninsula) the AAE for all three wavelength pairs considered exhibit high average values (>> 3), while for regions where lofted dust~~

1312 ~~through long-range transport is observed (Northern India, Eastern China, parts of Sahel) the average~~

1313 ~~AAE has a range between 2 to 3.~~

1314

1315 **Urban aerosols**

1316 a) Urban aerosols (ω_o ~0.87±0.04 and 0.84±0.08 at 340 nm and 646 nm) are highly absorbing and exhibit

1317 distinct seasonality (higher absorption during JJA than SON) at Sao Paulo, South America. The urban

1318 aerosols noted here are likely mixtures of carbonaceous particles transported over the region and

1319 prevailing pollution from local sources.

1320 b) Polluted aerosols observed over Mexico City show high absorption in UV extending to visible spectrum

1321 during DJF (ω_o ~0.88±0.04 and 0.84±0.09 at 340 nm and 646 nm) and SON (ω_o ~0.88±0.04 and

1322 0.80±0.08 at 340 nm and 646 nm) months.

1323 c) Polluted aerosols noted over the Middle East are highly absorbing and exhibit weak spectral dependence

1324 (ω_o ~0.87-0.89±0.03 and 0.87-0.90±0.07 at 340 nm and 646 nm).

1325 d) Polluted aerosols noted over the Northern India are highly absorbing and exhibit weak spectral

1326 dependence (ω_o ~0.88±0.03 and 0.87±0.07 at 340 nm and 646 nm).

1327 ~~a) Urban aerosols ($\omega_o(340)$ ~0.87) are more absorbing than the carbonaceous aerosols ($\omega_o(340)$ ~0.90) and~~

1328 ~~exhibit distinct seasonality (higher absorption during JJA than SON) in South America at CUIABA and~~

1329 ~~Sao Paulo. The urban aerosols noted here are likely mixtures of carbonaceous particles transported over~~

1330 ~~the region and prevailing pollution from local sources.~~

1331 ~~b) High absorption from UV ($\omega_o(340)$ ~0.87) extending to the blue spectral region ($\omega_o(466)$ ~0.90) is noted~~

1332 ~~for most sites in Europe during SON and/or DJF months indicating the presence of organic matter due to~~

1333 ~~local fuel combustion sources.~~

1334 ~~c) Polluted aerosols observed over Mexico City shows high absorption in UV ($\omega_o(340)$ ~0.88) extending to~~

1335 ~~visible ($\omega_o(466)$ ~0.85) spectrum during DJF and SON months.~~

1336

1337 As mentioned, the results presented here are limited to our subset of retrievals, where SSA is retrieved for all five

1338 wavelengths from UV-Visible range with $\tau_{440} > 0.4$. ~~However, relaxing the τ_{440} up to 0.2 (see supplementary~~

1339 ~~materials) does not yield significant changes in the derived variability of aerosol absorption and its spectral~~

1340 ~~dependence.~~ Since one of our objectives is to derive UV-Visible spectral dependence (AAE) of aerosols, ~~without~~

1341 ~~prior assumptions,~~ and given the inherent sampling bias of the OMI, MODIS and AERONET colocations – the

1342 analysis method employed here is well justified. In other words, we made use of the best available data synergy

and derive unique aerosol absorption data set with no prior assumptions on wavelength dependence, which otherwise is assumed in the standard satellite-based aerosol retrieval algorithm. ~~Although~~ It should be noted that our results may be biased toward dense pollution/industrial, smoke, and dust events~~, less absorbing low aerosol amounts seldom have dependency on the ω₀~~. In addition, the regional aerosol absorption derived here may not be representative of the entire region due to limited sampling and fewer sites used. However, these absorption models offer essential guidance for selecting spectral absorption in satellite aerosol retrievals using UV (OMI), Vis (MODIS), and even spanning the UV-Vis spectrum, such as planned under the upcoming PACE mission.~~Therefore, the regional aerosol absorption models derived here offer essential guidance for selecting spectral absorption in satellite aerosol retrievals spanning the UV-Vis spectrum.~~ From our analysis of worldwide inland sites: (a) it is suggested that satellite aerosol retrieval techniques could employ regional dynamic absorption models to avoid potential bias in τ retrievals noted in earlier studies, and (b) the spectral dependence of aerosol absorption noted here for the UV (354-388 nm), visible (466-646 nm) and UV-Visible (340-646 nm) range for all aerosol types other than black carbon varies considerably. Overall, the UV absorption data set well compliments and provides more information on the regional aerosol absorption than with the visible data set alone.

Given the lack of aerosol absorption information at near-UV wavelengths in the currently existing AERONET ~~record~~ inversion products and limited availability of insitu measurements, the UV-Vis aerosol absorption data set developed here, perhaps for the first time, offers a valuable source of information useful for a variety of aerosol and trace gas studies. As mentioned earlier the newer models of AERONET sunphotometers include sky radiance measurements at 380 nm, and the derived SSA at this near UV wavelength is expected in the future upgrade of AERONET inversion product. ~~The analysis presented here focuses on regional aerosol absorption using a subset of results.~~ The derived spectral dependency can be used with either subset of the results or all SSA retrievals to construct and investigate long-term trends in UV-Visible aerosol absorption. Further, the spectral aerosol SSA derived here could be used to parameterize absorption in models and better understand the radiative effect of aerosols. Our ongoing investigation utilizing the complete data set developed here will explore some of these applications in the future.

Competing Interests

The authors declare no conflict of interests.

Author Contributions

Omar Torres (OT) and Hiren Jethva (HJ) had conceptualized the research. Vinay Kayetha (VK) developed the data set, performed formal analysis, and wrote the manuscript with inputs from OT and HJ. All authors reviewed results, helped with the data interpretation and edited the manuscript to make a final version.

Data Availability

The spectral aerosol absorption data set developed here will be made available upon request to the authors.

Tables

Table 1: Description of the ground and satellite data products used in this work.

Purpose	Instrument	Product	Level & Version	Parameter(s)
For SSA retrieval in this work	AERONET	AOD	L2, V3	AOD and extinction Ångström exponent.
		Inversion	L2, V2	Particle size distributions, and real part of refractive index at 440 nm.
	OMI	OMLERWAVE, OMAERUV	L2, V1.8.9.1	TOA reflectances (with QFs), Aerosol type, LER, Aerosol layer height obtained from CALIPSO.
	MODIS	MYD04	L2, C006	TOA reflectances (with QFs) provided by Deep-Blue algorithm.
		MAIAC - MCD19A1	L2, C006	Surface reflectance at 466 and 646 nm.
Comparison	AERONET	Inversion	L2, V3	SSA at 440 and 675 nm.

Table 2: Theoretical estimated uncertainties in the retrieval of aerosol SSA due to error in the input variables. Configuration of sensitivity tests are: SZA = 20º, VZA = 40º, RAA = 130º, and $\omega_0(388) = 0.9$.

	Input Uncertainty	Theoretical SSA Uncertainty ($\Delta\omega_0$) for $\tau_{440} = 0.4$					
		$\lambda = 340$ nm			$\lambda = 646$ nm		
		Carb.	Dust	Urban	Carb.	Dust	Urban
Extinction AOD	$\lambda < 400$ nm, $\Delta\tau = \pm0.02$ $\lambda > 400$ nm, $\Delta\tau = \pm0.01$	0.002	0.001	0.002	0.009	0.007	0.011
Particle sizes	ΔVMR $= \pm20\%$	0.018	0.003	0.014	0.044	0.0006	0.040
Real part of RI.	ΔRRI $= \pm0.04$	0.007	0.007	0.009	0.001	0.002	0.002
Calibration of TOA measurements	OMI $= \pm1.8\%$ MODIS $= \pm1.9\%$	0.026	0.021	0.027	0.020	0.027	0.037
Surface reflectance	$\Delta\rho_{surf} = \pm0.01$	0.006	0.011	0.006	0.032	0.022	0.050
Aerosol layer hgt.	ΔALH $= \pm1$ km	0.021	0.028	0.006	0.001	0.001	0.0006
Presence of cloud	$\tau_{cloud} = 0.5$	0.016	0.020	0.017	0.042	0.041	0.056
Trace gaseous absorption	$\lambda = 466$ nm, $\tau_{gas} = 0.004$ $\lambda = 646$ nm, $\tau_{gas} = 0.034$	-	-	-	0.011	0.009	0.024

Satellite	AERONET	
Measured TOA reflectances	Measured spectral AODs	Derived aerosol properties (Inversion Product)

Satellite

Measured TOA reflectances

OMI : 340, 354, 388 nm
Ancillary data
- aerosol type
- aerosol layer height
- surface pressure
- surface reflectance

MODIS : 466, 646 nm
Ancillary data
- terrain height
- MAIAC MCD19A1 BRF or surface reflectance

AERONET

Measured spectral AODs

- Within ± 2 hrs of satellite overpass
- 50 km radius around the site

Derived aerosol properties (Inversion Product)

- Particle sizes
a) sigma, mean, n.conc.
b) fine, coarse modes
- Real refractive index (440 nm)

Inversion

Seasonal LUT of radiances as a function of:
- wavelength
- surface pressure
- aerosol layer height
- aerosol optical depth
- satellite-sun geometry
- imaginary refractive index

SSA at 340, 354, 388, 466 and 646 nm

1677
Figure 4: Retrieved aerosol SSA over the GSFC site for the satellite observations period of 2005 – 2016. Average and standard deviation of retrieved SSA for the observations with $\tau_{440} > 0.4$ is shown in red. Abbreviations used: n is the number of satellite-AERONET collocated observations, and ret. is the number of observations for which SSA is retrieved.
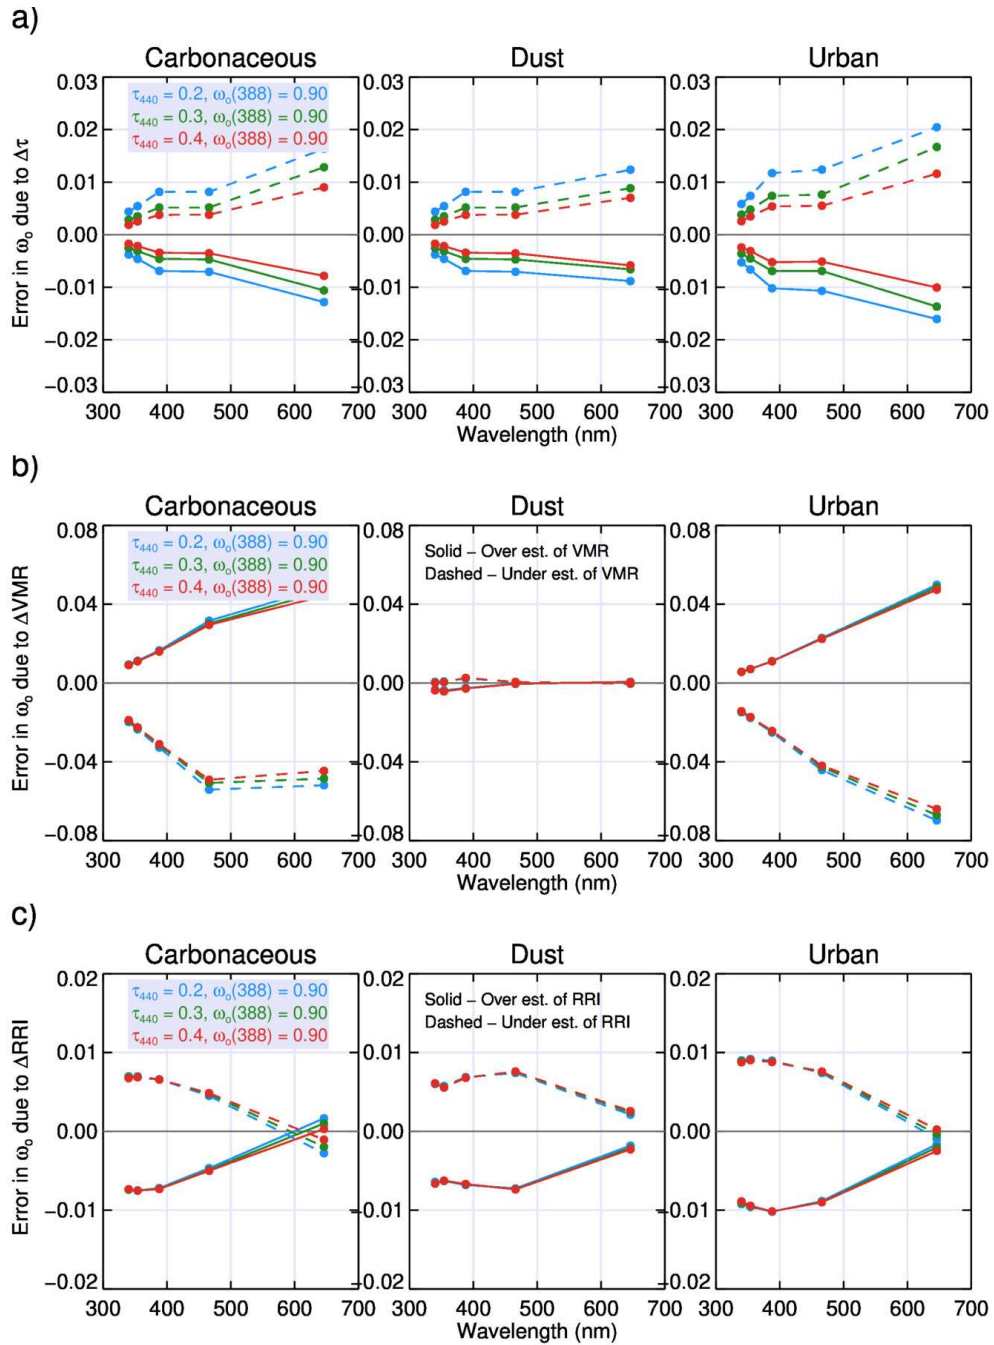

Figure 5: Theoretical uncertainty in SSA retrievals due to changes in (a) ±0.02 (λ < 400 nm) and ±0.01 (λ > 400 nm) AOD, (b) ±20% volume mean radius, and (c) ±0.04 real part of refractive index.

1690
