10 **Abstract.** Measuring spectral aerosol absorption remains a challenging task in aerosol studies, especially in the UV region, where the ground and airborne measurements are sparse. In this research, we introduce an algorithm that synergizes ground measurements with satellite observations for the derivation of spectral single scattering albedo (SSA, ω_0) of aerosols in the UV to visible range (340-670 nm). The approach consists in explaining satellite measured near-UV radiances (340, 354 and 388 nm) by the Ozone Monitoring Instrument (OMI), and
15 visible radiances (466 and 646 nm) by MODerate Imaging Spectrometer (MODIS), in terms of ground-based Aerosol Robotic Network (AERONET) measurements of total column extinction aerosol optical depth (AOD, τ), and retrieved total column wavelength dependent SSA using radiative transfer calculations. Required information on aerosol particle size distribution is taken from an AERONET-based climatology specifically developed for this project. This inversion procedure is applied over 110 AERONET sites distributed worldwide, for which
20 continuous, long-term AERONET measurements are available. Using the derived data set we present seasonal and regional climatology of $\omega_0(\lambda)$ for carbonaceous, dust and urban/industrial aerosol types. The UV-Visible spectral dependence of ω_0 obtained for the three major aerosol types from the synergy algorithm is found to be consistent with the insitu measurements reported in the literature. A comparison to standard AERONET SSA product at 646 nm shows absolute differences within 0.03 (0.05) for 40% (59%) of the compared observations.
25 The derived aerosol $\omega_0(\lambda)$ data set provides a valuable addition to the existing aerosol absorption record from AERONET by extending the absorption retrieval capability to the near-UV region. The combined UV-Visible data set, in addition to improving our understanding of spectral aerosol absorption properties, also offers wavelength-dependent dynamic aerosol absorption models for use in the satellite-based aerosol retrieval algorithms.

30 1 Introduction

Atmospheric aerosols play a significant role in the Earth's climate system through scattering and absorption of solar radiation, thus capable of perturbing radiation budget. The ratio of the amount of the light scattering to the total extinction referred to as single scattering albedo (SSA, ω_0) is a fundamental variable used to gauge the absorbing nature of aerosols. Mie-theory indicates ω_0 equals to one for purely scattering aerosols and less than
35 one towards zero for increasingly absorbing nature of aerosols. Studies show that the estimates of net aerosol radiative forcing is sensitive to the aerosol ω_0 , and small changes to it could potentially alter the forcing on atmosphere (Chyacutelek and Coakley, 1974; Hansen et al., 1997). Models are often fed with essential aerosol properties to estimate the forcing on the atmosphere. These properties include aerosol optical depth (AOD, τ), complex refractive index, and phase function. Here, the knowledge on spectral dependence of such properties is
40 crucial in quantifying the overall effects of aerosols. For example, absorbing aerosols can lead up to a 50% increase in the near-UV irradiance compared to the similar load of only scattering aerosols in the atmosphere (Bais et al., 2005). A report by Intergovernmental Panel on Climate Change suggests that the lack of spectral aerosol absorption is one of the major contributors leading to significant uncertainties in quantifying the net aerosol radiative effects on the Earth's climate (IPCC, 2013).

45

Developments in ground-based and satellite aerosol retrieval techniques have greatly improved our understanding of atmospheric aerosols over the last two decades. However, knowledge on spectral aerosol absorption properties is limited due to difficulties in measurements (e.g., Heintzenberg et al., 1997) and larger uncertainties in remote sensing retrievals (e.g., Dubovik et al., 2000). Direct measurements of aerosol absorption can be obtained by
50 using instruments that measure scattering and extinction coefficients. Such measurements are limited to discrete wavelengths and associated with few ground stations, laboratory measurements, or airborne field campaigns. Aerosol absorption can also be inferred from the sky radiance and extinction measurements that rely on fitting ground observations to radiative transfer calculations (Nakajima et al., 1996; Dubovik et al., 1998; Cattrall et al., 2003). Detailed reviews of measurements and techniques to retrieve aerosol absorption are available in several
55 papers (e.g., Clarke et al., 1967; Bond and Bergstrom, 2006; Moosmüller et al., 2009). Among the ground-based sensors, currently, AERONET provides long-term aerosol absorption record at four discrete wavelengths from the visible (Vis) to near Infrared (NIR) spectrum over many sites distributed worldwide. The known limitation of AERONET absorption product is the lack of near-UV wavelengths, besides higher aerosol load ($\tau_{440} > 0.4$) and

high solar elevation angle required to obtain reliable absorption in Vis-NIR spectrum. These limitations make it
60 imperative to look for alternate data retrieval methods or sources to fill the knowledge gap.

For a few decades now, satellite remote sensing is used as an essential tool to gain a global perspective of
aerosols distribution in the atmosphere. The satellite measured TOA reflectances are sensitive to both τ and ω_0 , in
addition to the surface reflectance. Most satellite aerosol retrieval techniques require making assumptions on
65 particle sizes (phase function) and ω_0 to retrieve τ . On the other hand, several efforts have been made to estimate
aerosol ω_0 from direct satellite measurements at visible wavelengths (e.g., Kaufman, 1987; Kaufman et al., 2002;
Satheesh and Srinivasan, 2005; Zhu et al., 2011) and near-UV wavelengths (Torres et al., 2007, 2013). However,
the variety of natural surface types, choice of wavelengths, and aerosol models pose limitations on such
techniques. In terms of wavelength, enhanced molecular scattering in the near-UV region acts as a strong
70 background and helps identify absorbing aerosols. However, to retrieve aerosol absorption using near-UV
measurements, quantitative information on aerosol layer height (ALH) is required. The existing satellite aerosol
retrieval techniques that rely on observations in the visible assume a constant ω_0 value, and for a few sensors, it is
still assumed wavelength-independent. A review on the commonly used satellite aerosol products singled out
aerosol absorption as an inherent problem common to all sensors (Li et al., 2009). Studies using the evolving
75 ground-based aerosol record provides evidence that satellite retrieved τ can lead to large biases if the assumed
aerosol ω_0 is wavelength-independent (Jethva and Torres, 2011), and constant (Lyapustin et al., 2011; Eck et al.,
2013). These studies highlight the importance of using wavelength-dependent aerosol ω_0 and account for its
spatial and temporal variability in the assumptions made for satellite retrieval of aerosol products.

80 In the past, few studies used both ground and satellite measurements to retrieve aerosol absorption properties. Li
et al., (1999) used visible band radiances from AVHRR and in situ measured τ during SCAR-B experiment to
derive absorption from biomass burning aerosols. Sinyuk et al., (2003) used UV-radiances from TOMS and
aerosol extinction from AERONET to derive the imaginary refractive index of dust particles over a few stations
in the Sahara belt region. Lee et al., (2007) estimated the aerosol SSA across a few stations over China using
85 combined ground and satellite (MODIS) measurements at visible wavelengths. Nonetheless, these studies are
limited and do not provide a comprehensive characterization of absorbing aerosols from the UV-Visible
spectrum.

The objectives of the present work are to derive columnar aerosol $\omega_o(\lambda)$, and its spectral dependence in the UV-Visible part of the spectrum. This approach makes use of the measured τ , and derived particle size distribution from AERONET in an inversion procedure. The A-train constellation of satellites that includes OMI and MODIS makes routine TOA measurements from the UV-Visible spectrum. Near-simultaneous measurements from A-train satellites provide an excellent opportunity to combine satellite and ground measurements during the overpass times (local noon, $\sim 13:30$ hrs) over the AERONET sites.

95

The organization of the remaining manuscript is as follows: section 2 describes the ground-based and satellite measurements used in this work. Section 3 describes the methodology adopted to derive aerosol $\omega_o(\lambda)$. Section 4 provides the sensitivity tests conducted to estimate the error incurred in the proposed aerosol absorption retrievals. Section 5 presents the seasonal variability in aerosol $\omega_o(\lambda)$ derived for sites distributed across major aerosol environments worldwide. Section 6 provides a discussion of the regional aerosol absorption models derived in this work. Section 7 presents a comparison of retrieved SSA with the AERONET absorption product. Finally, section 8 provides a summary of the work, along with the key findings and outlook for further studies.

100

2 Data sets

The details of ground-based and satellite data sets used in this work are provided in Table 1. Our usage of satellite data is strictly limited to the TOA reflectances, satellite-sun geometry, and other ancillary information (quality flags, aerosol type) but not the aerosol retrievals (τ) themselves from OMI and MODIS.

105

2.1 AERONET

Aerosol Robotic Network (AERONET) employs an automatic sun-tracking photometer to measure sun and sky radiances (Holben et al., 1998). The direct sun measurements are made at nine nominal wavelengths of 340, 380, 440, 500, 675, 870, 940, and 1020 nm typically for every 15 minutes interval. The extinction τ obtained from these measurements are accurate within ± 0.01 (± 0.02) at the visible (near-UV) wavelengths (Dubovik and King, 2000). In addition to the direct sun measurements, the photometer also measures multi-angular diffuse sky radiances along the almucantar plane at four distinct wavelengths from visible to the near-Infrared spectrum (440, 675, 870 and 1020 nm) with near-hourly frequency. An inversion procedure that uses both direct sun and angular sky radiances together is implemented to derive aerosol particle size distribution and complex refractive indices (Dubovik et al., 1998; Dubovik and King, 2000). The uncertainty in the derived spectral aerosol SSA provided by

115

the AERONET inversion Level 2 product is estimated to be ± 0.03 for $\tau_{440} > 0.4$ (Dubovik et al., 2000). For the locations, where aerosol loading is usually low, the derived aerosol absorption properties have much higher retrieval error (Level 1.5 inversion product). In this work, we use AERONET measured columnar τ as a
120 constraint to derive aerosol absorption from satellite TOA measurements. The particle size distributions provided by AERONET products are used for constructing a representative aerosol model for the associated sites. Aerosol absorption properties from AERONET Level 2 Version 3 product are used for comparison with our retrievals at visible wavelengths. Figure 1 shows the location of the total 110 AERONET sites used in this work for which long-term (> 7 years) quality assured Level 2 (version 3) measurements are available.

125 2.2 OMI

Launched in July 2004, the Ozone Monitoring Instrument (OMI) onboard NASA's EOS Aura satellite is a nadir-viewing hyper-spectral imaging radiometer (Levelt et al., 2006). OMI measures the TOA radiances in the wavelength range 270-500 nm with a ground pixel spatial resolution of 13 km x 24 km at nadir. OMI achieves daily global coverage in 14-15 orbits with a swath of 2600 km scanning the entire earth's surface. In this work,
130 we use OMI radiances (340, 354, and 388 nm) provided in the in-house product OMLERWAVE and publicly accessible OMAERUV Level 2 aerosol product (V1.8.9.1). The OMLERWAVE product reports radiances and Lambertian equivalent reflectivity (LER) at several discrete wavelengths in the near-UV and visible parts of the spectrum. Additionally, we also use ancillary information on the quality of pixel (cloud contamination, land/sea mask, etc.), aerosol type, LER, and ALH data set used in the operational OMAERUV product. The OMAERUV
135 product primarily relies on the measured near-UV aerosol index and AIRS-retrieved carbon monoxide information to categorize aerosols into Carbonaceous, Dust, and Urban/Industrial types. Since mid-2007, OMI suffers from an external obstruction that affects the quality of radiance measurements in a few rows (cross-track pixels). This is referred to as 'row anomaly' that restricts the current usage of OMI observations for the scientific purpose to about half in a total of 60 cross-track rows (Schenkeveld et al., 2017). Extensive documentation about
140 how the row anomaly affects the OMAERUV aerosol product is available at Torres et al., (2018).

2.3 MODIS

The MODerate resolution Imaging Spectro-radiometer (MODIS) onboard NASA's EOS Aqua and Terra satellites are nadir-viewing, multi-spectral radiometer. MODIS measures the TOA radiances in 36 wavelength bands ranging from 0.41-14.23 μm with a ground pixel spatial resolution between 250-1000 m. MODIS scans the
145 earth's surface with a 2300 km wide swath to provide near-global coverage on a daily basis. In this work, we use

Aqua-MODIS radiances (at 466 and 646 nm) provided in the 10-km aerosol product (MYD04_L2) from the Deep-Blue (DB) aerosol algorithm. This aerosol product provides cloud-free radiances and ancillary information on the quality of pixel and estimated cloud fraction.

3 Methodology

150 A schematic flowchart of the method adopted in this work to derive wavelength-dependent aerosol absorption is shown in Figure 2.

3.1 Computation of site-specific Look-up table of TOA reflectances

To start, we compile a seasonal climatology of aerosol particle size distributions and real part of the refractive index (440 nm) from the AERONET Level-2 Version-2 inversion product for each site considered in the study.

155 Here, we assume that the spectral variability of the real part of the aerosol refractive index through UV-Visible is minimal and, therefore, values derived at 440 nm were assumed to be wavelength-independent across the UV-Visible spectrum range considered in this study. The resulting climatology of aerosol size distribution are fed to a radiative transfer model (RTM) to generate look up table (LUT's) of outgoing top of the atmosphere (TOA) reflectances at 340, 354, 388, 466, and 646 nm with varying nodal points of satellite-sun geometry, surface

160 pressure, τ , ALH, and imaginary component of the refractive index. The Gauss-Seidel radiative transfer code (Mie theory) used for this purpose accounts for gaseous absorption, molecular and aerosol multiple scattering (Herman and Browning, 1965). Thus, a database of AERONET site-specific seasonal LUT of reflectances for the aerosols observed over each site in the study is created. Figure 3 shows the calculated net aerosol reflectance at the TOA over the GSFC site (38.92° N, 76.84° W) using particle sizes derived from the AERONET product and

165 varying values of τ and ω_0 . These results illustrate that for a given satellite-sun geometry and observed radiance, multiple combinations of τ and ω_0 can explain the satellite measurements. This simulation demonstrates that in order to derive ω_0 from satellite measurements, an accurate characterization of τ , cloud-free radiances, and surface reflectances are required.

170 The site-specific LUTs developed here assume spherical particle shapes for carbonaceous and urban aerosols. However, mineral dust particles are assumed non-spherical and modeled as randomly oriented spheroid (Dubovik et al., 2006; Torres et al., 2018). To account for the non-spherical behavior of dust particles, a unified dust model is created using particle sizes from selected AERONET sites over Sahara and Arabian region that include: Saada,

SEDE_BOKER, Solar_Village, and Tamanrasset_INM. These sites were selected based on the observed
175 prevailing dust aerosol type. The particle sizes and real refractive index obtained at these sites are used with a
pre-computed set of kernels that assume a spheroidal shape with a fixed distribution of axis ratio to produce
phase function (Dubovik et al., 2006). The obtained phase matrix elements are input to the RTM to create
reflectance LUT's. The process of acquiring a unified dust model LUT is necessary to account for the non-
spherical shape of particles and save a considerable computational time, which otherwise would require to create
180 another set of site-specific LUTs.

3.2 Collocation of satellite and ground measurements

We use satellite measurements located within the 50 km radius of each AERONET site. In essence, we treat the
overlying atmospheric aerosols within a 50 km radius of the site as a representative of the AERONET measured
 τ . To allow for more sampling, we associate the AERONET observations within ± 2 hours of satellite overpass to
185 the measured TOA radiances. Here, we do not employ any averaging scheme for the AERONET data and keep it
intact. While with satellite measurements, we use native pixel resolution of 13 km x 24 km for the OMI
wavelengths (340, 354 and 388 nm) and 10 km x 10 km resolution radiances for the MODIS wavelengths (466
and 646 nm).

3.3 Retrieval of aerosol $\omega_0(\lambda)$

190 The proposed technique to derive aerosol absorption follows the procedure of obtaining the best quality assured
cloud free-TOA reflectances, identifying the aerosol type, optimal layer height, and characterize surface
reflectance. We select over-land pixels from both sensors with the best quality flags ('0'-OMI, '3'-MODIS-DB)
and cloud fraction < 0.2 in the retrieval procedure. Aerosol type information for the OMI wavelengths is directly
adopted from the OMAERUV product. While for the MODIS wavelengths, our algorithm looks for the nearest
195 OMI footprint to obtain and assign the corresponding aerosol type. Once an absorbing aerosol type i.e.,
carbonaceous smoke or mineral dust is identified, we choose the best estimate of ALH from the joint OMI-
CALIOP climatology derived from a 30-month long record of collocated observations (Torres et al., 2013).
While for a weakly absorbing aerosol (Urban), ALH is characterized with a Gaussian distribution of aerosols
with a peak at the surface. This is similar to the procedure adopted in the OMAERUV aerosol retrieval (Torres et
200 al., 2013). For the surface characterization at OMI wavelengths, we use a near-UV surface albedo database used
in the OMAERUV algorithm. At MODIS wavelengths, surface reflectance provided by MAIAC products
(Lyapustin and Wang, 2018) is used. Our retrieval technique gathers all above-mentioned information for each

205 pixel along with the associated AERONET τ to perform an inversion for each wavelength independently. The inversion procedure solves for the best fit of radiances and τ with the prior computed site-specific seasonal LUT radiances to derive aerosol $\omega_o(\lambda)$.

Figure 4 shows the retrieved aerosol SSA over the GSFC site as a function of measured τ . Located in the vicinity of a metro city, the prevailing aerosols over the GSFC site are the urban or industrial types that are relatively more scattering in nature. The mean aerosol SSA retrieved at the GSFC site for all τ observations at 340, 354, 210 388, 466 and 646 nm are 0.91, 0.93, 0.93, 0.90 and 0.85, respectively. The variability of the retrieved SSA is high at lower aerosol loading for all wavelengths. Particularly notable is the high variability of retrieved SSA in most τ bins for the visible wavelengths (i.e., MODIS bands). This is due to the weaker aerosol signal strength for urban type aerosols at lower aerosol loading in the visible spectrum, where the measured TOA radiances are dominantly contributed by the underlying surface. Also shown in figure 4 is the number of collocated observations that were 215 used in the inversion and the percent of observations for which SSA is retrieved. For about 12 years of the satellite and ground collocated observations used here, it is clearly evident that the number of observations from OMI is less than MODIS observations. The difference in the number of collocated observations stems partly from the OMI row-anomaly, cloud contamination, and the coarser pixel resolution. The percent of SSA retrieved observations varies widely even within the corresponding sensor wavelengths (OMI: 340, 354, 388 nm and 220 MODIS: 466, 646 nm). At times depending on the surface albedo used, the computed net aerosol reflectance might exceed the LUT limits and produce SSA values above one or less than the maximum absorption in the LUT. We avoid this by constraining our inversion procedure within the LUT limits and do not allow for any extrapolation of the inputs. However, this leads to the unequal number of retrieved observations within the sensor wavelengths. In other words, for a given observation within the OMI or MODIS sensor, it is possible to have 225 aerosol SSA retrieved at one wavelength and no retrieval (out-of-bounds) at other wavelengths. Also, it is worth mentioning that for few sites located along the coasts or in the islands (e.g., Mauna_Lao, Ascension_Island, Nauru), we were either unable to retrieve aerosol SSA or the number of days with retrieval is quite low. This is a consequence of OMI's large pixel size, where the satellite measured radiances are often contaminated by clouds and mixed-signal from the surface that are challenging to resolve and lead to out-of-bounds in the inversion.

230

To examine the seasonal variation of aerosol SSA and its spectral dependence, we create a subset of the data that includes observations for which aerosol SSA is retrieved for all the corresponding sensor wavelengths simultaneously (OMI: 340, 354, 388 nm and MODIS: 466, 646 nm) on any given day. This step reduces the

sample size drastically but eliminates the need for making prior assumptions on the wavelength dependence of
235 aerosol absorption angstrom exponent to fill those gaps. Instead, the obtained aerosol SSA in the UV-Visible
range is used to compute the resulting spectral dependence of aerosol absorption of the prevailing aerosols over
the corresponding AERONET sites in terms of the Aerosol Absorption Exponent (AAE), a measure of the
spectral dependence of aerosol absorption (Bond, 2001) using a power-law approximation, analogous to the
Angstrom Extinction Exponent (van de Hulst, 1957). The spectral dependence of aerosol absorption is reported
240 as Absorption Angstrom Exponent (AAE) defined as the slope of aerosol absorption optical depth with
wavelengths on a log-log scale. The aerosol absorption optical depth $\tau_{abs}(\lambda)$ is derived as shown in equation (1):

$$\tau_{abs}(\lambda) = (1 - \omega_0(\lambda)) \cdot \tau_{ext}(\lambda) \quad (1)$$

from which the AAE for wavelength range λ_1, λ_2 is calculated as shown in equation (2).

$$AAE(\lambda_1, \lambda_2) = - \frac{\ln(\tau_{abs}(\lambda_1)/\tau_{abs}(\lambda_2))}{\ln(\lambda_1/\lambda_2)} \quad (2)$$

245 In addition, we make use of the AERONET extinction angstrom exponent (α) at 440-870 nm to distinguish the
particles as coarse ($\alpha < 0.2$), fine ($\alpha > 1.2$), and in between as intermediate or mixed-mode. Since our aerosol
identification strictly uses three primary types, the use of qualitative indicator α helps delineate the mixture of
aerosols when applicable.

4 SSA retrieval sensitivity analysis

250 The inversion procedure employed here to derive aerosol absorption from the combined ground and satellite
measurements is susceptible to several systematic and random errors. These error sources include: (a) aerosol
extinction measurements, (b) estimation of particle size distribution, (c) real part of refractive index, (d)
calibration of satellite measured TOA radiances, (e) surface reflectance, (f) aerosol layer height, and (g) sub-pixel
cloud contamination. The retrieved aerosol absorption from our inversion procedure could be affected by all these
255 sources of uncertainties. Among these, error sources from (a-d) are inevitable for which we do not have any
direct control over them. However, we do have control only for the sources from (e-g) in our retrieval. Errors
associated with surface reflectance, aerosol layer height, and cloud contaminations on the satellite retrieved
optical depths are well documented in the literature (e.g., Fraser and Kaufman, 1985; Torres et al., 1998; Jethva et
al., 2014). In summary it is known that an: (i) overestimation (underestimation) of surface reflectance leads to
260 lower (higher) aerosol SSA, (ii) overestimation (underestimation) of τ leads to lower (higher) aerosol SSA, (iii)
overestimation (underestimation) of ALH produces higher (lower) aerosol SSA – more pronounced in the UV
than in visible wavelengths, and (iv) an increase in TOA reflectance due to sub-pixel cloud contamination

produces higher aerosol SSA. We use sensitivity tests for these key input variables to derive a quantitative estimate of the error percolated in the aerosol SSA retrieval due to changes in these variables.

265

Sensitivity tests are performed on observations that were reported with best accuracy (minimal cloud contamination in both OMI and MODIS data sets) for a few selected sites that include GSFC, Avignon, Tamanrasset_INM, Saada, Alta_Floresta, and Mongu. These sites were selected to include different types of aerosols observed over these sites. Figure 5 shows the error analysis of the retrieved SSA as a function of wavelength and optical depth given a change in the surface reflectance and ALH by an absolute change of ± 0.01 and ± 1 km ALH. The absolute error is computed as the SSA obtained with altered input minus the actual SSA. As expected, the error in retrieved SSA increases with increasing wavelength and decreasing τ due to changes in surface reflectance for all aerosol types. For less-absorbing (Urban) aerosols, the surface reflectance becomes increasingly important at the visible wavelengths than compared to absorbing aerosols. Our analysis shows that for small τ_{440} (~ 0.2), the error in retrieved SSA is much higher ($> \pm 0.05$) for visible wavelengths, while that in the near-UV region reaches up to ± 0.03 . However, for observations with $\tau_{440} \sim 0.4$, a reliable accuracy of within ± 0.05 is achieved even for the non-absorbing aerosols at 646 nm. In contrast to the surface reflectivity, the effect of ALH becomes prominent at near-UV wavelengths. The error in retrieved SSA due to changes in ALH decreases with wavelength because of the gradually diminishing the intensity of Rayleigh scattering and its radiative interactions with aerosols. The errors in the retrieved SSA are estimated to be better than ± 0.03 in the near-UV and negligible at visible wavelengths for both absorbing and non-absorbing aerosols.

Table 2 presents the achievable accuracy in our SSA retrievals at 340 nm and 646 nm. Overall, for the observations with τ_{440} equals to 0.4, the estimated accuracy in our retrieved SSA is within ± 0.03 (± 0.05) for absorbing (non-absorbing) aerosols through 340-646 nm. While for the observations with τ_{440} up to 0.2, the achievable accuracy in SSA reaches up to ± 0.05 ($> \pm 0.05$) for absorbing (non-absorbing) aerosols.

5 Results

The results presented hereafter include only a data subset that meets the following three conditions: (a) SSA retrievals are available for all five wavelengths on a given day, (b) $\tau_{440} > 0.4$, to ensure reliable accuracy spanning through UV-Visible wavelengths, and (c) there are at least 5 days of observations available per season per aerosol type. We include results of retrieved SSA for cases when $\tau_{440} \leq 0.2$ as supplementary materials. Table 3 presents

290

seasonal averages of aerosol SSA and AAE for all sites considered in this work. The spectral dependence of absorption quantified as AAE is reported for three different wavelength pairs covering the near-UV (354, 388), Vis (466, 646) and UV-Vis (340, 646) spectra.

295 **5.1 Biomass Burning**

5.1.1 South America

The AERONET sites located in South America include Alta_Floresta, Arica, CEILAP-BA, CUIABA-Miranda, Rio_Branco, Ji_Parana_SE, SANTA_CRUZ_UTEPSA, Sao_Paulo and Campo_Grande_SONDA. In general, carbonaceous aerosols over South America are dominantly emitted from biomass burning during southern
300 hemisphere spring (JJA) and summer (SON), with distinct peaks in August and September. Most aerosol emissions are associated with biomass burning for land and agricultural management practices. Further, densely populated places like Sao Paulo and CEILAP-BA are also affected by vehicular and industrial emissions. Aerosols from northern parts of the Amazon Basin advecting south or southeast, and long-range transport of aged smoke from Southern Africa are not uncommon over few locations in South America. Figure 6a shows regional
305 average SSA for carbonaceous particles at 466 nm is noted to be 0.92 (0.93) during JJA (SON) months. Average τ_{440} and $\alpha_{440-870}$ are about 1 and 1.8 respectively for both seasons, indicating dominantly fine mode nature of these particles. Spectral SSA increases from 340 nm (0.90) to 388 nm (0.93) followed by a decrease toward the visible wavelengths. For urban aerosols, the average τ_{440} (0.57) and $\alpha_{440-870}$ (1.70) are lower than those of carbonaceous particles. The average SSA at 466 nm for urban aerosols is 0.88 (0.92) for JJA (SON) months. We also find that
310 the urban aerosols in South America are more absorbing during JJA than in SON. Examining individual sites (Table 3) reveals high absorption during JJA at CUIABA and Sao Paulo. It is likely that the urban aerosol samples shown here attribute to a mixture of aerosols.

5.1.2 Southern Africa

The AERONET sites located in the Southern Africa are Mongu, Pretoria, and Skukuza. In addition to the natural
315 forest fires and emissions from crop residue burning, heavy industrial facilities and episodic dust commonly dictate the aerosol amounts over Southern Africa. Figure 6b shows the regional average SSA derived for aerosols over the Southern Africa. For the carbonaceous and urban aerosols observed over the region, maximum absorption is found in JJA period. The average SSA for carbonaceous particles increases from 340 nm to 466 nm and then decreases at longer wavelengths. Distinct seasonality in absorption for carbonaceous particles is
320 observed with maximum (minimum) value of 0.87 (0.90) at 466 nm for JJA (SON) months. The range of regional

average values of τ_{440} and $\alpha_{440-870}$ for carbonaceous particles are about 0.76 to 1.02 and 1.76 to 1.84 ranges respectively, while for urban aerosols the variability ranges are 0.55 to 0.73 and 1.68 to 1.74, respectively. As noted, τ_{440} and $\alpha_{440-870}$ are higher for carbonaceous particulate than for urban aerosols. For the latter, the average SSA shows similar spectral behavior as carbonaceous particles. However, the AAE of carbonaceous aerosols in the UV-Vis range is noted to be ~ 1.73 , while for urban aerosols it is ~ 2.2 . Notable seasonality for urban aerosols is observed for DJF where the average SSA is almost flat from 340 nm to 466 nm with a slight increase thereafter. Aerosols organic components are likely the cause of such absorption spectral feature.

5.1.3 Australia

In general, inland Australia is categorized as arid-region vastly covered with deserts. However, Northern and Western parts of the continent are covered with savanna grasslands, where biomass burning due to natural forest fires and land management practices are known to produce high aerosol emissions during the dry season (May-October). The regional average SSA for the aerosols observed over Northern Australia at the sites Jabiru and Lake_Argyle is shown in figure 6c. For the sample obtained in this work, carbonaceous and urban aerosols are found during spring (SON). The average τ_{440} and $\alpha_{440-870}$ for carbonaceous particles is 0.65 and 1.62, respectively. Average SSA increases with wavelength from 0.87 (340 nm) to 0.89 (388 nm) and then decreases to 0.87 (646 nm). Such behavior of fine-mode particles is likely a result of a mixture of black carbon and organic carbon amounts in the atmosphere, producing stronger (weaker) absorption in the UV (Vis) wavelengths. Although the mean $\alpha_{440-870}$ for both carbonaceous and urban aerosols is similar, the mean τ_{440} for urban particles is relatively low. The UV-Vis spectral dependence of urban aerosols (1.57) follows similar behavior as carbonaceous aerosols (1.42). Unlike the typical urban aerosol absorption, the spectral SSA observed here indicates a mixture of urban and carbonaceous particles.

5.2 Dust

5.2.1 Sahara

The seasonal average SSA of aerosols over the sites Saada and Tamanrasset is shown in figure 7a. As one would expect from the region, dominantly dust aerosols are observed with average τ_{440} and $\alpha_{440-870}$ ranging from 0.63 to 0.85 and 0.11 to 0.16, respectively. Regional average aerosol SSA obtained at 466 nm is ~ 0.94 . The spectral dependence of dust aerosols shows increase in SSA with wavelength, i.e., 0.86 at 340 nm to 0.97 at 646 nm. The UV-Vis AAE obtained for dust aerosols range from 2.8 to 3.3 with no distinct seasonality in the average spectral SSA. As noted, in addition to the coarse dust both sites constitute intermediate range of aerosols with average

350 $\alpha_{440-870}$ up to 0.3. Compared to coarse particles the intermediate sizes exhibit typical ‘dust’ absorption curve but has relatively low SSA (0.95) at 646 nm and therefore low UV-Vis AAE (2.1 to 2.5). This is consistent with the known dependence of scattering effects at longer wavelength for the dust particles.

5.2.2 Sahel

The AERONET sites located in the Sahel region are Agoufou, Banizoumbou, Dakar, IER_Cinzana, Ilorin, 355 Ouagadougou, and Zinder_Airport. Regional average SSA for the aerosols over Sahel region is shown in figure 7b. For dust aerosols, the average spectral SSA resembles typical dust absorption curve (increase in SSA with wavelength). No distinct seasonality in regional average absorption is observed. However, during SON months relatively low τ_{440} (0.64) and UV-Vis AAE (1.57) is noted compared to other seasons. Aerosols with intermediate size category ($0.2 < \alpha_{440-870} < 1.2$) are observed for all sites in the Sahel region. The spectral SSA obtained for 360 these aerosols clearly indicate mixture of dust and carbonaceous particles. Eck et al. (2003) reported smoke particles found toward southern parts of the West Africa are relatively coarse (α ranges 0.3 to 0.5) than those found elsewhere – likely a result of mixing with other aerosol types, coagulation, humidification or combination of such processes. Typical carbonaceous absorption curve noted here for the wet season (JJA and SON) is consistent with those reports. The average SSA for these (coarse-) carbonaceous particles is ~ 0.93 at 466 nm and 365 exhibit a UV-Vis AAE range 0.5 to 1.2. The average SSA observed for DJF and MAM (dry season) indicates a mixture of prevailing dust and carbonaceous particles. For the sample obtained over Sahel region, fine-mode carbonaceous and urban aerosols are observed at Ilorin during DJF and SON. Both these aerosol types show significant absorption with the average SSA at 340 nm and 646 nm is ~ 0.86 and 0.87, respectively, with nearly no spectral dependence. This likely indicates the presence of black carbon amounts over the Ilorin site during 370 DJF and SON. In addition to the biomass burning, fossil fuel combustion, and vehicular emissions, the vast number of gas flaring stations (> 300) around the Niger Delta produces high emissions (Onyeuwaoma et al., 2015). Highly absorbing black carbon amounts observed at Ilorin is possibly a result of such emissions.

5.2.3 Arabian Peninsula

The AERONET sites located in the Middle East/Arabian Peninsula region include Solar_Village, 375 SEDE_BOKER, Nes_Ziona, and Cairo_EMA_2. The regional average SSA of aerosols observed for these sites is shown in figure 7c. For dust aerosols, as expected, the average SSA increases with increasing wavelength. The regional average SSA ranges from 0.89 to 0.98 at 340 nm to 646 nm, with UV-Vis AAE in the range of 2.7 to 3.8. No distinct seasonality in SSA is found from our sample of observations. However, a slight increase in SSA

at UV wavelengths is noted during winter (DJF). Examining individual sites reveal this feature corresponds to the
380 aerosols over Solar_Village. The increase in SSA and high $AAE_{354-388}$ noted for Solar_Village during DJF likely
indicates transport of aerosols from neighboring regions. Intermediate range of particles with $0.2 < \alpha_{440-870} < 1.2$
are observed over all sites. The regional average SSA observed for these particles clearly indicate mixture of
aerosols. Carbonaceous aerosols found over Cairo from our sample have average SSA ranging from 0.89 to 0.91
at 340 nm to 646 nm. The UV-Vis AAE (1.91) obtained for these aerosols likely indicate mixture of black and
385 organic carbon amounts. For the urban aerosols observed over Cairo and Nes Ziona the regional average SSA is
found to be 0.89 at both 340 nm and 646 nm indicative of mixture of aerosols. While urban aerosols and pollution
prevail over Nes Ziona, emissions from crop residue burning (rice straws) over the Nile delta region during
winter (DJF) and heavy pollution dictate the aerosol absorption noted over Cairo.

5.3 Urban/Industrial

390 5.3.1 Western North America

Dominantly urban type aerosols are observed in Western North America primarily produced from industrial
activities and vehicle emissions. In addition, owing to the general meteorological and geographical setting of the
western North America, the region experiences drier months in the summer and fall that initiates natural forest
fires. The regional average aerosol SSA derived from our sample over the western North America is shown in
395 figure 8a. The average aerosol absorption for urban aerosols decreases in the wavelength range 340-388 nm
followed by an increase at longer wavelengths. Carbonaceous aerosols are observed in our sample over the
Missoula site located in the State of Montana. The average SSA retrieved for carbonaceous particles increases
with wavelengths from 340 nm to 466 nm (0.89 at 0.94) and then decreases towards 646 nm (0.88). The average
 τ_{440} , $\alpha_{440-870}$ and UV-Vis AAE obtained for the carbonaceous particles are 1.74, 1.8 and 1.72 respectively.

400 5.3.2 Eastern North America

Similar to the western part, atmospheric aerosols found over the eastern North America primarily originated from
the industrial activities and secondary aerosol processes (Malm, 1992). Biomass burning generated carbonaceous
particles and dust or mixture of aerosols over the eastern parts of the continent is a rare occurrence, except in the
events of long-range transport of smoke from the west. Thus, the average aerosol SSA retrieved over the
405 AERONET sites in this region follows a typical 'Urban' spectral absorption curve, as shown in figure 8b. It is
observed that aerosol SSA increases from the 340 nm to 388 nm or 466 nm and then decreases attaining a
maximum absorption (~ 0.90) at 646 nm. The regional average SSA for the MAM and JJA months at 466 nm is

0.89 and 0.87 respectively. It should be noted that for urban aerosols the retrieval error at visible wavelength is high (up to 0.05). Since there are no notable changes in the aerosol sources, the observed decrease absorption at 646 nm for JJA period is likely attributed from the retrieval uncertainty.

5.3.3 Europe

For the AERONET sites located in the Europe, dominantly urban aerosols are observed (figure 8c). The regional average SSA increases from 340 nm to 388 nm and then decreases reaching a minimum value (0.83) at 646 nm for most seasons. The observed aerosol absorption is similar for spring (MAM) and summer (JJA). However, there is an increase in absorption at wavelengths other than 646 nm for fall (SON) that reaches a maximum absorption 0.86 and 0.89 at 340 nm and 466 nm respectively. This likely suggests the presence of organic carbon amounts emitted from local fuel combustion sources. This feature is consistent with Ilias et al., (2019), that reports annual cycle of aerosol absorption over Thessaloniki site. Individual site observations reveal this increase in absorption is prominent for most locations in Europe during fall (Table 3) and winter (Table S1). While the aerosol loading is similar throughout the seasons, the average UV-Vis AAE for urban aerosols range from 1.0 to 1.26. In addition to the urban/industrial aerosols, long-range transport of dust from Sahara is not uncommon over central Europe and Mediterranean Basin. Although our sample over European sites do not constitute any coarse mode particles, intermediate range ($0.2 < \alpha_{440-870} < 1.2$) of aerosols are observed for most sites. The average SSA curve noted here indicates mixture of aerosols.

5.4 Mixed aerosol types

5.4.1 Mid-Atlantic North America

The seasonal average aerosol SSA obtained over the Mexico City is shown in figure 9a. Unlike typical urban aerosol absorption, the SSA curve obtained here shows steep decrease from 388 nm to 466 nm and remains flat or slightly decreases till the 646 nm. Seasonality in aerosol absorption is observed at UV wavelengths (< 400 nm) with maximum (DJF, SON) and minimum (MAM) absorption of 0.86 and 0.91 at 354 nm. It is clearly evident that such absorption curve and seasonal variation is a result of prevailing mixture of aerosols. Seasonal average $\alpha_{440-870}$ indicates the prevalence of fine mode particles over the Mexico City. The average SSA at 466 nm for DJF, MAM and SON months are 0.85, 0.86 and 0.84 respectively. Although the seasonal average UV-Vis AAE of aerosols over Mexico City ranges from 0.94-1.27, the $AAE_{354-388}$ is higher for (5.13) MAM than compared to (2.2) DJF and (0.6) SON months. In general, Mexico City is a densely populated urban location that is well known for its high pollution levels among the other megacities worldwide. In addition to the high concentration

of aerosols from fossil fuel combustion throughout the year, Mexico City also experiences biomass-burning aerosols during the relatively dry months of March-May from local sources (Eck et al., 1998).

5.4.2 North-Eastern Asia

440 The AERONET sites located in the Northeastern Asia include: Beijing, Osaka, Shirahama and XiangHe. Figure 9b shows the regional average SSA derived over Northeastern China. For the samples obtained, dust aerosols possibly mixed with regional pollution are observed over Beijing and XiangHe during spring (MAM). The spectral curve of regional average SSA shows an increase from 0.87 at 340 nm to 0.95 at 646 nm. The UV-Vis AAE obtained for the dust aerosols is 1.56. Among sites considered here, carbonaceous aerosols are observed
445 throughout the year at Beijing and XiangHe. The spectral behavior of carbonaceous aerosols shows increase in SSA from 340 nm to 466 nm and thereafter remains near constant or slightly decreases with an UV-Vis dependence ranging from 1.84 to 2.14. However, significant seasonality is noted with minimum (0.95 at 466 nm) and maximum (0.90 at 466 nm) absorption during JJA and DJF respectively. The increase in SSA likely caused the humidification and secondary aerosol processes during JJA. Carbonaceous and urban aerosols over the region
450 show high absorption in winter (DJF), likely due to high amounts of local fossil fuel combustion and agricultural waste burning. The spectral behavior of urban aerosols is similar to carbonaceous aerosols with decrease in magnitude of average SSA, AOD, and UV-Vis AAE. As expected from the local sources, mixture of aerosols categorized by particle sizes ($0.2 < \alpha_{440-870} < 1.2$) is observed at all sites in the region with widely varying spectral dependence.

455 5.4.3 Northern India

The AERONET sites located in Northern India include Jaipur, Gandhi College and Kanpur. Major source of aerosols over the region includes industrial and vehicular emissions, combustion of biomass and fossil fuels. In addition, desert dust passage from arid and semiarid regions of northwestern India, Pakistan, and Arabian Peninsula is commonly observed during spring and summer months. Figure 9c shows the regional average
460 aerosol absorption observed at Kanpur. As expected from the source regions, dust aerosols are observed during spring (MAM) and summer (JJA) months over Jaipur and Kanpur. The average SSA shows a steep increase from 340 nm (0.88) to 466 nm (0.95), and a relatively smaller increase from 466 nm to 646 nm (0.97). The dust aerosols noted here has average τ_{440} 0.73 to 0.77 and exhibit UV-Vis AAE between from 2.9 to 3.4. For our sample, carbonaceous aerosols are observed over Kanpur and Gandhi College with similar regional average
465 absorption during SON and DJF. The spectral behavior of carbonaceous aerosols shows increase in average SSA

from 340 nm (0.91) to 466 nm (0.93) and slight decrease till 646 nm (0.91). The regional average UV-Vis AAE for carbonaceous aerosols range 1.2 to 1.5. Emissions from crop residue burning during SON and biomass burning for residential heating in DJF prevail over the entire Indo-Gangetic plain and likely result in such absorption. In addition the vehicular and industrial emissions add an extra burden of aerosols to the atmosphere.

470 In other words, urban aerosols over the Northern India can be categorized as carbonaceous aerosols resulting from various carbon emitting, both black and organic carbon, sources such as crop residue burning, local biomass burning for house-hold heating purposes in DJF months, vehicular and industrial emissions. These urban aerosols are relatively more absorbing ($\omega_o(466) \sim 0.89$) than the carbonaceous aerosols ($\omega_o(466) \sim 0.93$) from industrial/vehicular activities observed over Northern India. Throughout the seasons, influence of pollution

475 aerosols is clearly evident in the observed urban aerosol absorption. Although the UV-Vis AAE is found to be in the similar range, the AAE_{354_388} values are low for urban than carbonaceous aerosols indicative of high organic amounts in crop-residue/biomass burning emissions. For the group of aerosols in between the fine and coarse mode the spectral variation of SSA varies widely.

6 Discussion

480 Through extensive studies in the literature it is known that optical properties of biomass burning aerosols depend on fuel/vegetation type, combustion processes, available moisture content (e.g., Ward, 1992; Reid and Hobbs, 1998; Reid et al., 1998; Eck et al., 2001). Such studies reported varying properties of aerosols emitted from two phases of vegetation burning: flaming and smoldering. While flaming phase rapidly oxidizes the available volatile hydrocarbons in the biomass, smoldering phase mostly requires a surface where slow diffuse oxygen

485 converts the biomass through exothermic reaction. In general, burning of grasslands happens through flaming combustion process that emits high amounts of soot, while smoldering combustion prevail the burning of woodlands/deciduous forest that emits less soot. The observed aerosol absorption at the biomass burning sites (figure 6) clearly makes this distinction. Over South America, in addition to the emissions from burning rainforest (near by Alta Floresta and Ji Parana), Cerrado (wooded grasslands) type vegetation dominates at most

490 sites considered here. Such biomass burning occurs through smoldering combustion exhibiting relatively high aerosol ω_o (0.93 at 466 nm). Compared to South America, the aerosols over Southern Africa have distinct seasonality and high absorption (figure 6b). Eck et al (2013) demonstrated that this seasonality in aerosol absorption is likely a result of shift in fuel type and combustion process. At the beginning of dry season (starting June), the central region is prone to undergo a rapid burning through flaming process, while in the late dry season

495 (ends November) the wooded lands located southeastern parts begins to burn through dominantly smoldering
process. For the savanna with open grasslands in the northern Australia, biomass burning happens through
flaming combustion producing high amounts of soot, as also noted in our retrievals. Figure 10 shows the regional
average AAE obtained for carbonaceous aerosols at three wavelength pairs. Overall, the average slope of
absorption in visible ($AAE_{466,646}$) and UV-Vis ($AAE_{340,646}$) for carbonaceous aerosols is found to be within 2.
500 This is consistent with the studies that report AAE of biomass burning aerosols from several field campaigns in
the range 1 to 3 (Kirchstetter et al., 2004; Schnaiter et al., 2005; Bergstrom et al., 2007; Clarke et al., 2007).
However, the average $AAE_{354,388}$ obtained is high up to 4 for most regions. This is likely a result of higher
organic matter in the regional biomass types and highlights the importance of UV spectral region in delineating
such group of aerosols. For the savanna grasslands in Australia where flaming combustion prevails the mean
505 $AAE_{354,388}$ is relatively low (2.2 or less) compared to other biomass burning regions. For the sample obtained at
Ilorin in Sahel and Cairo in the Arabian Peninsula, the mean AAE was found up to 2 for all wavelength pairs.
Further, it is noted that carbonaceous aerosols observed over Northern India, Northeastern China, Sahel, and
Arabian Peninsula has an average $\alpha_{440-870} \sim 1.4$ (i.e., at the lower end of the fine-mode range), while in South
America, South Africa and Australia has average ~ 1.8 . This indicates the role of aerosol mixing and secondary
510 processes in emanating the observed variability in aerosol absorption other than its composition alone.

For dust aerosols, minerals such as hematite and other form of oxides play role in scattering/absorption of
particles. The absorbing nature of pure dust aerosols close to the source is sensitive to the presence of hematite
than other minerals at shorter wavelengths (Sokolik and Toon, 1999). In addition to the sedimentation of coarse
515 aggregates, the dust aerosols observed away from the source are often found to have mixed (internally or
externally) with anthropogenic aerosols altering its absorbing nature. For example, ω_o of dust aerosols were
reported as 0.83 to 0.87 near the source and ~ 0.9 far away from the source over the tropical North Atlantic Ocean
using satellite measurements at 331 nm (Torres et al., 2002). For the dust aerosol samples obtained in this work,
high absorption at 340 nm with a regional average of ~ 0.86 is noted for Sahara, while relatively lower absorption
520 ~ 0.90 is noted for the Sahel region. The mixing of dust with biomass burning emissions and local pollutants over
the Sahel likely attributed to the observed low absorption. Similar low absorption (0.90) of dust at 340 nm is
observed for the Arabian Peninsula region. However, the UV-Vis spectral dependence noted at the Sahel, and
Arabian Peninsula varies significantly. Figure 11 shows the regional average AAE obtained for dust aerosols at
three-wavelength pairs. Among the dust-prone regions considered here, the regional average of the UV-Vis
525 spectral dependence ($AAE_{340,646}$) is found to be close to or greater than 3 for all, except the Sahel and Eastern

China, where average value ranges 1.5 to 2.5. Although no distinct seasonal variation in spectral absorption of dust is noted, the variability in spectral dependence over the regions is quite evident. Overall the regional average of AAE for dust aerosols observed here is consistent with insitu measurements that report values ranging 1.5 to 3.5 (Bergstrom et al., 2004, 2007; Müller et al., 2009; Petzold et al., 2009). However, observations at individual sites (Table 3) show that the spectral dependence of the observed dust for few sites is relatively high than those reported by insitu measurements. Considering our retrieval method where aerosol absorption is derived independently for each wavelength and have computed the dependence, our results agree reasonably well with the insitu measurements reported in the literature.

While urban aerosols constitute dominantly sulfates and other forms of nitrate particles, industrial emissions and fossil fuel combustion produces various forms of carbon that contribute to the overall optical properties. Further the aerosol size growth due to increase in relative humidity in the atmosphere and coagulation processes are known to alter the absorbing nature of aerosols. Figure 12 shows the regional average AAE obtained for urban aerosols at three-wavelength pairs. Urban aerosols in highly polluted environments such as over the Mexico City have near unity spectral dependence. While the passage of biomass burning emissions over such environment show unusual decrease in absorption at the UV region attributing to high AAE_{354_388} . This is consistent with studies that report relatively high AAE in UV region and near unity in visible region for the aerosol mixture consisting of organic matter and black carbon amounts (Barnard et al., 2008; Vanderlei Martins et al., 2009; Bergstrom et al., 2010; Jethva and Torres, 2011). The urban aerosols found in our sample over Northern Indian and Eastern China are highly absorbing exhibiting $AAE_{340_646} \sim 1.5$ than the carbonaceous aerosols with $AAE_{340_646} \sim 2$. These results suggest the combination of magnitude of aerosol absorption and its spectral dependence in UV, visible and UV-Visible spectrum could be used to partition mixture of aerosol types found in such environments. Overall the regional average UV-Visible AAE for the urban aerosols is found to be near 2.

7 Comparison with AERONET SSA product

We compare of our aerosol SSA retrievals at the visible wavelengths with that available from AERONET data set. The comparison of SSA retrievals is limited to $\tau_{440} > 0.4$ and where AERONET Level-2 inversion is available. It should be noted that since AERONET SSA is a derived quantity and cannot be considered as 'ground truth', this comparison serves as a consistency check rather than a validation exercise. For ease in comparison, we transform the AERONET SSA at 440 and 675 nm to MODIS wavelengths of 466 and 646 nm

555 respectively following interpolation. This conversion will unlikely introduce any bias in our comparison as the difference in the nearest wavelengths of both data sets is very low (< 30 nm).

First, we investigate the consistency of retrieved SSA for selected sites for which the prevailing aerosol types and local source environment are well known as documented in several studies in the literature. We use the AERONET SSA from time period 2005-2016 for the comparison. Figure 13 shows the comparison of average spectral SSA for three distinct aerosol types sampled from the selected sites. The vertical bars shown in the figure corresponds to the uncertainty estimate provided by AERONET (± 0.03) and the estimate due to change in ± 0.01 surface reflectance for our retrieved SSA (± 0.05). For dust aerosols, the retrieved average SSA show good agreement with AERONET SSA obtained at Dakar and Ouagadougou (within ± 0.008), while the differences in SSA (retrieved minus AERONET) at Tamanrasset and Solar Village are $+0.02$ and $+0.05$ respectively at 466 nm. Although our sample is limited for few days that met our criteria for subset, the observed differences in SSA are within the uncertainty estimates as also noted from the overlapping error bars. For carbonaceous particles, the retrieved and AERONET SSA agree well with differences of less than 0.015 for Alta_Floresta, CUIABA and Mongu. However, notable difference in SSA (0.045) is observed at the Lake_Argyle with high absorption for AERONET than our retrieved value at both 466 nm and 646 nm. It should be noted that, while AERONET version 3 employs surface reflectance following BRDF parameters from MODIS BRDF/Albedo CMG Gap-Filled Snow-Free Product MCD43GF (Sinyuk et al., 2020), we use MODIS MCD19A1 surface reflectance product. For absorbing aerosols, the SSA differences observed here is likely a result of different surface reflectances data employed by the two data sets. For urban/industrial aerosols at GSFC, Avignon, Moldova and Cairo the retrieved SSA agrees within the uncertainty estimates. Particularly notable difference (-0.05) is found for Avignon at 646 nm.

Figure 14 shows the comparison of retrieved SSA with AERONET for all collocated observations. For the SSA at 466 nm, the observations within ± 0.03 (± 0.05) envelopes are 26% (59%), 38% (63%) and 34% (56%) for dust, carbonaceous, and urban aerosol types, respectively. It is observed that for dust aerosols, the observations are well concentrated in a narrow range of SSA (retrieved values range from 0.92 to 0.99 at 466 nm), while for carbonaceous (0.86 to 0.95 at 466nm) and urban types (0.84 to 0.98 at 466 nm) the observations become increasingly scattered through wide range of SSA. In terms of wavelength, the observations at 646 nm are more widely scattered than for the SSA at 466 nm for all aerosol types. For the SSA at 646 nm, the observations within ± 0.03 (± 0.05) envelopes are 73% (87%), 39% (60%) and 28% (45%) for dust, carbonaceous, and urban aerosol

types, respectively. The root mean square error (RMSE) of the SSA ranges from 0.04 to 0.09 with lowest error for dust particles at 646 nm and highest error for urban aerosols at 646 nm. Among the aerosol types, it is noted that our retrieved SSA for dust at 466 nm has relatively high scattering than AERONET, while for other types the results are found to be consistent.

590

Figure 15a shows the comparison of retrieved SSA with AERONET by combining all aerosol types together. Our retrieved SSA at 466 and 646 nm agree with AERONET SSA for 34% (0.06) and 40% (0.07) of observations (RMSE) respectively. The absolute difference in retrieved and AERONET SSA as a function of optical depth is shown in figure 15b. The differences in SSA for both wavelengths at 466 nm and 646 nm are higher for lower τ and become negligible for higher τ . It is observed that at 466 nm, the observations with positive differences are relatively more than that at 646 nm. It is important to note here that our retrieval method and that used in the AERONET inversion differ fundamentally in several aspects. Other than the different source of surface reflectance data used, one major distinction between the two methods is that the present inversion algorithm retrieves SSA at different UV and Vis wavelengths independently, whereas the AERONET algorithm internally applies a condition ensuring the spectral shape of SSA follows an expected pattern for the observed aerosol type (private communication with Thomas Eck, NASA GSFC). The differences noted between our SSA retrievals and that from AERONET at different wavelengths could be attributed, at least partially, to this treatment of reported values of SSA.

600

8 Summary

Ground-based measurements of direct solar radiation under cloud-free conditions over worldwide sites are providing valuable insights into regional aerosol characteristics. Long-term measurements obtained from such network, such as from AERONET, are widely used to develop regional aerosol climatology and investigate seasonal/annual variability. Satellite measurements of TOA radiances are able to provide global distribution of columnar aerosol amounts. However, deriving aerosol optical properties from satellite measurements require constraints on particle sizes and optical properties. Reliable aerosol measurements from ground-networks and airborne/field campaigns are traditionally used to validate and improve the constraints in satellite aerosol retrievals. In this work, we use AERONET measured extinction τ as constraint in a robust inversion technique that uses satellite measured TOA radiances from OMI and MODIS to derive spectral aerosol absorption in the UV-Vis part of the spectrum. Other than cloud contamination of the TOA radiances, major sources of error in our

610

615 retrieved SSA come from surface reflectance, and aerosol layer height. We use TOA radiance observations with
minimal or no cloud-contamination reported by both OMI and MODIS products. Sensitivity tests show that our
retrieved aerosol SSA has reliable accuracy up to ± 0.03 from UV-Visible wavelengths for absorbing aerosols
(carbonaceous and dust) with $\tau_{440} > 0.4$. However for less-absorbing aerosols the error in SSA retrieval reaches
up to ± 0.05 . For the sites with low aerosol loading (i.e, τ_{440} up to 0.2) the accuracy of retrieved SSA reaches up to
620 ± 0.05 at the UV wavelengths, while in the visible it exceeds ± 0.05 . Using a subset of results where SSA is
retrieved independently for 340, 354, 388, 466 and 646 nm wavelengths for the same day with observations $\tau_{440} >$
0.4, we examine the seasonal variability in aerosol SSA and derive spectral dependence (AAE) at three
wavelength pairs in the UV-Vis spectrum.

625 Key observations noted from the spectral aerosol absorption data set derived here are highlighted below:

Biomass burning aerosols

- a) Among sites dominated by biomass burning aerosols, Mongu in Southern Africa has high absorption ω_o
~0.85 to 0.84 from 340 nm to 646 nm.
- b) Strong seasonality in absorption of carbonaceous aerosols is evident in Southern Africa indicating the
630 role of biomass types and combustion process. The average ω_o from 340 nm to 646 nm during JJA and
SON are ~0.85 to 0.84, and ~0.88 to 0.89, respectively.
- c) Carbonaceous aerosols found over Northern Australia are as strongly absorbing (ω_o ~0.87 to 0.86 from
340 nm to 646 nm) as smoke over Southern Africa but has relatively constant absorption from UV-Vis
spectra.
- 635 d) Carbonaceous aerosols found over Alta_Floresta in the Amazon Basin have similar absorption (ω_o ~0.89
to 0.91 from 340 nm to 646 nm) and UV-Vis AAE (1.8) to those found over Missoula in North America.
- e) Highly absorbing carbonaceous aerosols (ω_o ~0.86 to 0.87 from 340 nm to 646 nm) with weak spectral
dependence are found in Cairo and Ilorin in the Sahel region during winter (DJF). These carbonaceous
particles exhibit mean $\alpha_{440-870} < 1.4$, indicating possible mixture of fine and coarse modes.
- 640 f) Carbonaceous aerosols found over Northern India, Eastern China, Sahel, and Arabian Peninsula
exhibiting (ω_o ~0.86 to 0.89 at 340 nm) has low average $\alpha_{440-870}$ (< 1.4) than over other prominent
biomass burning regions, suggesting mixture of fine and coarse modes.
- g) Distinct seasonality in spectral absorption of carbonaceous and urban aerosols is noted for Eastern China.
For carbonaceous aerosols, the maximum and minimum absorption at 466 nm are found during DJF
645 ~0.90, and JJA ~0.95, respectively.

Dust aerosols

- 650 a) For desert dust aerosols, the SSA is known to increase with wavelength from UV to Visible spectrum. No distinct seasonality in SSA is noted. The regional averages of SSA for dust aerosols from 340 nm to 646 nm are 0.86 to 0.98, 0.88 to 0.96, and 0.90 to 0.99 over Sahara, Sahel and Arabian Peninsula respectively.
- 655 b) For regions where sources are nearby the sites (Sahara, Middle East/Arabian Peninsula) the AAE for all three wavelength pairs considered exhibit high average values ($\gg 3$), while for regions where lofted dust through long-range transport is observed (Northern India, Eastern China, parts of Sahel) the average AAE has a range between 2 to 3.

Urban aerosols

- 660 a) Urban aerosols ($\omega_o(340) \sim 0.87$) are more absorbing than the carbonaceous aerosols ($\omega_o(340) \sim 0.90$) and exhibit distinct seasonality (higher absorption during JJA than SON) in South America at CUIABA and Sao Paulo. The urban aerosols noted here are likely mixtures of carbonaceous particles transported over the region and prevailing pollution from local sources.
- 665 b) High absorption from UV ($\omega_o(340) \sim 0.87$) extending to the blue spectral region ($\omega_o(466) \sim 0.90$) is noted for most sites in Europe during SON and/or DJF months indicating the presence of organic matter due to local fuel combustion sources.
- c) Polluted aerosols observed over Mexico City shows high absorption in UV ($\omega_o(340) \sim 0.88$) extending to visible ($\omega_o(466) \sim 0.85$) spectrum during DJF and SON months.

As mentioned, the results presented here are limited to our subset of retrievals, where SSA is retrieved for all five
670 wavelengths from UV-Visible range with $\tau_{440} > 0.4$. However, relaxing the τ_{440} up to 0.2 (see supplementary materials) does not yield significant changes in the derived variability of aerosol absorption and its spectral dependence. Since one of our objectives is to derive UV-Visible spectral dependence (AAE) of aerosols without prior assumptions, and given the inherent sampling bias of the OMI, MODIS and AERONET collocations – the analysis method employed here is well justified. In other words, we made use of the best available data synergy
675 and derive unique aerosol absorption data set with no prior assumptions on wavelength dependence, which otherwise is assumed in the standard satellite-based aerosol retrieval algorithm. Although our results may be

680 biased toward dense pollution/industrial, smoke, and dust events, less-absorbing low aerosol amounts seldom
have dependency on the ω_0 . Therefore, the regional aerosol absorption models derived here offer essential
guidance for selecting spectral absorption in satellite aerosol retrievals spanning the UV-Vis spectrum. From our
analysis of worldwide inland sites: (a) it is suggested that satellite aerosol retrieval techniques could employ
685 regional dynamic absorption models to avoid potential bias in τ retrievals noted in earlier studies, and (b) the
spectral dependence of aerosol absorption noted here for the UV (354-388 nm), visible (466-646 nm) and UV-
Visible (340-646 nm) range for all aerosol types other than black carbon varies considerably. Overall, the UV
absorption data set well compliments and provides more information on the regional aerosol absorption than with
the visible data set alone.

690 Given the lack of aerosol absorption information at near-UV wavelengths in the existing AERONET record and
limited availability of insitu measurements, the UV-Vis aerosol absorption data set developed here, perhaps for
the first time, offers a valuable source of information useful for a variety of aerosol and trace gas studies. The
analysis presented here focuses on regional aerosol absorption using a subset of results. The derived spectral
dependency can be used with all SSA retrievals to construct and investigate long-term trends in UV-Visible
aerosol absorption. Further, the spectral aerosol SSA derived here could be used to parameterize absorption in
models and better understand the radiative effect of aerosols. Our ongoing investigation utilizing the complete
data set developed here will explore some of these applications in the future.

695 **Acknowledgments**

NASA ROSES (ACMAP) – 2016 provided financial support for this work under the grant NNH16ZDA001N.
The authors are grateful to Brent Holben and the entire AERONET team for their efforts on maintaining
AERONET sites worldwide and providing quality assured data to the community. The authors thank all PIs and
Co-PIs of the individual AERONET sites that were used in this work.

700 **Competing Interests**

The authors declare no conflict of interests.

Author Contributions

Omar Torres (OT) and Hiren Jethva (HJ) had conceptualized the research. Vinay Kayetha (VK) developed the data set, performed formal analysis, and wrote the manuscript with inputs from OT and HJ. All authors reviewed results, helped with the data interpretation and edited the manuscript to make a final version.

Data Availability

The spectral aerosol absorption data set developed here will be made available upon request to the authors.

Tables

940 **Table 1: Description of the ground and satellite data products used in this work.**

<i>Purpose</i>	<i>Instrument</i>	<i>Product</i>	<i>Level & Version</i>	<i>Parameter(s)</i>
For SSA retrieval in this work	AERONET	AOD	L2, V3	AOD and extinction angstrom exponent.
		Inversion	L2, V2	Particle size distributions, and real part of refractive index at 440 nm.
	OMI	OMLERWAVE, OMAERUV	L2, V1.8.9.1	TOA reflectances (with QFs), Aerosol type, LER, Aerosol layer height obtained from CALIPSO.
	MODIS	MYD04	L2, C006	TOA reflectances (with QFs) provided by Deep-Blue algorithm.
MAIAC MCD19A1		L2, C006	Surface reflectance at 466 and 646 nm.	
Comparison	AERONET	Inversion	L2, V3	SSA at 440 and 675 nm.

945

Table 2: Estimated uncertainty in the retrieval of aerosol SSA due an error in surface reflectance of ± 0.01 .

		$\tau_{440} = 0.2$		$\tau_{440} = 0.4$	
		340 nm	646 nm	340 nm	646 nm
Carbonaceous	± 0.01 Surf. Albedo	± 0.010	± 0.045	± 0.005	± 0.031
	± 1 km ALH	± 0.025	± 0.005	± 0.014	± 0.001
	± 0.02 AOD	± 0.004	± 0.040	± 0.001	± 0.018
Dust	± 0.01 Surf. Albedo	± 0.027	± 0.049	± 0.011	± 0.020
	± 1 km ALH	± 0.034	± 0.003	± 0.019	± 0.001
	± 0.02 AOD	± 0.006	± 0.036	± 0.004	± 0.018
Urban	± 0.01 Surf. Albedo	± 0.017	± 0.072	± 0.011	± 0.046
	+ 1 km ALH	0.009	0.0004	0.004	0.0003
	± 0.02 AOD	± 0.006	± 0.062	± 0.004	± 0.028

Table 3: Retrieved seasonal average SSA at 340, 354, 388, 466 and 646 nm and AAE at UV-Visible wavelength pairs for Carbonaceous, Dust, and Urban aerosols with observations $\tau_{440} > 0.4$ over individual AERONET sites from 2005 – 2016. Abbreviations used: AType is the aerosol type, NDays is the number of independent days, and NObs is the number of observations.

Site	AType	Season	NDays	NObs		τ_{440}	$Q_{440-870}$	Average SSA(λ)						Average AAE

Figure 2: Schematic flow chart of the methodology used to retrieve aerosol spectral single scattering albedo.

971

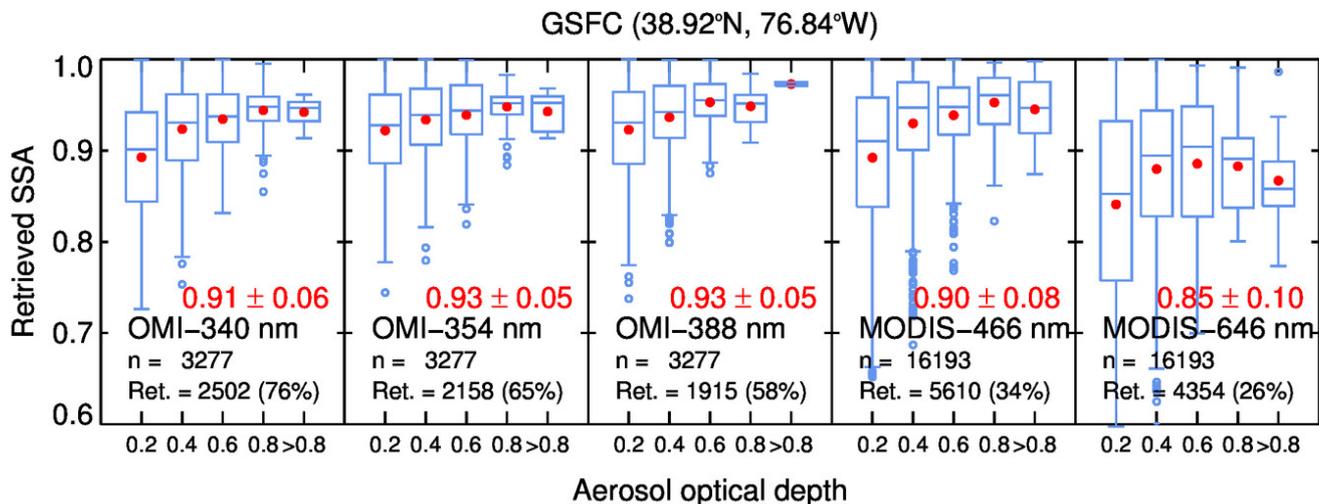

972
973
974
975

Figure 3: Simulated TOA radiances for the aerosols over the GSFC site as a function of τ and SSA in the UV-Visible range.

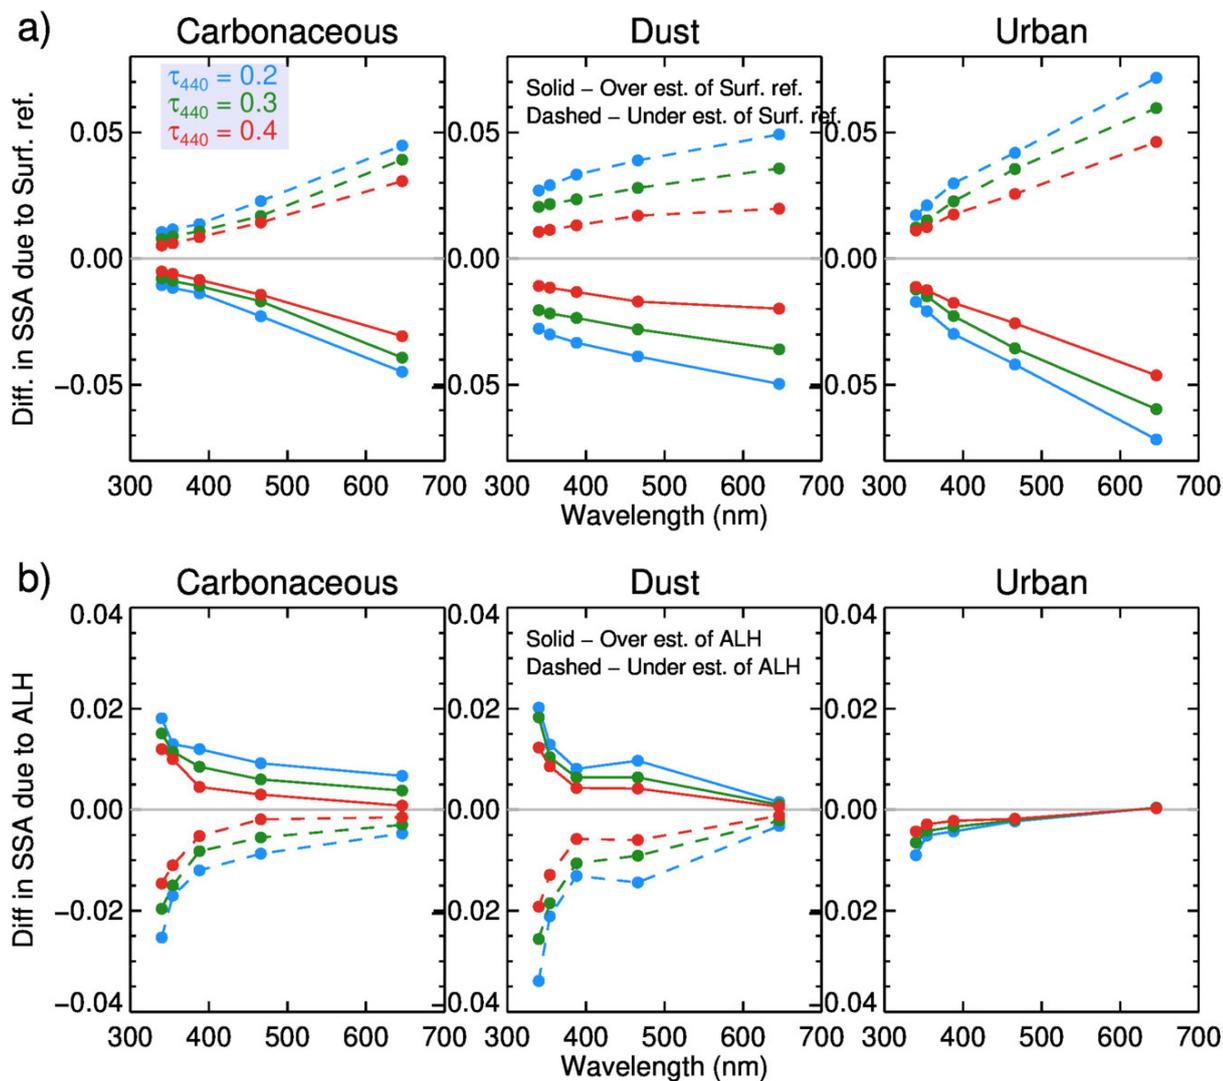

975

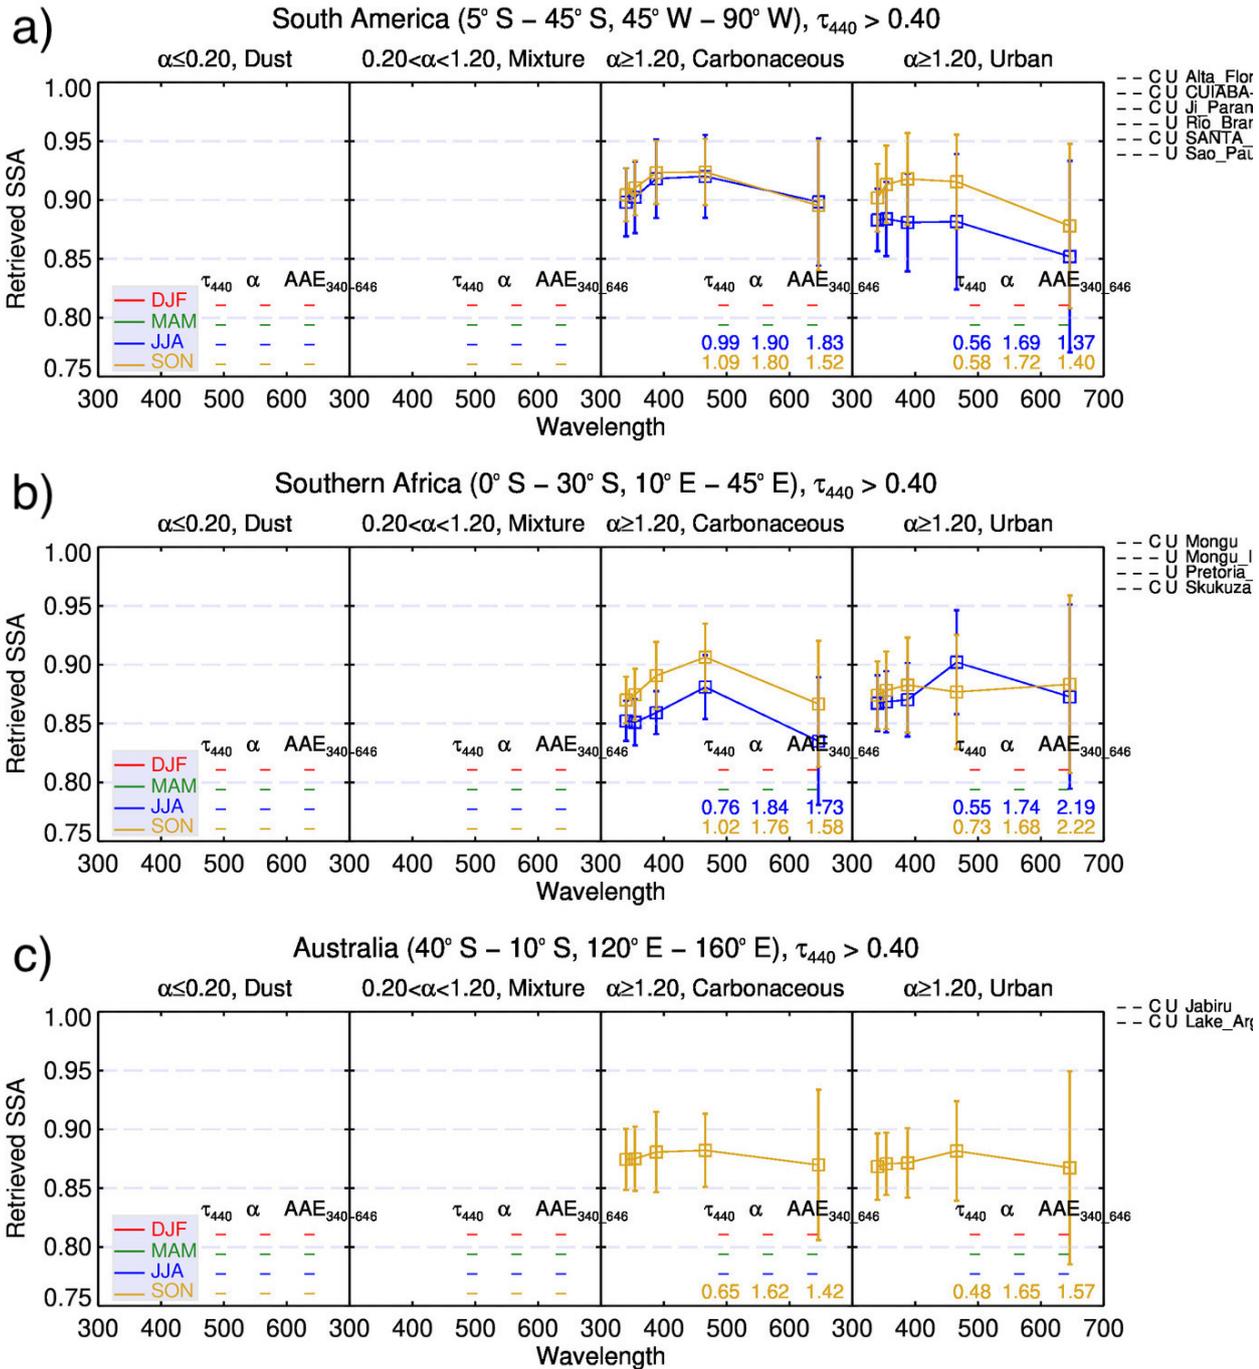

980

Figure 4: Retrieved aerosol SSA over the GSFC site for the satellite observations period of 2005 – 2016. Average and standard deviation of retrieved SSA for the entire range of AOD is shown in red. Abbreviations used: n is the number of satellite-AERONET collocated observations, and ret. is the number of observations for which SSA is retrieved.

985 **Figure 5: Uncertainty in SSA retrievals due to changes in (a) ± 0.01 surface reflectance, and (b) ± 1 km ALH.**

990

Figure 6: Regional average of spectral aerosol SSA derived for observations with $\tau_{440} > 0.4$ over (a) South America, (b) Southern Africa, and (c) Australia. The error bars represent the standard deviation of the observations.

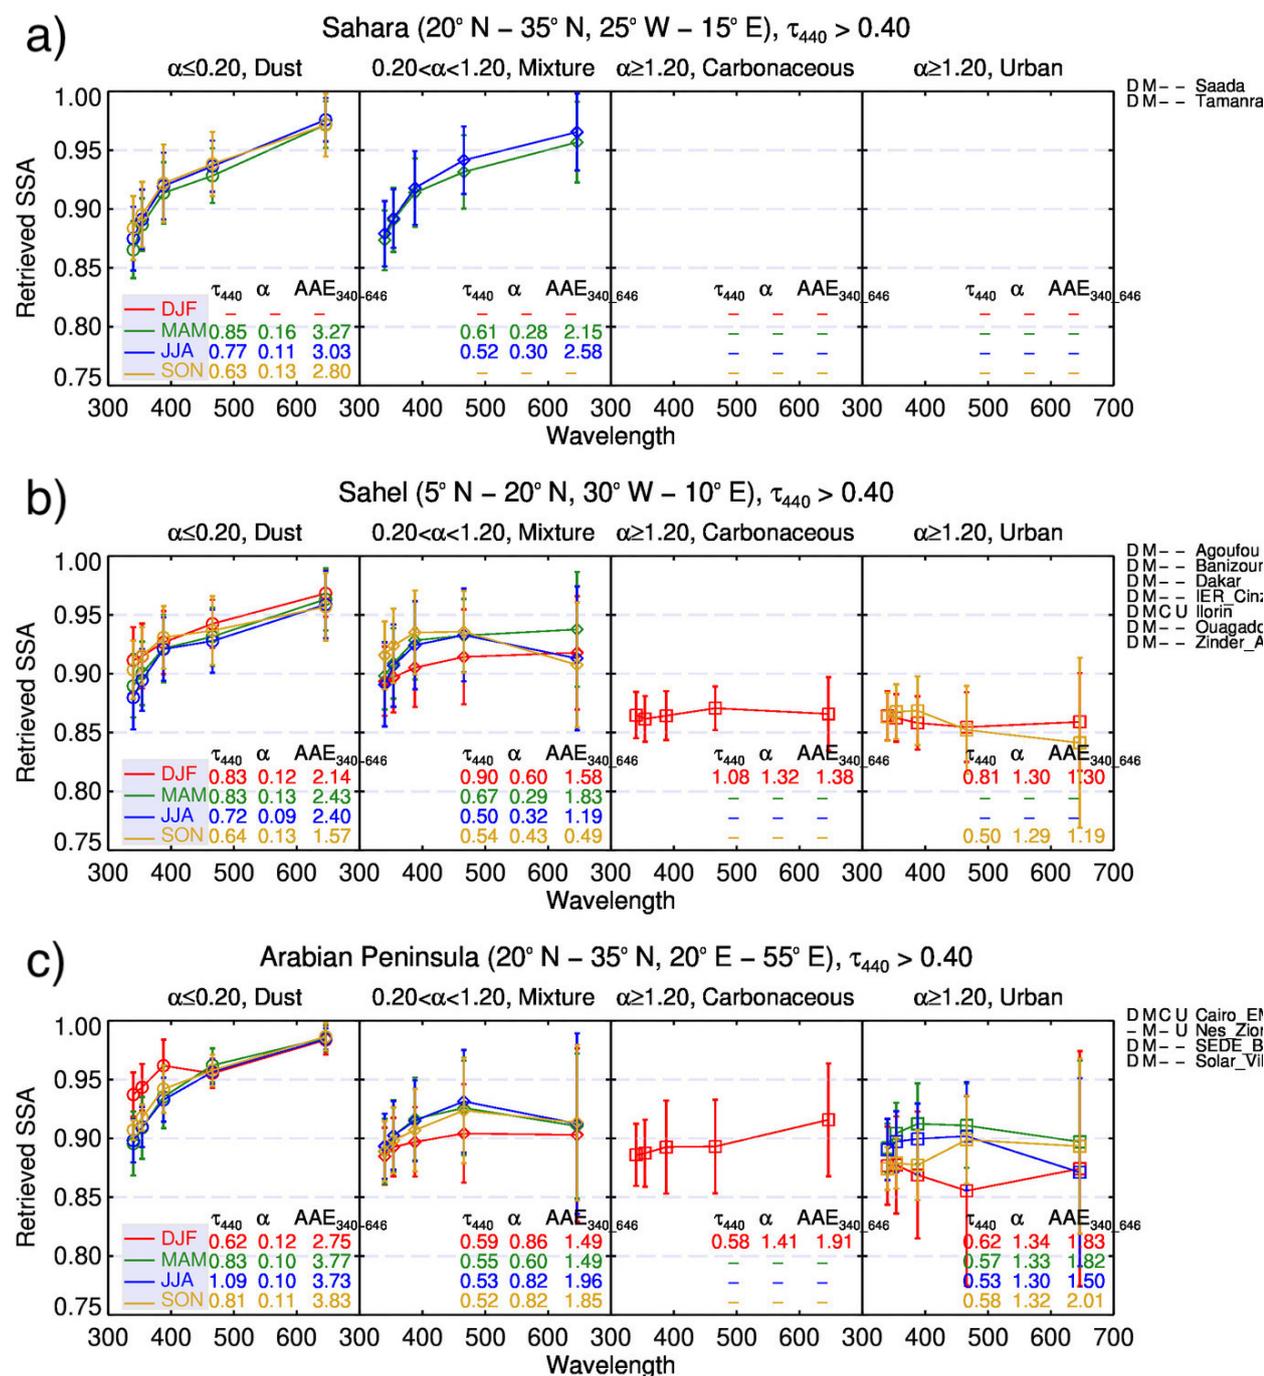

Figure 7: Same as in figure 6 but over (a) Sahara, (b) Sahel, and (c) Arabian Peninsula.

1000

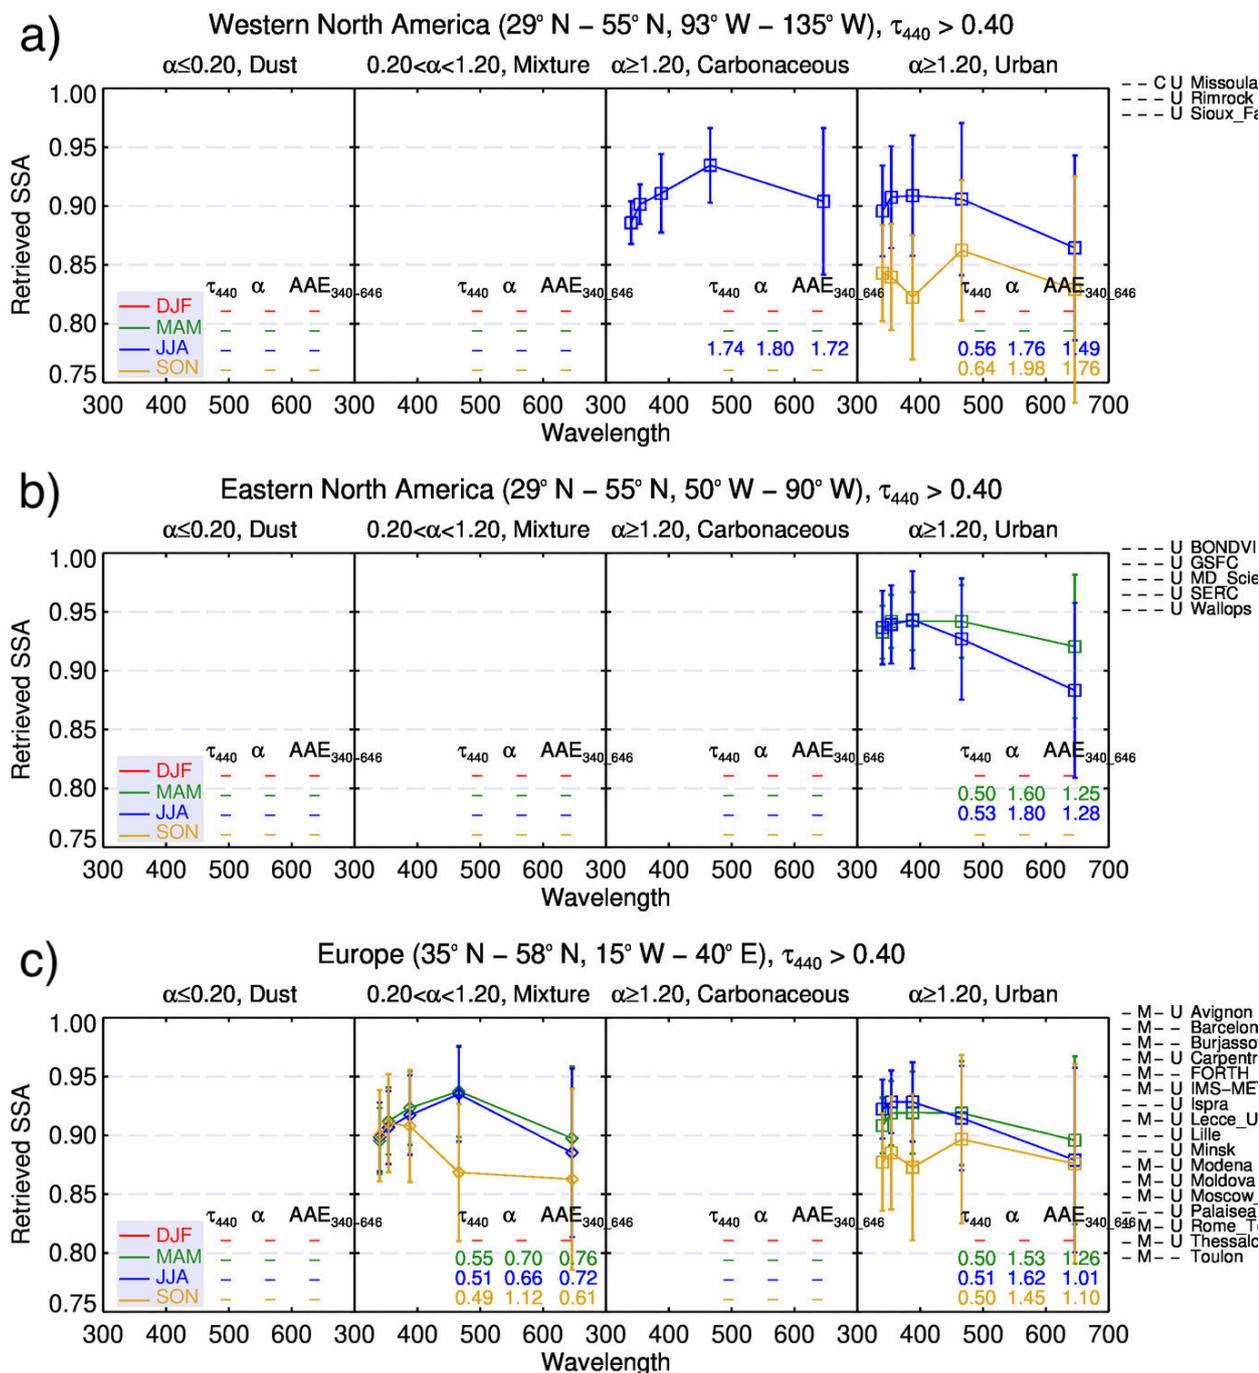

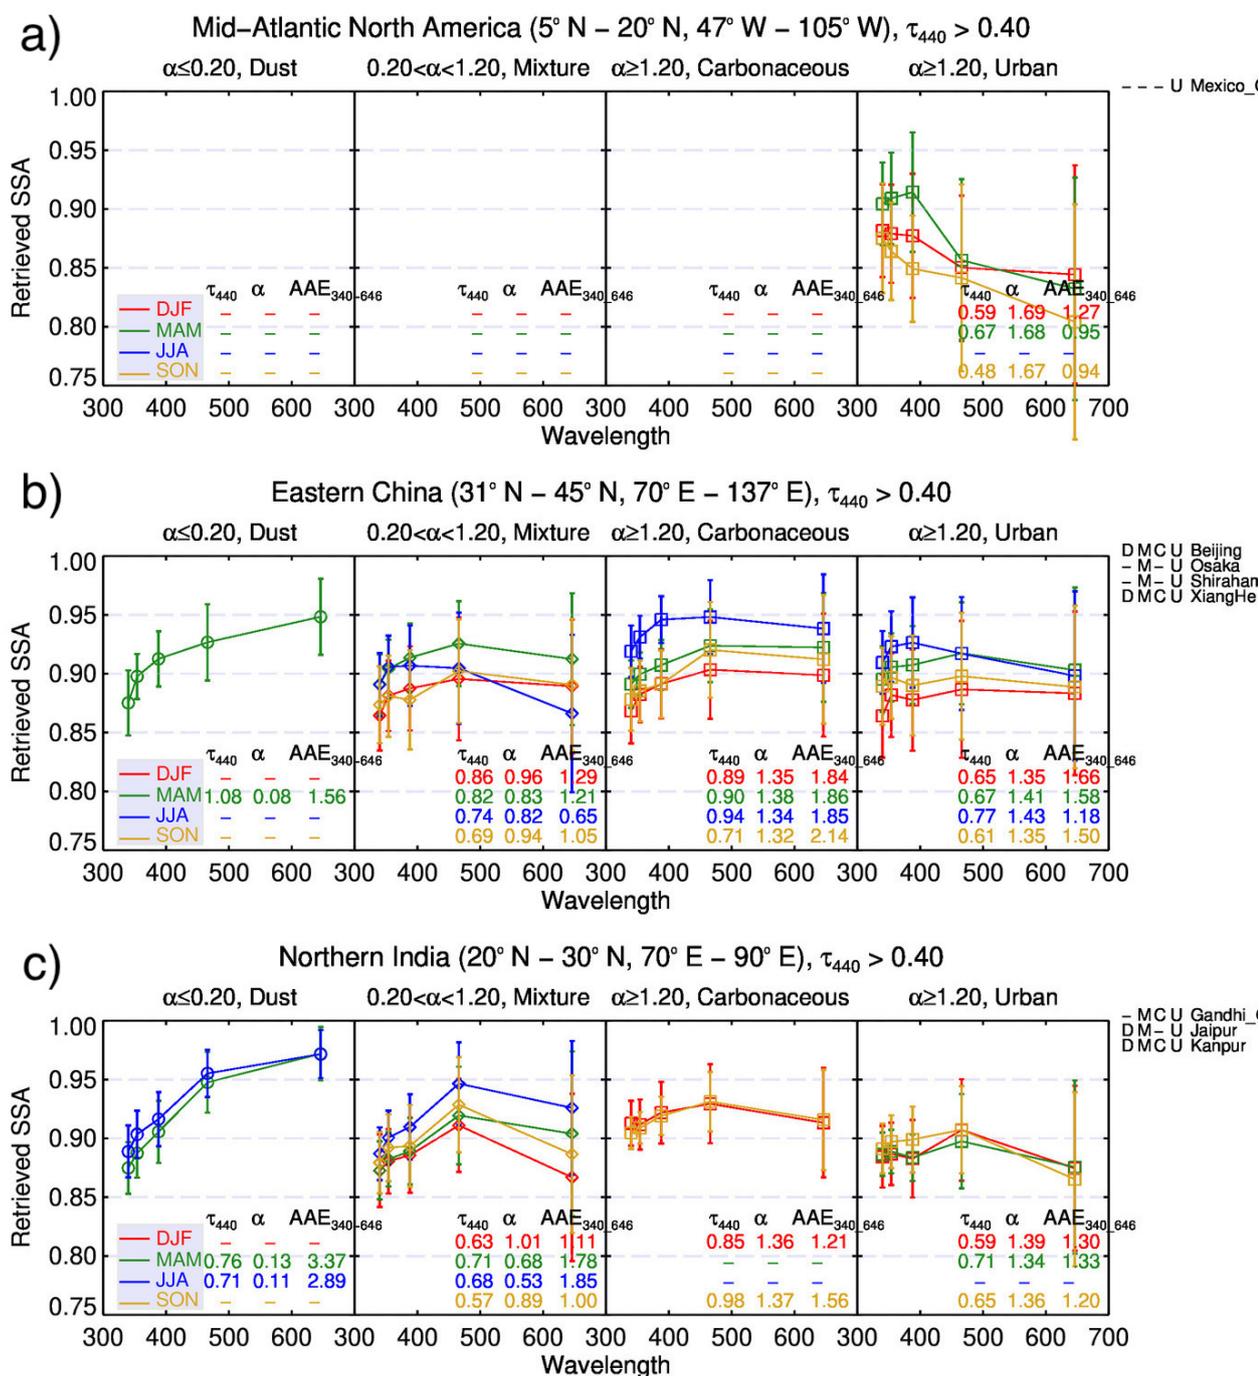

Figure 8: Same as in figure 6 but over (a) Western North America, (b) Eastern North America, and (c) Europe.

1005

1010 **Figure 9: Same as in figure 6 but over (a) Mid-Atlantic North America, (b) North-Eastern Asia, and (c) Northern India.**

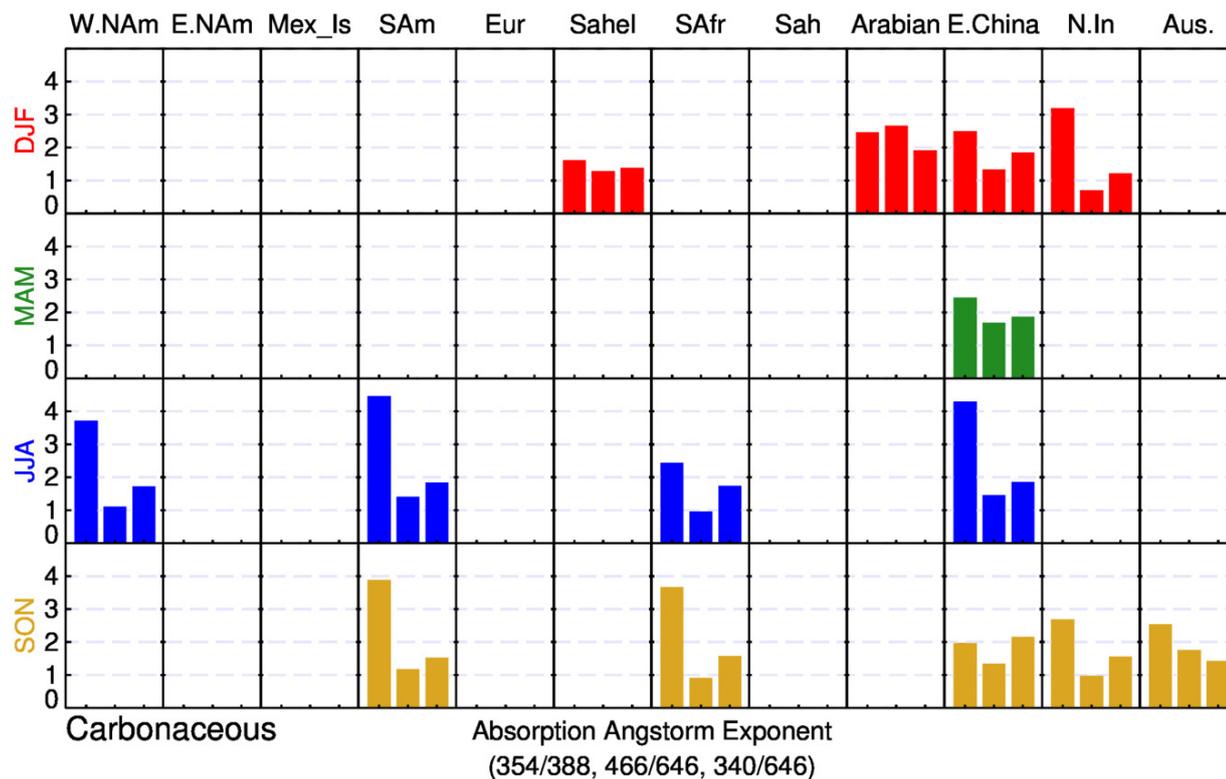

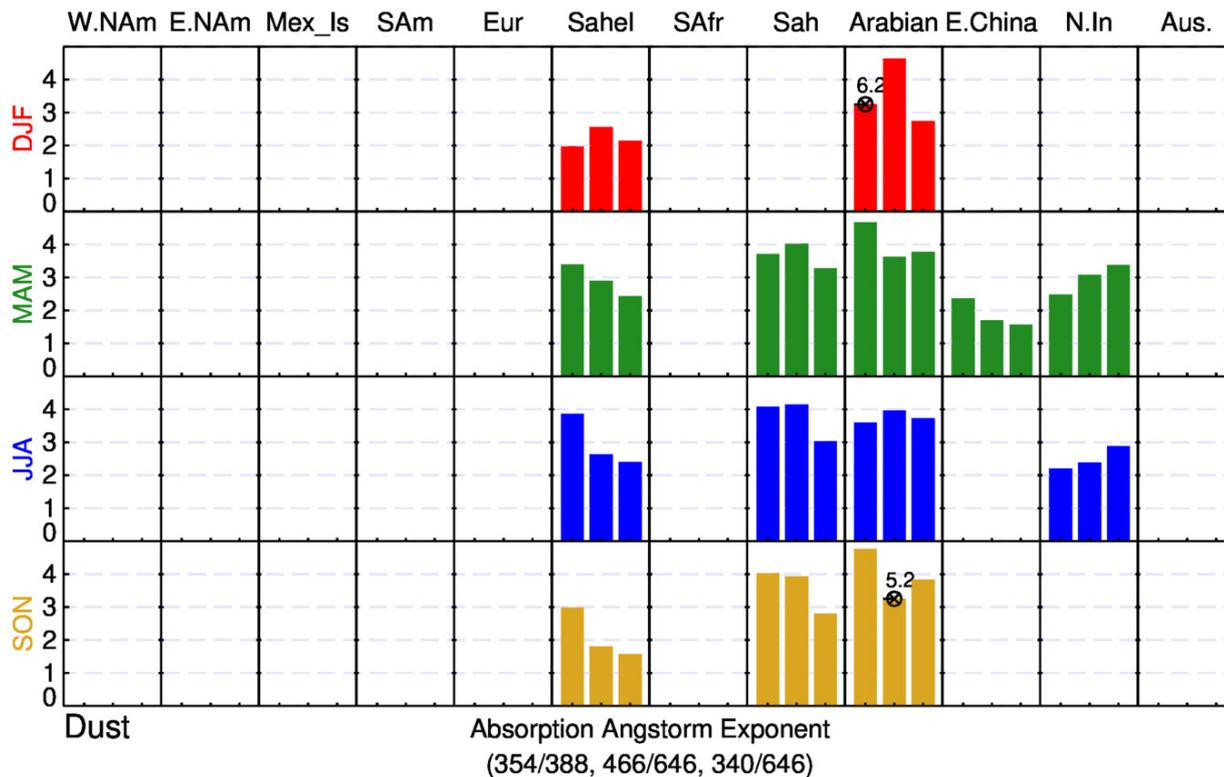

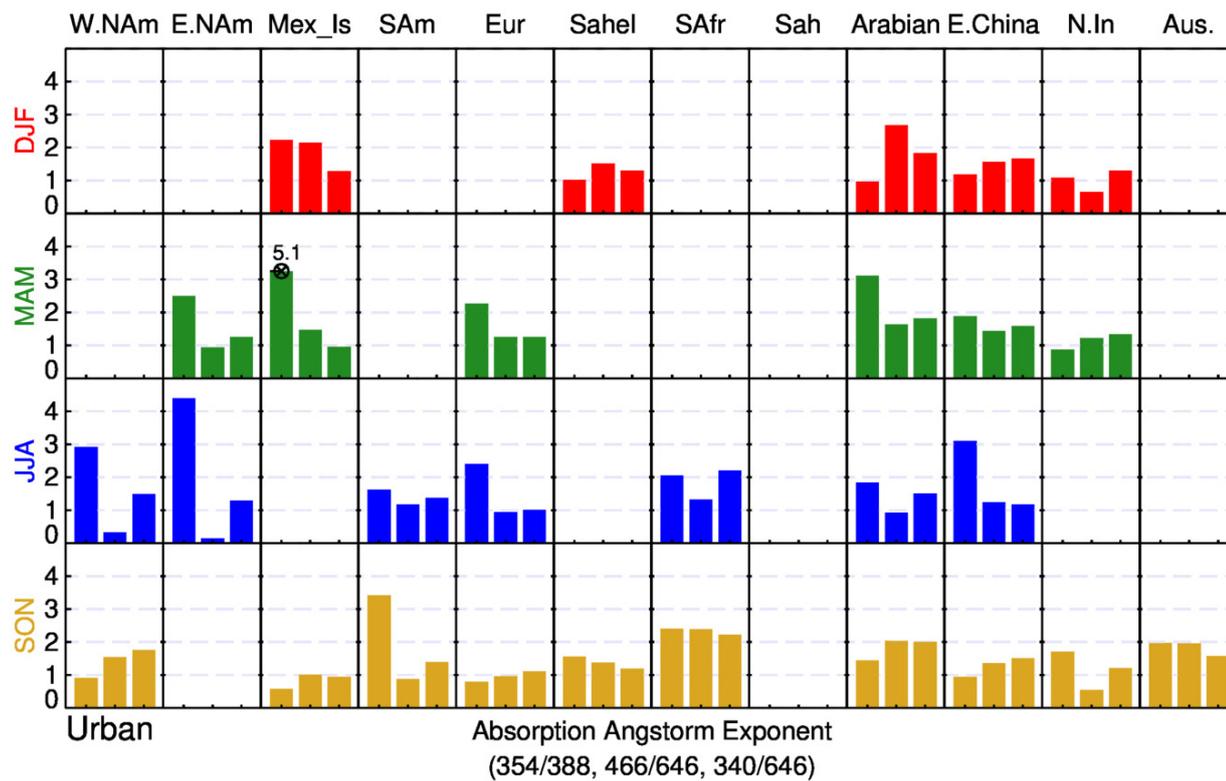

Figure 10: Regional average absorption angstrom exponent at three wavelength pairs from UV-Visible spectrum for Carbonaceous aerosols with $\tau_{440} > 0.4$.

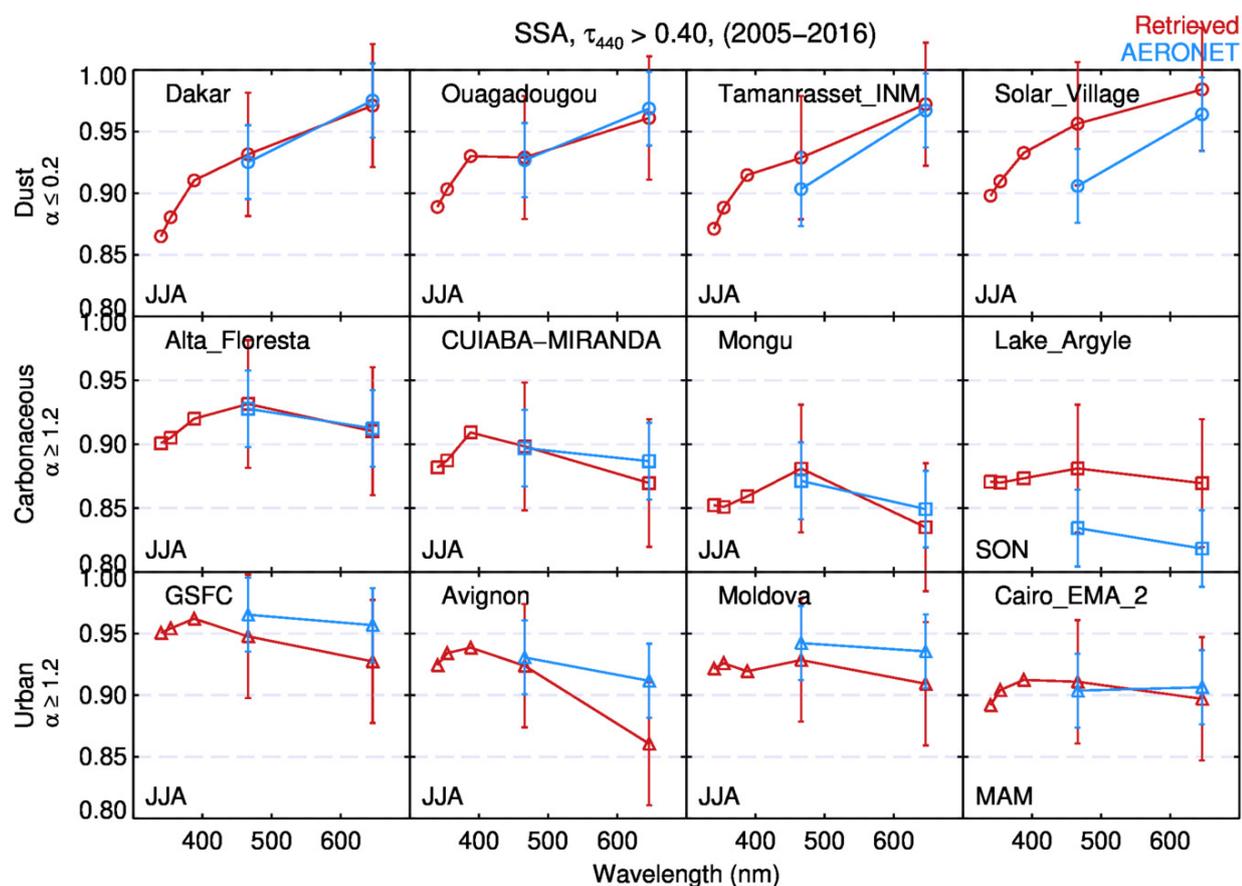

1015

1020 **Figure 11: Same as in figure 10 for Dust aerosols.**

1025 **Figure 12:** Same as in figure 10 for Urban aerosols.

1030

Figure 13: Comparison of retrieved aerosol SSA with that of AERONET for selected sites. The vertical bars represent uncertainty in retrievals – AERONET (± 0.03) and the present work (± 0.05).

1035

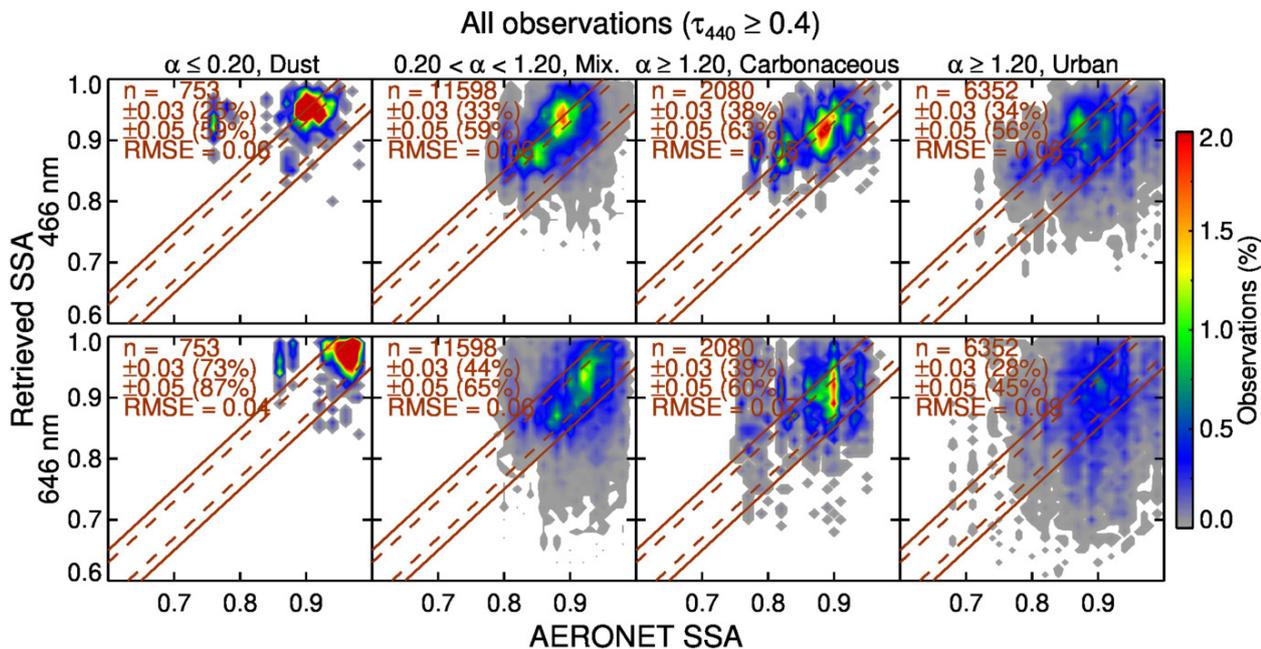

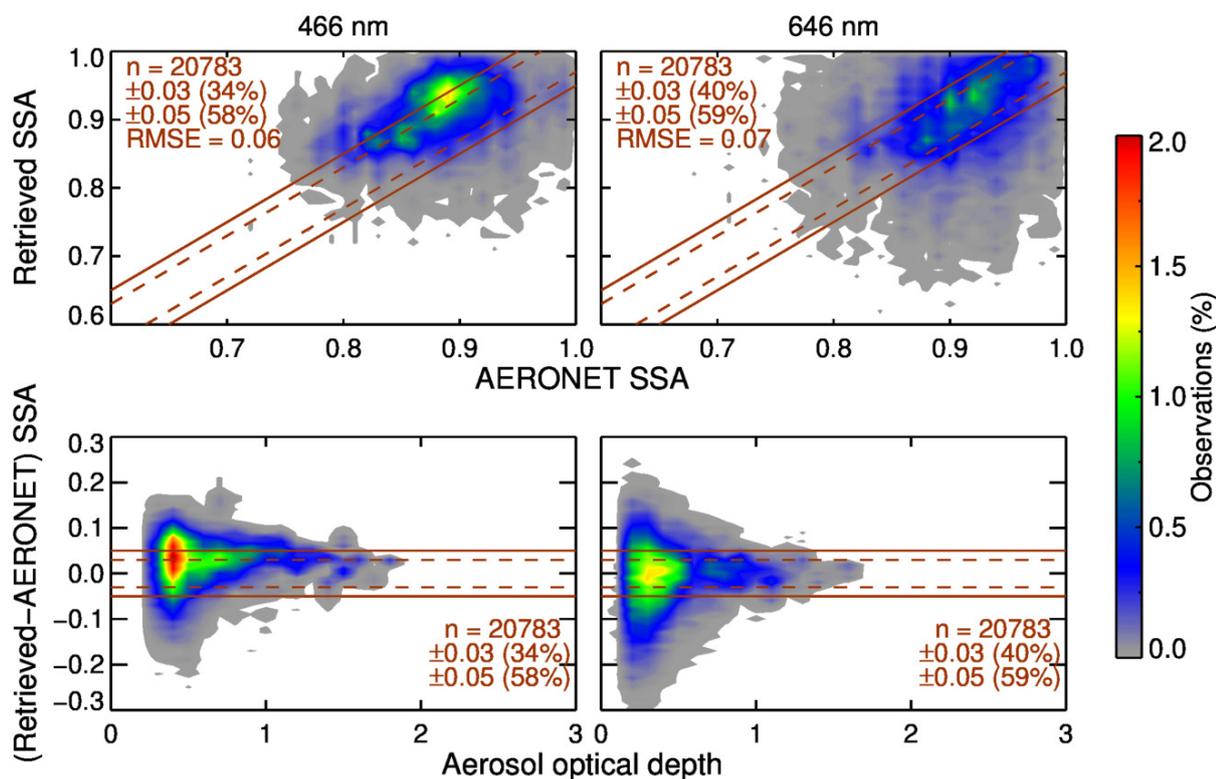

Figure 14: Retrieved SSA versus AERONET at 466 nm and 646 nm for all aerosol types with observations $\tau_{440} > 0.4$.

1040

1045 **Figure 15: (a) Retrieved SSA versus AERONET, and (b) absolute difference in SSA versus AOD - for observations with $\tau_{440} > 0.4$ and combined aerosol types at 466 nm and 646 nm.**
