**Abstract.** Methane, a major contributor to climate change, is emitted by a variety of natural and anthropogenic sources. Commercially available lab-grade instruments for sensing trace methane are expensive, and previous efforts to develop inexpensive field-deployable trace methane sensors have had mixed results. Industrial and commercial metal oxide semiconductor (MO<sub>x</sub>) methane sensors, which are intended for leak detection and safety monitoring, can potentially be repurposed and adapted for low-concentration sensing. As an initial step towards developing a low-cost sensing system, we characterize the performance of five off-the-shelf MO<sub>x</sub> sensors for 2-10 ppm methane detection in a laboratory setting (Figaro Engineering TGS2600, TGS2602, TGS2611-C00, TGS2611-E00, and Henan Hanwei Electronics MQ4). We identify TGS2611-C00, TGS2611-E00, and MQ4 as promising for trace methane sensing, but show that variations in ambient humidity and temperature pose a challenge for the sensors in this application.

## 1 Introduction

Methane is a major greenhouse gas of increasing importance, with a wide variety of natural and anthropogenic sources (Saunio et al., 2016). Commercially available instruments for measuring methane are expensive, limiting the spatiotemporal resolution of monitoring and leak detection (Siebenaler et al., 2016; Riddick et al., 2020a). High-resolution monitoring networks can aid in pollution mapping and source identification, for example in reducing leaks and fugitive emissions from fossil fuel production and distribution, one of the main anthropogenic sources of methane emissions (US EPA, 2017). Accordingly, researchers are investigating several options for lower-cost trace methane sensing with the goal of developing inexpensive sensor networks (Cho et al., 2022; Riddick et al., 2020a), low-cost drone-based solutions (Liu et al., 2021), and similar monitoring methods.

25 One approach is to repurpose off-the-shelf methane sensors designed for industrial or residential safety use. These sensors are intended for leak detection and similar applications, and are generally specified to measure methane concentrations above trace levels (>50 ppm). Atmospheric methane concentrations are currently close to 2 ppm (US Department of Commerce, 2021), and are often outside of such sensors' design parameters. However, the low cost and easy availability of such sensors supports further investigation into this possibility.

30

Off-the-shelf methane sensors are built around several different technologies; Aldhafeeri et al. (2020) summarized the working principle of several common types of methane sensors. Infrared sensors measure the narrow-band absorption of infrared light by methane, with inexpensive sensors using simplified versions of the techniques discussed by Kamieniak et al. (2015) and Shemshad et al. (2012). Pellistor sensors measure the energy released by the combustion of gas on a catalytic surface, with challenges posed by selectivity, high energy consumption, and effects from environmental conditions such as wind speed (Kamieniak et al., 2015). Metal oxide (MOx) sensors measure the change in electrical resistance of a semiconductor layer due to interactions with gas molecules and can be made inexpensively; difficulties with cross-sensitivities and lifespan can be addressed in part with different semiconductor formulations (Meixner and Lampe, 1996). Commercially available MOx sensors have shown promise for monitoring atmospheric levels of other air pollutants besides methane, including O<sub>3</sub>, CO, and NO<sub>2</sub> (Piedrahita et al., 2014; Peterson et al., 2017).

Pellistor and optical sensors are available off-the-shelf from companies such as Amphenol SGX Sensortech, at prices ranging from \$80 to \$300 from distributors (Mouser Electronics, Inc.). A typical example, the INIR-ME-5% optical sensor, priced at \$270, is specified with a lower limit of detection of 100 ppm and is designed for methane concentrations in the percent range (SGX Sensortech, 2018). MOx sensors are often less expensive still; the components we examine range in price from \$5 to \$20, ideal for developing very inexpensive sensor nodes. Due to their low cost and wide availability, we focus on MOx sensors in this study.

### 1.1 Previous studies

Other researchers have investigated MOx sensors for trace methane detection, with results summarized in Table 1. Eugster and Kling (2012) report a TGS2600 sensor (Figaro Engineering Inc.) to follow diurnal trends in methane concentrations in the 1.8-2 ppm range, although with an R<sup>2</sup> of only 0.19. However, Riddick et al. (2020a) found the same method not to work with a wider concentration range, instead developing a different model with excellent accuracy of 0.01 ppm. Collier-Oxandale et al. (2018) also found good results with TGS2600 sensors at two different sites, with RMSE better than 0.4 ppm; however, they found it necessary to use different calibration and regression models for the two sites, and found that their models were somewhat overfitted to other gasses and environmental parameters. Although these studies all found useful performance with the TGS2600, they also found that different calibration models were required for different sites, possibly due to different sources or environmental conditions: in particular, temperature and humidity are known to affect MOx sensor response, as do cross-sensitivities to other gasses (Wang et al. 2010; Huerta et al. 2016; Nabil Abdullah et al. 2020; Kim et al. 2021). It is also possible that these studies had overfitting to site-specific phenomena such as interfering gasses.

60

Van den Bossche et al. (2017) performed a laboratory calibration of a TGS2611-E00 sensor (Figaro Engineering Inc.), finding error around 1 ppm when corrected for humidity and temperature. Bastviken et al. (2020) reported similar errors with

65 TGS2611-E00 in a laboratory calibration and field deployment. Taguem et al. (2021) studied the response of a sensor array including TGS2611, TGS2602 (Figaro Engineering Inc.) and other sensors for biogas detection, which includes methane as a component; however, their analysis did not characterize sensor response to methane alone.

Riddick et al. (2020b) found an MQ4 sensor to match their reference instrument between 100 ppm and 9 % concentrations with an  $R^2$  of 0.99. Honeycutt et al. (2019) determined a lower limit of detection for MQ4 of 82 ppm. Neither study quantified sensor performance in the background to 10 ppm range.

Study	Sensor	Methane concentration	Performance
Eugster and Kling (2012)	TGS2600	1.85 to 2 ppm	$R^2=0.19$
Riddick et al. (2020a)	TGS2600	1.85 to 5.85 ppm	$\pm 0.01$ ppm
Collier-Oxandale et al. (2018)	TGS2600	approx. 2 to 7 ppm	RMSE=0.38 ppm
Van den Bossche et al. (2017)	TGS2611-E00	2 to 9 ppm	generally 1 ppm accuracy
Bastviken et al. (2020)	TGS2611-E00	2 to 500 ppm	$\pm 1.1$ ppm at near-atmospheric levels
Riddick et al. (2020b)	MQ4	100 ppm to 9 %	$R^2=0.99$
Honeycutt et al. (2019)	MQ4	1.85 to 995 ppm	Limit of detection=82 ppm

70 **Table 1. Summary of results of selected studies.**

## 1.2 Study goals

75 These previous studies suggest that some MOx sensors may be useful at ambient methane concentrations; however, as the studies use different experimental methods, algorithms, and concentration ranges, making direct comparisons between the sensors is difficult. In this study, we compare the performance of five MOx sensors for trace methane detection with the hope of clarifying the suitability of these low-cost devices for atmospheric and near-source applications. We characterize the effect of temperature and humidity on sensor response over a methane concentration range of background to 10 ppm. By systematically examining the effect of environmental conditions on sensor performance and by providing a consistent methodology, we provide a direct comparison between the different sensors and an indication of their suitability for trace methane sensing use.

## 80 2 Methods

### 2.1 Sensor selection and configuration

85 We selected five inexpensive, off-the-shelf MOx sensors to test, detailed in Table 2. Three of the sensors (TGS2611-C00, TGS2611-E00, and MQ4) are marketed specifically for methane response (Figaro, 2013; Henan Hanwei Electronics Co., n.d.); one sensor, TGS2600, is marketed for general air pollutant response (Figaro, 2021a); and one sensor, TGS2602, is marketed primarily for volatile organic compound (VOC) detection (Figaro, 2021b). We chose to include TGS2602, which is not

marketed as sensing methane, to confirm whether it could be used in sensor arrays to help account for cross sensitivities, as might be the case if it showed no response to methane.

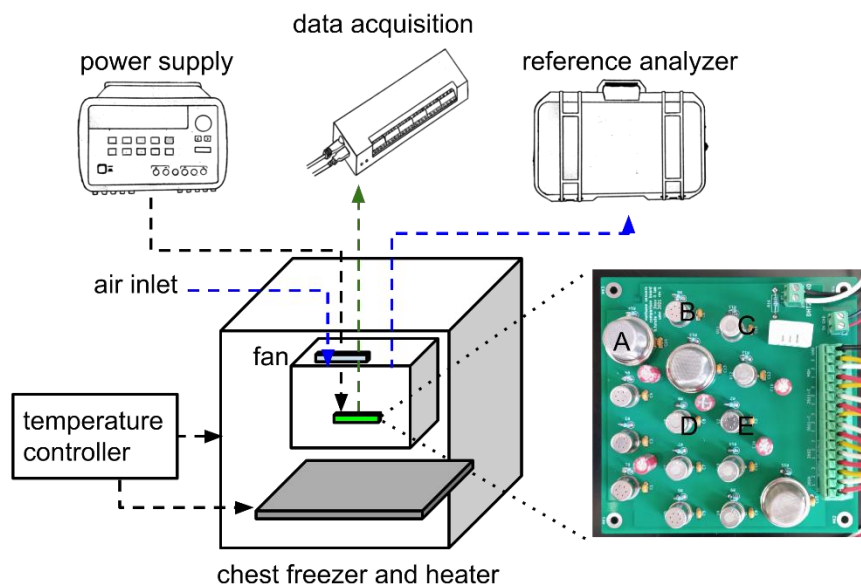

90 The TGS2611 models are built on the same base sensor, with the TGS2611-E00 including an additional filter to block possible interfering gases such as alcohols. TGS2600 and TGS2611-E00 have been characterized for trace methane sensing by the studies listed in Table 1.

Manufacturer	Model	Approximate Price	Target gas
Figaro Engineering Inc.	TGS2600	\$15	general air pollutants
Figaro Engineering Inc.	TGS2602	\$17	VOCs, odorous gas
Figaro Engineering Inc.	TGS2611-C00	\$20	CH <sub>4</sub> - fast response
Figaro Engineering Inc.	TGS2611-E00	\$20	CH <sub>4</sub> - filtered
Henan Hanwei Electronics	MQ4	\$5	CH <sub>4</sub>

**Table 2. Sensors used in this study. Prices for the Figaro sensors and MQ4 are from the distributors Maritex Co. and Pololu Corp., respectively.**

95 MOx sensors respond to gas concentrations with varying electrical resistances. To convert this to a voltage signal which our equipment could record, we placed each sensor in a voltage divider configuration with a 10 kΩ resistor. All of the sensors have internal heaters, which are intended to provide the stable elevated operating temperatures required for the metal oxide elements.

100 Our experiment tested three replicates of each sensor for a total of 15 sensors. We designed a printed circuit board (PCB) for the sensors and associated electronics, shown in Fig. 1. The PCB holds the sensors, voltage divider resistors, power supply bypass capacitors, and connectors for sensor signals and power. We randomized the order in which the sensors were placed on the PCB to minimize possible thermal differences between the edge and center positions. The sensor board and sensors were burned in for several days before use.

105 **Figure 1. Diagram of the experimental setup for experiment 1. One of each type of sensor is labeled on the circuit board: A = MQ4; B = TGS2602; C = TGS2611-E00; D = TGS2611-C00; E = TGS2600. In the actual experiment the data acquisition unit was placed inside the inner enclosure; for visual clarity it is shown outside in the diagram.**

## 2.2 Instrumentation and experimental setup

The sensor signals leaving the PCB are analog voltages which require digitization, which we performed with a data acquisition unit (LabJack Corp. T7) connected to our host computer. We used a standalone device (VWR International LLC Traceable  
110 Logger-Trac) placed next to the sensor PCB to measure and record relative humidity and temperature. The humidity and temperature logger recorded an entry every 30 seconds, which we later averaged to one minute.

We powered the sensor board with a regulated bench power supply (Keysight Technologies E3631A), with the data acquisition unit powered via USB from the host computer. The sensors were warmed up for two hours prior to beginning data collection.  
115 The data acquisition unit digitized the analog sensor voltage divider signals and sent voltage readings to the host computer, as directed by a program running in Python 3.7 (Python Software Foundation). The host computer paused for five seconds between consecutive samples; including the time required to acquire data and small variations in system timing, this resulted in an entry of readings from all 15 sensors every five to six seconds, which we averaged later to one minute resolution.

120 We used an LI-7810 trace gas analyzer (LI-COR Inc.) as a reference instrument. The LI-7810 measures methane with better  
than 1 ppb precision and water vapor with better than 50 ppm precision (LI-COR, 2021). The reference instrument produced  
readings every second, which we later averaged to the minute. The analyzer was still in its initial factory calibration period.

We built our test chamber around a commercially available chest freezer, shown as a diagram in Fig. 1. We placed a heater  
125 (Vivosun 10"×20.75" seedling heat mat) at the bottom of the freezer, with both the freezer and heater controlled by a  
temperature controller (Inkbird ITC-308). We placed a plastic tub inside the freezer with the sensor PCB, data acquisition unit,  
and temperature and humidity logger enclosed. The host computer, reference instrument, and power supply were outside of  
the chamber, with connections made through the lids of the freezer and tub. The reference instrument continuously drew air  
from the test chamber by its internal sampling pump. Makeup air was provided from ambient laboratory air via an open inlet  
130 tube. A small fan inside the test chamber ensured mixing.

To generate methane pulses, we drew a small portion of gas from a 99.99% methane cylinder (GASCO Affiliates, Ltd.) into a  
syringe and then injected the gas into the inlet tube, flushing the tube several times with ambient air. This caused a sharp spike  
in methane concentrations inside the test chamber, which then slowly decayed to background levels as the air was replaced  
135 with ambient air. With our chamber and reference instrument air flow, a 10 ppm concentration decayed to the background 2  
ppm in around a day.

We examined sensor performance at five temperatures: 10°C, 15°C, 20°C, 25°C, and 30°C. We injected two methane pulses  
at each temperature for a total of ten methane decay curves over ten days. We recorded methane and water vapor concentrations  
140 with the LI-7810 reference instrument, and temperature and relative humidity with the VWR logger. Due to high ambient  
humidity in the laboratory we were unable to control humidity in our test chamber.

### 2.3 Data processing and analysis

We averaged all collected data to a one-minute timescale, and then associated the data from the sensor PCB, reference  
instrument, and temperature/humidity logger by their timestamps. As we are interested in sensor performance at background  
145 and near-source methane concentrations, we discarded data points with a reference instrument methane reading above 10 ppm.

MOx sensors convert gas concentrations into electrical resistances. Our sensor PCB converted these resistances to voltage  
signals with a voltage divider arrangement with a 10 kΩ fixed resistor and a 5 V voltage supply. To convert a recorded sensor  
voltage  $V_S$  to its originating sensor resistance  $R_S$ , we use the standard voltage divider equation Eq. 1. We used these resistances  
150  $R_S$  for our analyses.

$$R_S = \frac{(5V)(10000\Omega)}{V_S} - 10000\Omega \quad (1)$$

### Equation 1. Voltage divider equation

155 Due to the decaying pulse approach used, the dataset is heavily biased towards lower methane concentrations. To better evaluate sensor performance across the entire concentration range of interest, we performed our analysis by stratifying the dataset. We divided the data into three equally sized bins by methane concentration, spaced between the minimum recorded concentration and 10 ppm. We then randomly chose an equal number of samples from each bin, with the number chosen from each bin being equal to the size of the smallest bin, and used this sampled dataset for further analysis.

160 MOx sensors are sensitive to environmental conditions, particularly humidity and temperature (Abdullah et al., 2020). In our experiment, ambient temperature and water vapor concentrations were highly correlated (Pearson's  $R=0.95$ ). Humidity directly affects MOx sensor response (Wang et al., 2010); the sensors we used all have internal heaters to provide elevated temperatures for their elements, and further work would be required to quantify the effect of ambient temperature on these operating conditions. As our experimental setup was poorly suited to differentiate between the effects of temperature and humidity, for  
165 our current data analysis we accordingly chose to only include water vapor concentration as an environmental factor, which had slightly stronger correlation with most of the sensors than temperature. Water vapor concentrations were measured by the LI-7810 in ppm, which we converted to percent.

To compare the sensors' suitability for trace methane monitoring, we performed multi-variable linear regressions individually  
170 for each sensor. As our goal is to compare the performance of the different sensors in a systematic way rather than to develop a field-deployable system, we chose to use a simple, easily interpreted model rather than a higher-performing but more complex algorithm. Each regression used methane concentration measured by the reference instrument as the target. Sensor response, water vapor concentration, and the interaction between sensor response and water vapor were predictor variables, as shown in Eq. 2.

$$175 \quad CH_4 = \alpha + \beta_1(\text{sensor resistance}) + \beta_2(H_2O) + \beta_3(H_2O)(\text{sensor resistance}) + \varepsilon \quad (2)$$

**Equation 2.  $\alpha$  and  $\beta$  terms are least-square regression parameters, and  $\varepsilon$  is the residual error.**

## 3 Results

Figure 2 shows the time series of the full dataset. This dataset contains 14,065 entries, representing one-minute averaged data for ten days. Gaps in the data represent periods with methane concentrations above 10 ppm due to overshooting the target  
180 concentration on pulse injections, which we removed from the dataset.

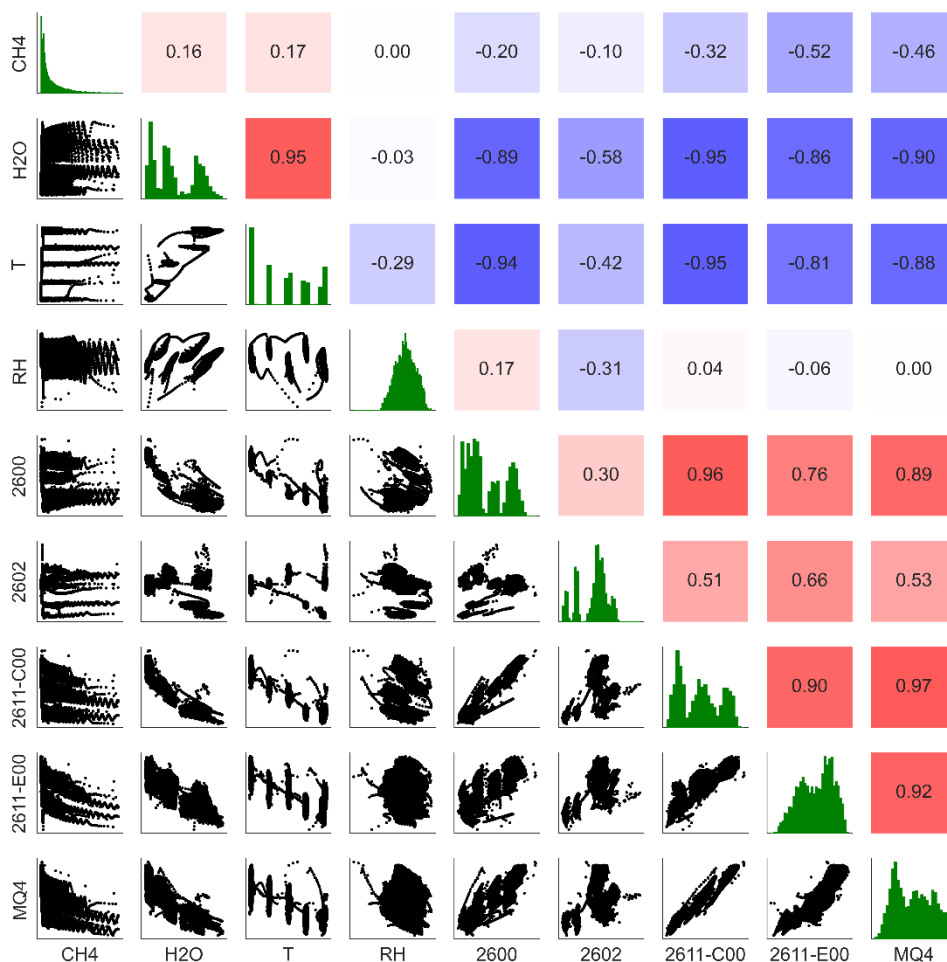

**Figure 2. Time series of the full dataset. The left plots show the entire experiment; the right plots show an expanded view of the two hours inside the dotted lines. For visual clarity, only one replicate of each sensor type is shown.**

185 Due to high humidity variation in the ambient laboratory environment, the experimental setup was unable to maintain stable relative humidity levels. Although this behavior was not desired, our experimental design still provided a range of humidity levels for our analysis. Humidity levels cycled synchronously with the heating and cooling adjustments of the test chamber, likely as the result of a condensation and evaporation cycle.

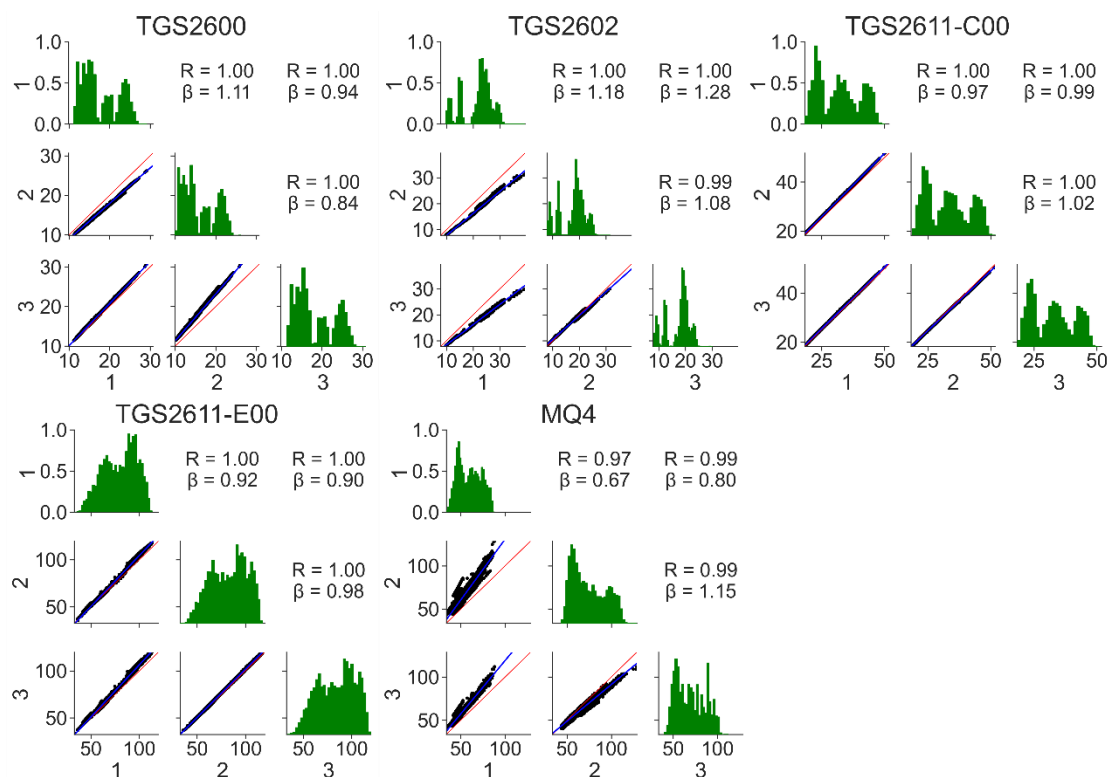

190 Figure 3 shows the sensors' response to methane concentration and environmental parameters, including absolute humidity, temperature, and relative humidity. This figure also demonstrates the correlations among the different sensors. Most of the MOx sensors show a strong correlation with temperature and water vapor concentration ( $|R| > 0.8$  for both parameters for all sensors except for TGS2602); temperature and water vapor concentrations were themselves highly correlated in our experiment. Sensor correlation with temperature and water vapor is stronger than their correlations with methane concentrations for all of the sensors, suggesting that accounting for environmental factors is critical to using these sensors. The  
195 MQ4 and TGS2611-E00 sensors are moderately correlated with methane ( $R = -0.46$  and  $-0.52$ , respectively). TGS2600, TGS2602, and TGS2611-C00 show low correlation with methane concentrations ( $R = -0.20$ ,  $-0.10$ , and  $-0.32$  respectively).

200 **Figure 3.** The lower triangle shows pairplots between variables; the upper triangle shows correlation values (Pearson's R); the green plots on the diagonal show distributions of each variable. 2600, 2602, 2611-C00, 2611-E00, and MQ4 are the MOx sensors; CH4 and H2O are methane and water vapor concentrations; T and RH are temperature and humidity. For clarity, only one of each type of sensor is shown.

Consistency of measured resistance between replicates of the same type of sensor is summarized in Fig. 4. Pair and relative frequency plots are shown for each sensor type. The TGS2611-series sensors show good correlations between replicates (R=1.00). The other sensors also show good correlation (R≥0.97) but have greater variation in slopes between units, suggesting  
 205 that individual, per-sensor calibration might be necessary.

210 **Figure 4.** The experiment contained three replicates of each sensor type; each subplot shows the relationship between the three replicates of a given sensor. The lower triangles show pairplots; the upper triangles show correlation values (Pearson's  $R$ ) and the slope  $\beta$  of the best fit line for each pair; the green plots on the diagonal show distributions. The x-axes for all plots and the y-axes for the lower triangles are electrical resistance values in  $k\Omega$ .

A comparison of the full and stratified sampled data set is shown in Fig. 5. The stratified dataset provides a better balance among the number of observations at different concentrations. Nonetheless, low methane concentrations still had more observations. This bias could be reduced by using more bins in the sampling, at further cost to the overall dataset size.

215

**Figure 5. Distributions of the full and sampled dataset. The full dataset has  $n = 14065$  points. The sampled dataset has  $n = 930$  points.**

Regression parameters and goodness-of-fit statistics for the regression model of Eq. 2 are given in Table 3. Plots of predicted versus observed methane concentrations are shown in Fig. 6. The coefficients of determination for TGS2600 and TGS2602 are poor, and there are essentially no trends between predicted and observed values for these sensors. Regression statistics for the TGS2611 sensors suggest that the regression relationships are capturing key trends in the observed methane concentrations. In general, their regression analyses tend to overpredict the low concentrations and underpredict higher concentrations. More advanced regression analysis may be successful in improving the performance of these sensors. The best regression relationships were obtained with the MQ4 and TGS2611-E00 sensors. Coefficients of determination were generally the largest, and the regression coefficients were significantly different from zero. However, the MQ4 sensors showed greater variability between units in goodness of fit than the TGS2611 sensors, with one of the three units performing worse than the TGS2611-E00 sensors.

## 4 Discussion and conclusion

### 4.1 Sensor performance

We tested five low-cost off-the-shelf MO<sub>x</sub> sensors to determine their suitability for monitoring methane at concentrations close to atmospheric levels. We identified TGS2611-C00 and TGS2611-E00 (Figaro Engineering Inc.), and MQ4 (Henan  
240 Hanwei Electronics Co. Ltd.) as promising candidates, with the best  $R^2$  ( $>0.65$ ) and RMSE ( $<1.5$  ppm).

TGS2600 and TGS2602 sensors (Figaro Engineering Inc.) did not correlate well with methane levels in the analysis we performed. Although it is possible that more complex algorithms could provide useful results, as in Eugster and Kling (2012), the inconsistent results of these algorithms in previous studies (Riddick et al., 2020a) and the availability of apparently better  
245 sensors for the same cost leaves little reason to use TGS2600 or TGS2602 for future trace methane work.

Our RMSE values for TGS2611-E00 of 1.2 ppm were close to the errors of approximately 1 ppm reported by van den Bossche et al. (2017) and Bastviken et al. (2020). Our  $R^2 = 0.16$  for TGS2600 was close to the  $R^2 = 0.19$  reported by Eugster and Kling (2012). However, our RMSE for TGS2600 of 2.3 ppm was worse than the impressive 0.38 ppm and 0.01 ppm errors reported  
250 by Collier-Oxendale et al. (2018) and Riddick et al. (2020a) respectively; unlike these previous studies, we did not find that TGS2600 was sensitive to methane at low levels. Possibly these studies had site-specific effects that led to better sensor performance which were not present in our experiment, or our errors could be reduced with more sophisticated models.

We found that the TGS2611 sensors had similar performance between units of the same type, but that the MQ4 units showed  
255 greater variability. The three MQ4 sensors we tested gave  $R^2$  values in our model from 0.70 to 0.82; by comparison, the three TGS2611-C00 had  $R^2$  values from 0.67 to 0.68, and the TGS2611-E00 sensors from 0.76 to 0.78. The slope of the response also varied more between units for the MQ4 units than for the TGS2611 sensors. As a result, individual calibration or sensor selection may be necessary for the MQ4, adding to the cost and labor required in assembling a sensor network. In contrast, other types of inexpensive electrochemical sensors have been shown to perform well for other air pollutants without individual  
260 calibration (Malings et al., 2019).

### 4.2 Suitability for atmospheric sensing and potential applications

As background methane levels are around 2 ppm, RMSE values of greater than 1 ppm suggest that these sensors are not suitable for detecting variations in methane levels around atmospheric concentrations without more sophisticated algorithms or sensing system designs. In particular, more precisely accounting for temperature and humidity response may allow better performance  
265 than we found. This could be achieved by regulating the temperature and humidity levels of the sampled air or by characterizing sensor response to temperature and humidity separately and developing a more complex algorithm to remove these interferences.

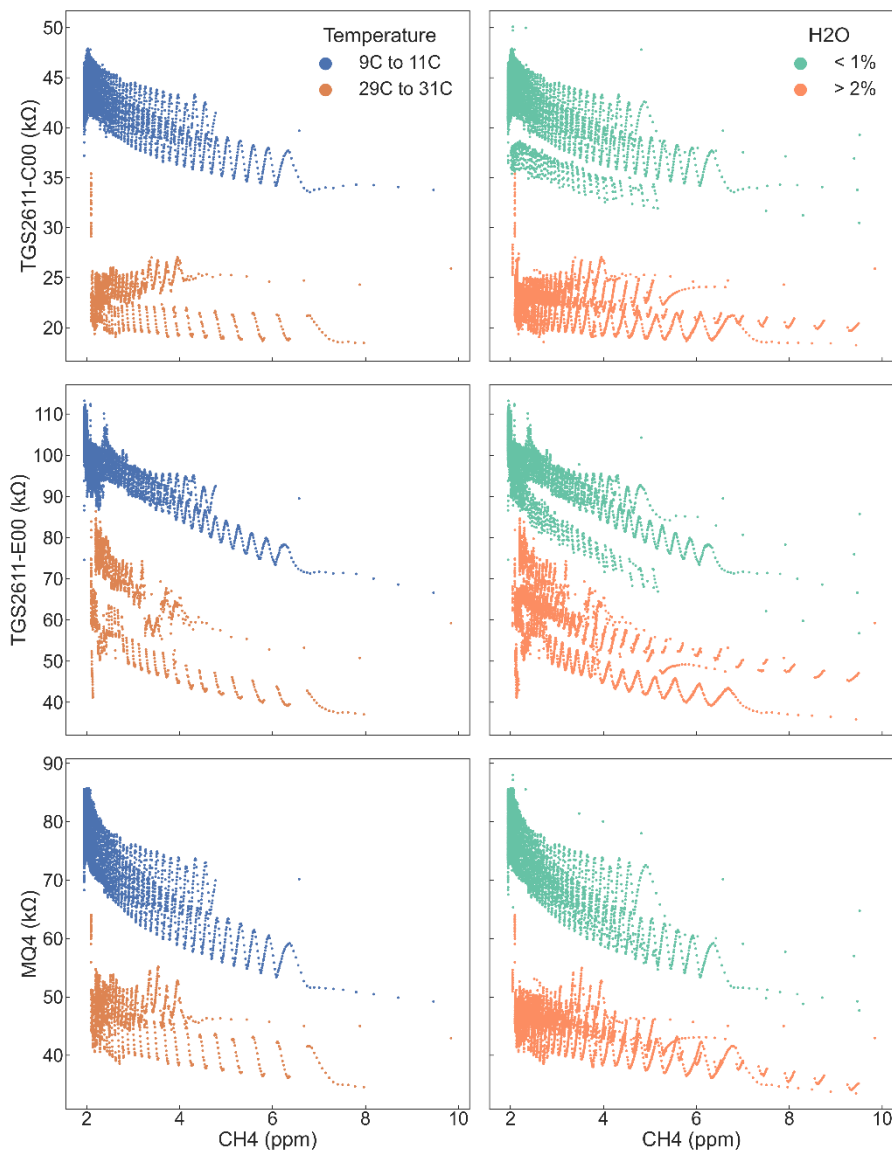

270 The level of accuracy we found from TGS2611 and MQ4 may be usable without further improvement in sensor networks for  
major leak detection in urban areas, which show methane enhancements above 1ppm in surveys, with levels sometimes  
exceeding 10 ppm (Phillips et al., 2013; Defratyka et al., 2021). Leaks around natural gas infrastructure (Cho et al., 2022)  
should also be easily detectable, with even regional-scale enhancements exceeding 1.5 ppm around production sites (Caulton  
et al., 2014). Due to the low cost of these sensors, such leak detection sensor networks could provide an accessible method for  
identifying and correcting major fugitive emission sources.

#### 275 **4.3 Sensitivity to environmental conditions**

Water vapor and temperature have a large effect on sensor response, as shown by previous studies (Wang et al., 2010; Huerta  
et al., 2016; Abdullah et al., 2020; Kim et al., 2021). Our results show a strong correlation between absolute humidity and  
sensor response ( $|R| > 0.85$  for the TGS2611 sensors and MQ4), but little correlation with relative humidity ( $|R| < 0.1$  for the  
same sensors).

280

Figure 7 illustrates the importance of temperature and humidity by showing the responses of three sensors at high and low  
temperatures and humidity levels. In the methane concentration range we examined, the change in sensor response due to  
environmental conditions can exceed the change in sensor response due to methane levels. Field deployments of these sensors  
will require system designs that control temperature and humidity, co-located measurements and algorithms to account for  
285 these factors, or both.

**Figure 7. Sensor response (y axis) to environmental conditions can be greater than to methane (x axis) at low concentrations.**

#### 4.4 Study limitations and conclusion

Our study had several limitations that will need to be addressed for future development. Most importantly, our experimental  
290 setup was unable to accurately control humidity levels independently of temperature, leaving us unable to distinguish sensor  
sensitivities between the two factors. We also did not test for cross-sensitivities to other gases, such as VOCs or CO, which  
may be important factors in real-world deployments (Collier-Oxandale et al., 2018). The lack of response from TGS2600 and  
TGS2602 to methane suggests they might be useful in detecting these interfering gasses in a sensor array. Further development

of this idea will require characterizing the sensors' responses to common interfering gasses and then developing algorithms to  
295 account for cross-sensitivities using multiple sensors.

Environmental conditions have a large effect on MO<sub>x</sub> sensors, dominating the sensor response at low methane levels.  
Applications of these sensors for monitoring trace methane will require careful sensor calibration and algorithms to address  
humidity, or system designs that reduce environmental variation. We believe that addressing environmental sensitivity is the  
300 main challenge to real-world applications with the studied sensors, but that their potential to enable inexpensive sensor  
networks, particularly for leak detection, merits further development.

#### **Code availability**

Code and circuit board design files are available by request.

#### **Data availability**

305 Data is available at <https://conservancy.umn.edu/handle/11299/226714>

#### **Author contributions**

Jiayu Li and AP conceived of the project; Jiayu Li and DF designed and performed the experiment; Jiayu Li, DF, TS, BW and  
AP analyzed the data; DF and Jinsheng Li wrote the manuscript draft; all authors reviewed and edited the manuscript.

#### **Competing interests**

310 Albert Presto is an editor for Atmospheric Measurement Techniques.

#### **Acknowledgements**

This work was funded by the US Department of Energy through the University Coalition for Fossil Energy Research (Grant  
S000663-USDOE).

Randi Shandroski assisted in figure preparation.
