23 **Abstract**

24 Since 2018, the Aeolus satellite of the European Space Agency (ESA) acquires wind HLOS
25 (horizontal line-of-sight) profiles throughout the troposphere and up to the lower stratosphere, filling
26 a critical gap of the Global Observing System (GOS). Aeolus, carrying ALADIN (Atmospheric LAsEr
27 Doppler INstrument), the first UV HSRL (High Spectral Resolution Lidar) Doppler lidar ever placed
28 in space, provides also vertically resolved optical properties of particulates (aerosols, clouds). The
29 present study focuses on the assessment of Aeolus L2A particulate backscatter coefficient (baseline
30 2A11), retrieved by the Standard Correct Algorithm (SCA), in the Eastern Mediterranean, a region
31 hosting a variety of aerosol species. Ground-based retrievals acquired by lidar instruments operating
32 in Athens (central Greece), Thessaloniki (north Greece) and Antikythera (southwest Greece) serve as
33 reference. All lidar stations provide routine measurements to the PANACEA (PANhellenic
34 infrastructure for Atmospheric Composition and climatE chAnge) network. A set of ancillary data
35 including sunphotometric observations (AERONET), reanalysis products (CAM5, MERRA-2),

Deleted: along with wind HLOS profiles

Deleted: capital of

39 satellite observations (MSG-SEVIRI, MODIS-Aqua) and backward trajectories modelling
40 (FLEXPART) are utilized towards an optimum characterization of the probed atmospheric conditions
41 under the absence of a classification scheme in Aeolus SCA profiles. First, emphasis is given on the
42 assessment of Aeolus SCA backscatter coefficient under specific aerosol scenarios over the
43 Antikythera island. Due to the misdetection of the cross-polar component of the backscattered lidar
44 signal, Aeolus underestimates the aerosol backscatter coefficient by up to 33% when non-spherical
45 mineral particles are recorded (10th July 2019). A good performance is revealed on 3rd July 2019,
46 when horizontally homogeneous loads of fine spherical particles are confined below 4 km. For other
47 two cases (8th July 2020, 5th August 2020), due to noise issues, the SCA performance degrades in
48 terms of depicting the stratification of aerosol layers composed of particles of different origin.
49 According to the statistical assessment analysis of 43 identified cases, it is revealed a poor-to-
50 moderate performance for the unfiltered (aerosols plus clouds) SCA profiles which improves
51 substantially when cloud contaminated profiles are excluded from the collocated sample. This
52 improvement is evident at both Aeolus vertical scales (regular, 24 bins and mid-bin, 23 bins) and it
53 is justified by the drastic reduction of the bias (from 0.45 Mm⁻¹sr⁻¹ to 0.27 Mm⁻¹sr⁻¹ for SCA and from
54 0.69 Mm⁻¹sr⁻¹ to 0.37 Mm⁻¹sr⁻¹ for SCA mid-bin) and root-mean-square-error (from 2.00 Mm⁻¹sr⁻¹ to
55 1.65 Mm⁻¹sr⁻¹ for SCA and from 1.88 Mm⁻¹sr⁻¹ to 1.00 Mm⁻¹sr⁻¹ for SCA mid-bin) scores. In vertical,
56 the SCA performance degrades at the lowermost bins due to either the contamination from surface
57 signals or the increased noise levels for the aerosol retrievals. Among the three PANACEA stations,
58 the best agreement is found at the remote site of Antikythera with respect to the urban sites of Athens
59 and Thessaloniki. Finally, all key Cal/Val aspects necessary for future relevant studies, the
60 recommendations for a possible Aeolus follow-on mission and an overview of the ongoing related
61 activities are thoroughly discussed.

62

63 1. Introduction

64 Atmospheric aerosols constitute a critical component of the Earth system by acting as a major
65 climatic driver (Charlson et al., 1992; Boucher et al., 2013; Li et al., 2022) whereas upon deposition
66 they can affect terrestrial (Okin et al., 2004) and marine ecosystems (Jickells et al., 2005; Li et al.,
67 2018). It is also well documented that they affect several anthropogenic activities with concomitant
68 economic impacts (Middleton et al., 2018; Kosmopoulos et al., 2018). In addition, aerosols
69 accumulation at large concentrations cause an air quality degradation (Kanakidou et al., 2011) with
70 adverse health effects (Pöschl, 2005; Lelieveld et al., 2015) increasing the mortality rates (Health
71 Effects Institute, 2019; Pye et al., 2021). Therefore, their multifaceted role in multidisciplinary
72 research fields highlights the growing scientific concern in understanding and describing the

Deleted: Aeolus

Deleted: downgrades

80 emission, removal, and transport mechanisms governing airborne particles' life cycle. Due to their
81 pronounced heterogeneity, aerosol burden exhibits a remarkable spatiotemporal variability thus
82 imposing deficiencies in depicting adequately its features and constraints towards a robust assessment
83 of the induced impacts.

84 Passive satellite sensors, providing columnar retrievals of aerosol optical depth (AOD), have
85 been able to reproduce adequately aerosol loads across various spatiotemporal scales. This has been
86 justified via the assessment of AOD versus corresponding sun-photometric measurements (e.g., Wei
87 et al., 2019). Nevertheless, the main drawback arises from the sensors' inability to provide
88 information in vertical. Therefore, this deficiency hampers a reliable quantification of the suspended
89 particles' load within the planetary boundary layer (PBL), related to health impacts. Moreover, it is
90 not feasible to depict the three-dimensional structure of transported loads in the free troposphere,
91 linked to aerosol-cloud-radiation interactions and associated impacts on atmospheric dynamics (Pérez
92 et al., 2006; Gkikas et al., 2018; Haywood et al., 2021). Likewise, passive aerosol observations are
93 not suitable for monitoring stratospheric long-lived plumes that affect aerosol-chemistry interactions
94 and perturb the radiation fields (Solomon et al., 2022). On the contrary, ground-based lidars, relying
95 on active remote sensing techniques, obtain vertical profiles of aerosol optical properties at high
96 vertical and temporal resolution, through multi-wavelength and polarization measurements. Such
97 observations are performed either at networks distributed across Europe (EARLINET; Papalardo et
98 al., 2014; PollyNET; Baars et al., 2016; Engelmann et al., 2016), United States (MPLNET; Campbell
99 et al., 2002), Asia (AD-NET; Sugimoto et al., 2014) and South America (LALINET; Guerrero-
100 Rascado et al., 2016), or at dedicated experimental campaigns (Ansmann et al., 2011; Weinzierl et
101 al., 2016) or even at open seas (Bohlmann et al., 2018). The reproduction of aerosols' vertical
102 structure at global (Liu et al., 2008) and regional (Marinou et al., 2017; Proestakis et al., 2018) scales
103 has been realized through the utilization of measurements acquired by the Cloud-Aerosol Lidar and
104 Infrared Pathfinder Satellite Observation (CALIOP; Winker et al., 2009) and the Cloud-Aerosol
105 Transport System (CATS; McGill et al., 2015; Lee et al., 2019) mounted on the CALIPSO (Cloud-
106 Aerosol Lidar and Infrared Pathfinder Satellite Observation) satellite and the International Space
107 Station (ISS), respectively.

108 On 22nd August 2018, the European Space Agency (ESA) launched its Earth Explorer wind
109 mission, Aeolus, which was a major step forward for Earth Observations (EO) and atmospheric
110 sciences. The Aeolus satellite carries ALADIN (Atmospheric LAsEr Doppler INstrument), the first
111 space-based high spectral resolution (HSRL) Doppler wind lidar worldwide. ALADIN emits a linear
112 polarized beam which after going through a quarter-wave plate is transmitted with a circular
113 polarization (at 355 nm) and receives the co-polarized backscatter from molecules and

114 particles/hydrometeors in two separate channels (Ansmann et al., 2007; Flamant et al., 2008). The
115 main mission product is profiles of the horizontally projected line-of-sight winds, and spin-off
116 products are the backscatter and extinction coefficient profiles from particles and hydrometeors. The
117 key scientific objective of Aeolus is to improve numerical weather forecasts and our understanding
118 of atmospheric dynamics and their impacts on climate (Stoffelen et al., 2005; Isaksen and Rennie,
119 2019; Rennie and Isaksen, 2019). After about 1.5 years of instrument and algorithm improvements,
120 the Aeolus L2B wind product was of such good quality (e.g., Witschas et al., 2020; Lux et al., 2020;
121 Martin et al., 2021) that the European Centre for Medium Range Forecasts (ECMWF) could start
122 operational assimilation (January 2020). In May 2020, three further European weather forecast
123 institutes (DWD, Météo-France and the UK MetOffice) started the operational assimilation of Aeolus
124 winds. All meteorological institutes reported that Aeolus winds had significant positive impact on the
125 short and medium term forecasts. The most beneficial impact is found in remote areas (Tropics, S.
126 Hemisphere, polar regions) less covered by other direct wind observations (e.g. ECMWF 2020;
127 Rennie et al., 2021).

128 A series of errors induced by the instrument, by the retrieval algorithm, or by the type of
129 scatterers probed by ALADIN can affect the product quality. It is therefore necessary to perform
130 extensive calibration and validation (Cal/Val) studies utilizing independent reference measurements
131 (e.g. ground-based, aircraft). This task has been performed by the Aeolus Cal/Val community,
132 responding to the Aeolus Announcement of Opportunity to perform product calibration and
133 validation. Such critical tasks are prerequisites to the acceptance of the Mission as “fit for purpose”
134 as it is underlined in the Aeolus Implementation Cal/Val Plan. In contrast to Aeolus wind retrievals,
135 a limited number of studies are focused on the quality of the L2A [SCA](#) optical properties. Abril-Gago
136 et al. (2022) performed a statistical validation versus ground-based observations from three Iberian
137 ACTRIS/EARLINET lidar stations affected mainly by dust and continental/anthropogenic aerosols.
138 In their Cal/Val study, they processed AERONET optical properties related to particles’ size and
139 nature along with HYSPLIT air-mass backtrajectories towards characterizing the prevailing aerosol
140 conditions. Baars et al. (2021) reported an excellent agreement between [SCA](#) and Polly^{XT} particle
141 backscatter profiles and adequate agreement of extinction and lidar ratio profiles, between 4 and 12
142 km, for a case of long-range transport of wildfire smoke particles from California to Leipzig
143 (Germany).

144 Here we focus on the comparison of Aeolus [SCA](#) particle backscatter coefficient profiles
145 against ground-based profile observations acquired at three lidar stations (Antikythera, Athens,
146 Thessaloniki) contributing to the Greek National Research Infrastructure (RI) PANACEA, an

149 ACTRIS component (<https://www.actris.eu>). All stations are located in the Eastern Mediterranean, a
150 crossroad of air masses (Lelieveld et al., 2002) carrying particles of different nature. The broader
151 Greek area encompasses a variety of aerosol species consisting of: (i) pollutants from industrialized
152 European regions (Gerasopoulos et al., 2003; 2009), (ii) dust aerosols from the nearby deserts (Balis
153 et al., 2004; Papayannis et al., 2005; Gkikas et al., 2016, Marinou et al., 2017), (iii) anthropogenic
154 aerosols from urban areas and megacities (Kanakidou et al., 2011), (iv) biomass burning particles
155 originating in the eastern Europe and the Black Sea (Amiridis et al., 2009; 2010; 2012), (v) smoke
156 aerosols subjected to transport at planetary scale (Baars et al., 2019; Gialitaki et al., 2020), (vi) sea-
157 salt particles produced by bursting bubbles during whitecap formation attributed to wind-wave
158 interactions (e.g. Varlas et al., 2021), (vii) biogenic particles such as airborne fungi and pollen grains
159 (Richardson et al., 2019) and (viii) volcanic ash mixed with sulfate aerosols ejected at high altitudes
160 from explosive Etna eruptions (Zerefos et al., 2006, Kampouri et al., 2021).

161 The manuscript is structured as follows. In Section 2, a brief overview of the Aeolus satellite
162 and the ALADIN instrument is given. The key elements of the Standard Correct Algorithm (SCA)
163 are summarized in Section 3. The technical information of the ground-based lidars as well as the
164 description of aerosols' regime, in the surrounding area of the PANACEA stations, are presented in
165 Section 4. The collocation criteria between ground-based and spaceborne profiles are described in
166 Section 5. The assessment of Aeolus ~~SCA~~ product under various aerosol scenarios and for the whole
167 collocated sample are discussed in Section 6. The Cal/Val aspects, the recommendations for future
168 relevant studies and the necessary upgrades on ALADIN observational capabilities and Aeolus L2A
169 data content are highlighted in Section 7. Finally, the main findings and the conclusions are drawn in
170 Section 8.

171

172 2. AEOLUS - ALADIN

173

174 A brief description of Aeolus' orbital features, ALADIN's observational geometry and its
175 measurement configuration is given in the current section. This short introduction serves as the
176 starting point for the reader to be familiar with Aeolus' nomenclature. Further details and a more
177 comprehensive overview of the Aeolus satellite mission can be found at ESA technical reports (ESA,
178 1999; 2008; 2016) and at recently published studies (e.g., Lux et al., 2020; Witschas et al., 2022; Lux
179 et al., 2022).

Deleted: L2A

181 ESA's Aeolus satellite, named after the 'keeper of winds' according to the Greek mythology
182 (Ingmann and Straume, 2016), flies in a polar sun-synchronous orbit circling the Earth at an altitude
183 of 320 km with a repeat cycle of 7 days (Kanitz et al., 2019a; Straume et al., 2019). The orbital plane
184 forms an angle of 97° with the equatorial plane, the ground track velocity is about 7.7 km/sec and a
185 complete circle around the Earth takes about 90 minutes for each orbit (Lux et al., 2020; Witschas et
186 al., 2020; Straume et al., 2020). Aeolus is flying over the terminator between day and night
187 (dawn/dusk orbits), with its telescope pointing to the right of the flight direction (aiming into the night
188 hemisphere) for minimizing the solar background illumination (Kanitz et al., 2019).

Deleted: solar panels facing towards the sun direction

189 ALADIN, the single payload on the Aeolus satellite platform, is an HSRL (Shiple et al.,
190 1983) equipped with a Nd-YAG laser that emits short laser pulses (~40 to 70 mJ, Witchas et al., 2020)
191 of a circular polarized light at ~355 nm with a 50.5 Hz repetition frequency. The photons that are
192 backscattered from molecules and particulates (aerosols, cloud droplets and ice crystals) at
193 atmospheric altitudes lower than 30 km are collected by a Cassegrain telescope of 1.5 m diameter.
194 The collected photons are directed to the Mie optical channel (Fizeau interferometer) for the analysis
195 of the Doppler shift induced by particulates while the molecular return signals (Rayleigh) are analyzed
196 in two sequentially coupled Fabry-Pérot interferometers (Witchas et al., 2020).

Deleted: lidar

197 ALADIN provides wind and particulate vertically resolved retrievals along the Line-Of-Sight
198 (LOS) by pointing the Earth at a slant angle of 35° off-nadir (see Figure 1 in Flament et al., (2021))
199 which corresponds to an angle of about 37.6° with the Earth surface, due to its curvature. In contrast
200 to CALIOP and CATS, ALADIN can retrieve particulate optical products without requiring an a
201 priori assumption of the lidar ratio (S), which is characterized by a remarkable variability among
202 aerosol types due to its dependency on particles' shape, composition and size distribution (Müller et
203 al., 2007). However, ALADIN only measures the co-polar part of the atmospheric backscatter and at
204 a single wavelength. Therefore, the discrimination between aerosols and clouds and their respective
205 subtypes is challenging.

Deleted: it is very challenging

Deleted: and to distinguish further among their

206 The instrument detector design allows the sampling of the atmospheric backscatter in 24
207 vertical bins, with a varying resolution from 0.25 (near surface) to 2 km (upper atmosphere). The
208 laser pulses are integrated on-board the satellite along the flight direction, to yield measurements of
209 ~3 km resolution (integration of ~20 laser pulses). During the on-ground data processing, the
210 measurements are accumulated further to yield an "observation" (also called a *Basic Repeat Cycle*
211 *(BRC)*), which corresponds to a distance of ~90 km. The SCA optical properties are part of the L2A
212 product which will be described in the next section, and are derived by the so-called Standard Correct
213 Algorithm (SCA) (Flament et al., 2021). They are provided at the observation scale (on a horizontal

Deleted: satellite

221 [resolution of ~90 km\) and are available through the Aeolus Online Dissemination System](https://aeolus-ds.eo.esa.int)
222 [\(https://aeolus-ds.eo.esa.int\)](https://aeolus-ds.eo.esa.int)

224 3. Standard Correct Algorithm (SCA)

225 In the current Cal/Val study, we are assessing the performance of the Aeolus L2A particulate
226 products derived by the Standard Correct Algorithm (SCA). Here, we are providing a short overview
227 of the SCA whereas its complete description is available in the Algorithm Theoretical Baseline
228 Document (ATBD; Flamant et al., 2021). The SCA product is derived from the measured signals in
229 the Mie and Rayleigh channels, which are dependent on the instrument calibration constants (K_{ray} ,
230 K_{mie}), the channel cross-talk coefficients C_1 , C_2 , C_3 and C_4 , the laser pulse energy (E_0) and the
231 contributions from the pure molecular (X) and particulate (Y) signals (see Equations 1 and 2 in
232 Flamant et al. (2021)). The latter ones, at each bin, result from the vertical integration of the
233 backscatter (either molecular or particulate) where the squared one-way transmission through the
234 atmosphere is taken into account (see Equations 3 and 4 in Flamant et al. (2021)).

235 The separation of the molecular and particle signals on each channel is imperfect, due to the
236 HSRL instrument design, which makes necessary a cross-talk correction. The channel cross-talk
237 corresponding to the transmission of the Rayleigh-Brillouin spectrum (depending on the temperature,
238 pressure and the Doppler shift) through the Rayleigh and Mie channels is expressed by the calibration
239 coefficients C_1 and C_4 , respectively (Flamant et al., 2021). The other two coefficients, C_2 and C_3 ,
240 refer to the transmission of a Mie spectrum (depending on the Doppler shift) through the Mie and
241 Rayleigh channels, respectively. Along with the cross-talk coefficients, the instrument calibration
242 constants (K_{ray} , K_{mie}) (see in Flamant et al., 2021) are included in the AUX_CAL files.

243 Finally, the cross-talk corrected signals, normalized with the range bin thickness and corrected
244 by the range between the satellite and the observed target, are utilized for the retrieval of the vertically
245 resolved backscatter (β) and extinction (α) coefficients. The former, at each bin, is derived by the Y/X
246 ratio multiplied with the molecular backscatter coefficient (see Equations 9 and 10 in Flamant et al.,
247 2021) computed from the pressure and temperature ECMWF simulated fields (Collis and Russel,
248 1976). For the SCA extinction retrievals, derived via an iterative process from top to bottom, the
249 normalized integrated two-way transmission (NITWT) is applied, using measured and simulated pure
250 molecular signals, under the assumption that the particles' extinction at the top-most bin is zero (see
251 equations 11-14 in Flamant et al., 2021). This consideration makes the downwards solution of the
252 integral equations quite sensitive to the noise within the topmost bin (at altitudes ~20-25 km), which
253 is used as reference for the normalization, particularly under low SNR conditions due to the low
254 molecular density. This is a challenge frequently faced for the SCA observations due to the weaker

Deleted: The L2A optical properties product which will be described in the next section, derived by the so-called Standard Correct Algorithm (SCA) (Flamant et al., 2021), are provided at the observation scale (on a horizontal resolution of ~90 km) and are available through the Aeolus Online Dissemination System (<https://aeolus-ds.eo.esa.int>). ¶

266 measured signals than those of the pre-launch expectations (Reitebuch et al., 2020) as well as to the
267 possible presence of stratospheric aerosols within the top-most range bin or above. In principle, the
268 extinction is retrieved recursively taking into account the attenuation from the overlying bins and by
269 contrasting observed and simulated molecular signals. By differentiating two consecutive bins,
270 unrealistically high positive or negative extinctions can be retrieved (see Fig. 10 in Flament et al.,
271 (2021)) resulting from fluctuations between strong and weak attenuation.

272 In the case of negative extinction values, the SCA algorithm regularizes the solution by
273 resetting to zero (Flament et al., 2021), which can lead to an underestimation of the partial column
274 transmission. In order to compensate the impacts of the aforementioned issues, it has been shown by
275 error propagation calculations (see equations 18 and 19 in Flament et al. (2021)), that averaging two
276 consecutive bins the retrieved extinction becomes more reliable at the expense of the vertical
277 resolution (23 bins; “mid-bin” vertical scale). In contrast to SCA, in the SCA mid-bin negative
278 extinction values can be found since the zero-flooring constraint is not implemented. For consistency
279 reasons, the averaging between two neighboring bins is applied also in the backscatter coefficient
280 thus allowing the derivation of the lidar ratio.

281 The inherent weaknesses of the SCA algorithm have been mitigated in the Maximum
282 Likelihood Estimation (MLE) algorithm (Ehlers et al., 2022). Its main principle relies on the
283 exploitation of all available information and the definition of constraints on the positivity of the
284 retrieved optical properties and on the expected range of the lidar ratio. Under these restrictions, the
285 particle extinction is derived when the particle backscatter is available and vice versa. According to
286 the evaluation versus ground-based observations and SCA end-to-end simulated optical products, it
287 is revealed a remarkable improvement (up to one order) on the precision of the extinction and the
288 lidar ratio due to effective noise dampening. Moreover, there is also a beneficial impact on the co-
289 polar backscatter coefficient. Another new algorithm that outperforms SCA is the AEL algorithm
290 (adjusted from the EarthCARE-ATLID algorithms) providing a feature mask (AEL-FM) at the
291 highest available resolution and aerosol/clouds extinction and lidar ratios via a multi-scale optimal
292 estimation method (AEL-PRO). Both MLE and AEL retrievals have been released at a more recent
293 baseline (2A14) than those used in the current study (2A11) and for this reason are omitted from our
294 Cal/Val analysis.

295

296 **4. Ground-based lidars (PANACEA)**

297 The ground-based observational datasets used herein, are taken from stations contributing to
298 the PANhellenic infrastructure for Atmospheric Composition and climatE chAnge (PANACEA)
299 initiative. Within PANACEA, different measurement techniques and sensors are utilized in a

300 synergistic way for monitoring the atmospheric composition and climate change related parameters
301 in Greece.

302 The locations of the stations providing routine measurements to the PANACEA network are
303 shown in Figure 1-i. For the assessment analysis of Aeolus ~~SCA optical properties~~, we utilize
304 available measurements from PANACEA stations, namely Antikythera (ANT), Athens (ATH) and
305 Thessaloniki (THE), equipped with multiwavelength polarization lidar systems. All stations comply
306 with the quality-assurance criteria established within EARLINET (e.g. see Freudenthaler et al., 2016)
307 so as to assure the provision of high-quality aerosol related products. Consequently, the derived
308 datasets can be considered for any validation purpose. To ensure the homogeneity and the consistency
309 of the optical property profiles derived from the adverse lidar systems operating at each station, the
310 Single Calculus Chain algorithm (SCC; D' Amico et al., 2016; Mattis et al., 2016) was used; an
311 automatic processing chain for lidar data, developed within EARLINET. All systems employ multiple
312 detectors, operating either in the photon-counting or analog mode. Herein elastically and inelastically
313 backscattered signals at 355 and 387 nm, were used to evaluate Aeolus products. The optical property
314 profiles were derived using the Raman and Klett-Fernald-Sassano inversion methods (Ansmann et al.
315 1992; Fernald, 1984; Klett, 1981; Sasano and Nakame, 1984) during night-time and daytime
316 measurements respectively.

317

318 4.1 Antikythera

319 Regular lidar measurements have been performed at the PANGAEA observatory (PANhellenic
320 GEophysical observatory of Antikythera; lat=35.86° N, lon=23.31° E, alt=193 m asl.) contributing to
321 this study. The lidar system deployed at PANGAEA is operated by the National Observatory of Athens
322 (NOA). It is a Polly^{XT} (Engelmann et al., 2016) multi-wavelength Polarization-Raman-Water vapor
323 lidar, designed for unattended, continuous operation. Polly^{XT} deploys an Nd:YAG laser which emits
324 linearly polarized light at 355, 532 and 1064 nm. The radiation elastically and inelastically
325 backscattered from aerosol, cloud particles, nitrogen (at 387 and 607 nm) and water vapor (at 407
326 nm) molecules, is collected using a near-range (spherical mirror of 50 mm diameter, focal length
327 f=250 mm and 2.2 mrad field of view (FOV)) and a far-range receiver (Newtonian telescope with a
328 300 mm diameter primary mirror, f=900 m and 1 mrad FOV) at a raw vertical resolution of 7.5m.
329 The combined use of the near-range and far-range receivers allows for the retrieval of the aerosol
330 optical properties from 500 m up to ~12-14 km above the ground. A detailed description of the
331 technical characteristics of Polly^{XT} can be found in Engelmann et al. (2016).

332

333 4.2 Athens

Deleted: L2A

Deleted: products

336 The Laser Remote Sensing Unit of the National and Technical University of Athens, Greece
337 (LRSU; NTUA; lat=37.96° N, lon=23.78° E, alt=200 m asl.), is part of the EARLINET since May
338 2000. Currently, the Athens lidar station performs simultaneous measurements with two different
339 lidar systems, EOLE and DEPOLE. The EOLE lidar is an advanced 6-wavelength elastic
340 backscatter/Raman lidar system able to provide the aerosol backscatter coefficient at 355, 532 and
341 1064 nm, the aerosol extinction coefficient at 355 and 532 nm and water vapor mixing ratio profiles
342 in the troposphere. EOLE is based on a pulsed Nd:YAG laser system and a 300 mm diameter
343 receiving Cassegrain telescope (f=600 mm, FOV =1.5 mrad) which collects all elastically
344 backscattered lidar signals (355-532-1064 nm), as well as generated by the vibrational Raman effect
345 (by atmospheric N₂ at 387-607 nm and by H₂O at 407 nm). The full overlap (i.e. the altitude from
346 which upwards the whole lidar beam is within the telescope FOV) of EOLE is reached at,
347 approximately, 812 m a.s.l.. EOLE has been validated within EARLINET at hardware level by two
348 intercomparison campaigns (Matthias et al., 2004), in order to fulfill the standardized criteria.

349 The DEPOLE lidar is a depolarization lidar, able to provide profiles of the aerosol backscatter
350 coefficient and the linear particle/volume depolarization ratio at 355 nm. DEPOLE is based on a
351 pulsed Nd:YAG laser system which emits linearly polarized light at 355 nm. The elastically
352 backscattered lidar signals at 355 nm are collected by a 200 m diameter Dall-Kirkham/Cassegrain
353 telescope (f=600 mm, FOV=3.13 mrad) and the full overlap is reached at, approximately, 500 m a.s.l..
354

355 *4.3 Thessaloniki*

356 Thessaloniki's multiwavelength Polarization Raman lidar system (THELISYS) belongs to the
357 Laboratory of Atmospheric Physics that is located at the Physics Department of the Aristotle
358 University of Thessaloniki (lat = 40.63° N, lon = 22.96° E, a.s.l. = 50m). Thessaloniki is a member
359 station of the EARLINET since 2000, providing almost continuous measurements, according to the
360 network schedule (every Monday morning, ideally close to 12:00 UTC, and every Monday and
361 Thursday evening) and during extreme events (e.g., Saharan dust outbreaks, smoke transport from
362 biomass burning, volcanic eruptions) and satellite overpasses. THELISYS has been validated within
363 EARLINET at hardware level by two intercomparison campaigns (Matthias et al., 2004), in order to
364 fulfill the standardized criteria. The system is based on the first (1064 nm), second (532 nm), and
365 third harmonic (355 nm) frequency of a compact, pulsed Nd:YAG laser emitted with a 10 Hz
366 repetition rate. THELISYS setup includes three elastic backscatter channels at 355, 532 and 1064nm,
367 two nitrogen Raman channels at 387 nm and 607nm, and two polarization sensitive channels at 532
368 nm. The acquisition system is based on a LICEL Transient Digitizer working in both the analogue
369 and photon counting (250 MHz) mode. The vertical resolution of the elastic raw signal at 355 nm is

370 equal to 3.75 m and is recorded in both analog and photon counting mode. The full overlap height is
371 almost 800m a.s.l. A detailed description of THELISYS can be found in Siomos et al. (2018) and
372 Voudouri et al. (2020).

373

374 4.4. Aerosols' load variability in the vicinity of the PANACEA sites

375 The variability of the atmospheric aerosol load in the vicinity of ~~the~~ three PANACEA stations
376 (Fig. 1-i) is discussed in this section. The aim of this introductory analysis is to investigate the
377 horizontal homogeneity of the aerosol optical depth (AOD) in the respective broader areas, playing a
378 key role in the comparison of ground-based and spaceborne profiles, which are not spatially
379 coincident as it will be shown in Section 5. For the purposes of this analysis, we have processed the
380 mid-visible (550 nm) columnar AOD retrievals, over the period 2008-2017, acquired by the MODIS
381 sensor, mounted on the Aqua polar orbiting satellite. More specifically, we have analyzed the Level
382 2 (L2; swaths; 5-min segments) MODIS-Aqua AODs, obtained by the latest version (Collection 6.1)
383 of the operational retrieval algorithms (Remer et al., 2008; Levy et al., 2013; Sayer et al., 2013). The
384 aforementioned data are accessible via the Level 1 and Atmosphere Archive and Distribution System
385 (LAADS) Distributed Active Archive Center (DAAC) (<https://ladsweb.modaps.eosdis.nasa.gov/>, last
386 access: ~~23 January 2023~~).

387 For each station, we have calculated the arithmetic mean of AODs ~~within progressively larger~~
388 circular areas, with radii spanning from 10 to 100 km ~~and~~ with an incremental step of 10 km (Fig. 1-
389 ii). Figure 1-iii illustrates the resulting AODs for each station (x labels) and at each radius (colored
390 bars). In order to ensure the reliability of the obtained results, only the best (QA=3) MODIS-Aqua
391 AOD L2 retrievals are considered whereas the spatial averages (computed individually for each
392 circle) are calculated only when the satellite observations are simultaneously available at all circles.
393 In the urban areas of Athens (ATH) and Thessaloniki (THE), the contribution of anthropogenic
394 aerosols on the columnar load fades for increasing radii. On the contrary, at Antikythera (ANT), the
395 spatial AOD means remain almost constant revealing a horizontal homogeneity of the aerosol load in
396 the broader area. An alternative way to compare the differences in the AOD spatial representativeness
397 between the urban (ATH, THE) and the remote (ANT) sites has been performed. Fig. 1-iv illustrates
398 the normalized values for each radius with respect to the AOD levels of the inner circle (i.e., up to 10
399 km distance from the station). In both urban sites the values are lower than one (dashed line),
400 decreasing steadily in THE and smoothly in ATH after an abrupt reduction from 10 to 20 km. In
401 ANT, the blue curve resides almost on top of the dashed line throughout the circles radii (i.e., range
402 of distances) indicating the absence of significant horizontal variation of the aerosol load suspended
403 in the surrounding area.

Deleted: , representative over the period 2008-2017,

Deleted: of the station

409 A key aspect which has not been adequately addressed in Fig. 1-iii is the temporal variability
410 of aerosol loads since the spatiotemporally averaged AODs “hide” such information. A useful
411 measure for this purpose is the coefficient of variation (CV), defined as the ratio of the standard
412 deviation and the arithmetic mean of AOD (Anderson et al., 2003; Shinozuka and Redemann, 2011),
413 both calculated in temporal terms. Figure 1-v displays the CV values (expressed in percentage)
414 computed for each circle at each station. The highest levels (up to 90%) are recorded in Antikythera
415 whereas lower values (up to 70%) are recorded in THE and the lowest ones are found in ATH (up to
416 60%). This discrepancy is mainly attributed to the higher frequency of dust outbreaks affecting the
417 southern parts of Greece in contrast to the central and northern sectors of the country (Gkikas et al.,
418 2013; 2016). It is noted that all the PANACEA sites are also under the impact of advected loads
419 composed by anthropogenic/biomass particles originating at distant areas. Nevertheless, their
420 frequency of occurrence and their concentration is rarer and weaker, respectively, than those of the
421 advected Saharan dust. Between the remote (ANT) and urban (ATH, THE) sites there is clear
422 difference of the CV dependence with respect to the circle radius. In ANT, the CVs increase steadily
423 from the inner to the outer circle while an opposite tendency is found in THE and ATH. The increasing
424 trend in ANT is mainly regulated by the range of the Saharan plumes transported towards
425 southwestern Greece. On the contrary, the declining trend revealed in the two main Greek cities
426 indicates that the temporal variability of the local sources (i.e., two first circles) is more pronounced.
427 For completeness, we have also computed the spatial autocorrelation (Anderson et al., 2003;
428 Shinozuka and Redemann, 2011) among the averaged AODs of each circle area. The correlation
429 matrices for each station are presented in Fig. S1. Among the three PANACEA sites, the R values in
430 Athens (Fig. S1-i) drop rapidly, with respect to the first circle (10 km radius), highlighting the strong
431 spatial contrast of AODs between the city and the surrounding areas. For the outer domains, this
432 transition becomes significantly smoother and the R values are higher than 0.90 in most of the
433 combinations indicating a spatial coherence. In Thessaloniki (Fig. S1-iii), the pattern of the R values
434 onto the correlation matrix is similar with those of Athens but the high R values (> 0.89) indicate a
435 better spatial AOD homogeneity according to Anderson et al. (2003). Finally, under the absence of
436 local sources in Antikythera and strong AOD spatial homogeneity in the vicinity, the computed R
437 value between the inner (10 km radius) and the outer (100 km radius) circle is higher than 0.94 and
438 increases at shorter distances.

439 5. Collocation between Aeolus and ground-based lidars

441 The assessment of Aeolus SCA backscatter profiles has been performed against the
442 corresponding measurements acquired at the three EARLINET/PANACEA lidar stations. In Figure
443 2, three examples of the collocation between ground-based and spaceborne retrievals are illustrated

Deleted: L2A

450 in order to describe our approach as well as to clarify points needed in the discussion of the evaluation
451 results (Section 6). At each station, we identify the observations (BRCs), considering their
452 coordinates at the beginning of the ALADIN scan, falling within a circle of 120 km radius (black
453 dashed circle) centered at the station coordinates (black dot). Following this approach there is a
454 possibility of including BRCs where more than half of their length to fall outside of the defined circle.
455 This might affect the evaluation outcomes because we are not considering the BRC center in the
456 collocation. Nevertheless, we are expecting a negligible impact on the statistical analysis since the
457 77% of the BRCs would have been selected using alternatively the coordinates at their center. Based
458 on the defined spatial criterion, the number of BRCs residing within the 120 km circle should be at
459 least one and cannot be more than three. We denote each one of them, along the ALADIN
460 measurement track (white stripe), with different colors (red, blue and magenta) in Fig. 2. The green
461 arrow shows the flight direction of the satellite for the dusk (ascending) or dawn (descending) orbits.
462 For the ground-based observations, the aerosol backscatter profiles are derived considering a time
463 window of ± 1 hour around the satellite overpass. Nevertheless, this temporal collocation criterion
464 has been relaxed or shifted in few cases to improve the quality of the ground-based retrievals (i.e., by
465 increasing the signal-to-noise ratio) as well as to increase the matched pairs with Aeolus SCA profiles.
466 Both compromises are applied since the weather conditions favoring the development of persistent
467 clouds may eliminate the number of simultaneous cases. It is noted, however, when the temporal
468 window is shifted or relaxed we are taking into account the homogeneity of the atmospheric scene
469 (probed by the ground lidar). For the Antikythera station we did not deviate from the pre-defined
470 temporal criterion apart from one case study. In Thessaloniki and Athens, the time departure between
471 Aeolus and ground-based profiles can vary from 1.5 to 2.5 hours. Overall, 43 cases are analyzed out
472 of which 15 have been identified over Antikythera, 12 in Athens and the remaining 16 in Thessaloniki.

473 The ground-based profiles are derived under cloud free conditions in contrast to Aeolus SCA
474 backscatter profiles providing aerosol and/or cloud backscatter. Therefore, a cloud screening of the
475 SCA data using auxiliary cloud information was applied. In the framework of the present study, the
476 exclusion of cloud contaminated SCA profiles relies on the joint processing of the cloud mask product
477 (CLM; <https://www.eumetsat.int/media/38993>; CLOUD MASK PRODUCT GENERATION)
478 derived from radiances acquired by the SEVIRI (Spinning Enhanced Visible and Infrared Imager)
479 instrument mounted on the Meteosat Second Generation (MSG) geostationary satellite (Schmetz et
480 al., 2002). It should be noted, however, that the CLM product serves as an indication of clouds
481 presence, without providing information about their macrophysical properties (i.e., cloud coverage),
482 their phase (i.e., ice, water, mixed) or their categories (i.e., low, middle, high). According to the
483 product user guide (https://www-cdn.eumetsat.int/files/2020-04/pdf_clm_pg.pdf; Section 3.4),

490 artificial straight lines can be found because the ECMWF temperature/humidity fields are not
491 interpolated in time and space. Moreover, due to the limited number of levels of ECMWF temperature
492 profiles, required for the atmospheric correction, the cloud detection in the lower troposphere is
493 impacted. Finally, broken clouds with limited spatial extension as well as thin cirrus are likely
494 misdetected by MSG. In the illustration examples of Figure 2, the grey shaded areas represent the
495 CLM spatial coverage at each PANACEA site. Based on the filtering procedures, the Aeolus SCA
496 backscatter retrievals, throughout the probed atmosphere by ALADIN, are removed from the analysis
497 when the grey shaded areas overlap with a BRC.

498 6. Results

499 6.1 Assessment of Aeolus SCA backscatter under different aerosol scenarios

Deleted: L2A

500 In the first part of the analysis we assess the quality of the Aeolus SCA backscatter under
501 various aerosol regimes aiming to: (i) investigate the capabilities of the ALADIN spaceborne lidar to
502 detect aerosol layers, (ii) investigate how the horizontal homogeneity and vertical structure of the
503 aerosol layers can affect the level of agreement between spaceborne and ground-based retrievals and
504 (iii) demonstrate the synergistic use of various datasets for a better characterization of the prevailing
505 aerosol conditions. All of these aspects are necessary towards a comprehensive Cal/Val study to
506 facilitate the interpretation of our findings and to identify possible upgrades on SCA retrievals.
507 Overall, four cases over the Antikythera island (southwest Greece) are analyzed for the Aeolus SCA
508 aerosol backscatter retrievals (Baseline 2A11). The obtained results are depicted in Figure 3. The
509 identified cases have been selected because they are representing some of the most typical aerosol
510 conditions in the E. Mediterranean. Note that for each case we are selecting the nearest Aeolus BRC
511 to station coordinates that falls entirely within the circle area.

Deleted: L2A

Deleted: Aeolus

Deleted: L2A

512 As it has been already mentioned, SCA retrievals are provided at coarse spatial (BRC level;
513 ~90 km) and vertical (minimum 250 m) resolution, while currently there is no scene classification
514 scheme. In order to overcome this inherent limitation, as much as possible, several ancillary data and
515 products are utilized in parallel with those of the MSG-SEVIRI CLM product. Based on the
516 FLEXPART v10.4 Lagrangian transport model (Stohl et al., 2005; Ignacio Pissso et al., 2019) we have
517 reproduced the 5-day air masses backtrajectories prior to their arrival at 7 altitudes above the ground
518 station. FLEXPART was driven with 3-hourly meteorological data from the National Centers for
519 Environmental Prediction (NCEP) Global Forecast System (GFS) analyses provided at $0.5^\circ \times 0.5^\circ$
520 resolution and for 41 model sigma pressure levels
521 (https://nomads.ncep.noaa.gov/txt_descriptions/GFS_half_degree_doc.shtml). To depict the spatial
522 patterns of the mid-visible (550 nm) total and speciated AOD, we are relying on the MERRA-2

Deleted: Aeolus

530 (Modern-Era Retrospective analysis for Research and Applications version 2; Buchard et al., 2017;
531 Randles et al., 2017; Gelaro et al., 2017) and CAMS (Copernicus Atmosphere Monitoring Service;
532 Inness et al., 2019) reanalysis datasets, both providing AODs of high quality (Gueymard and Yang,
533 2020; Errera et al., 2021). Finally, AERONET sun-direct measurements (Level 2.0, Version 3; Giles
534 et al., 2019; Sinyuk et al., 2020) of spectral AODs and Ångström exponent as well as the Fine Mode
535 Fraction (FMF at 500nm) derived from the spectral deconvolution algorithm (O'Neill et al., 2003)
536 are also used for the characterization of the aerosol load and size over the station.
537

538 6.1.1 Dust advection on 10th of July 2019

539 The first case refers to the advection of dust aerosols from northwest Africa towards
540 Antikythera with dust-laden air masses crossing southern Italy prior to their arrival from northwest
541 directions (Figure S2). This route of air masses, driven by the prevailing atmospheric circulation
542 (Gkikas et al., 2015), is typical during summer when Saharan aerosols are advected towards the
543 eastern Mediterranean (Balis et al., 2006). MERRA-2 (Fig. S3-i) and CAMS (Fig. S3-ii) show a
544 reduction of AODs (at 550nm) from west to east whereas the large contribution (>80%) of dust
545 aerosols to the total aerosol load is evident in both reanalysis products (results not shown here). The
546 moderate-to-high AOD values are confirmed by the ground-based sunphotometric measurements
547 (Fig. S4) which are associated with low Ångström exponent (calculated between 440 nm and 870
548 nm) values (0.2 – 0.4) and FMF (Fig. S5) lower than 0.35 thus indicating the prevalence of coarse
549 mineral particles (Dubovik et al., 2002). This is further supported from Polly^{XT} measurements (Fig.
550 S6) revealing persistent dust layers associated with volume linear depolarization ratio (VLDR) values
551 of 5-10% at 355 nm, stretched from altitudes close to the ground and up to almost 6 km.

552 This case is suitable for evaluating SCA backscatter retrievals since non-spherical mineral
553 particles are probed by ALADIN, which does not detect the cross-polar component of the
554 backscattered lidar signal. Therefore, a degradation of ALADIN's performance is expected (i.e.,
555 underestimation of the backscatter coefficient and overestimation of the lidar ratio) when aspherical
556 particles (e.g., dust, volcanic ash, cirrus ice crystals) are probed. In Figure 3, the SCA backscatter
557 coefficient step-like vertical profiles at the regular (brown) and mid-bin (black) vertical scales are
558 compared against those acquired by the Polly^{XT} (pink) at 355 nm. The colored dashed lines (Aeolus)
559 and the pink shaded area (Polly^{XT}) correspond to the statistical uncertainty margins of the spaceborne
560 (see Section 2.3.1 in Flament et al., (2021)) and the ground-based (D'Amico et al., 2016) retrievals,
561 respectively. Both refer to the photocounting noise following a Poisson distribution. At a first glance,
562 it is evident that the geometrical structure of the dust layer, extending from 1 to 6 km, is generally
563 well captured by ALADIN (except at altitude ranges from 1 to 2.5 km), but the backscatter magnitude

Deleted: L2A

Deleted: from Aeolus

Deleted: revealed

567 is constantly lower. A fairer comparison requires the conversion of the backscatter retrievals
568 assuming that Polly^{XT} emits circularly polarized radiation (instead of linearly polarized) thus
569 resembling ALADIN. Under the assumption of randomly oriented particles and negligible multiple
570 scattering effects, this transformation is made based on theoretical formulas (Mishchenko and
571 Hovenier, 1995; Roy and Roy, 2008), as it has been shown in Paschou et al. (2022). Following this
572 approach, the Aeolus-like backscatter (i.e., circular co-polar component; blue curve in Fig. 3) is
573 reproduced for the ground-based profiles at altitudes where UV depolarization measurements are
574 available. Thanks to this conversion, the Aeolus-Polly^{XT} departures diminish and the Aeolus-like
575 curve resides closer to those of SCA (brown) and SCA mid-bin (black) backscatter levels. The
576 difference between pink and blue backscatter profiles, ranging from 13 to 33% in this specific case,
577 reflects the underdetermination of the particle backscatter coefficient in case of depolarizing aerosols
578 being probed, due to the missing cross-polar backscatter component.

Deleted: negative biases

580 6.1.2 Long-range transport of fine aerosols on 3rd July 2019

581 Under the prevalence of the Etesian winds (Tyrlis and Lelieveld, 2013), anthropogenic
582 aerosols from megacities (Kanakidou et al., 2011) and biomass burning particles originating in the
583 eastern Europe (van der Werf et al., 2017) are transported southwards. Based on the FLEXPART
584 simulations (Fig. S7), the air masses carrying fine particles, gradually descend till their arrival over
585 Antikythera from north-northeastern directions. During early morning hours, when ALADIN probes
586 the atmosphere at a distance of ~90 km westwards of the ground station (dawn orbit; descending),
587 moderate AODs (up to 0.15 at 340 nm), very high Ångström exponent values (>1.2) and FMFs
588 varying from 0.6 to 0.7 are measured with the Cimel sunphotometer (Fig. S8 and Fig. S9). The aerosol
589 load is confined below 2.5 km consisting of spherical particles as it is revealed from the Polly^{XT}
590 volume linear depolarization ratio (VLDR) values, which do not exceed 5% at 355 nm (Fig. S10). In
591 the vicinity of the PANGEA observatory, MERRA-2 (Fig. S11-i) and CAMS (Fig. S11-ii) AODs,
592 mainly attributed to organic carbon, sulphate and sea-salt aerosols, do not exceed 0.2 and they are
593 coherent in spatial terms (i.e., horizontal homogeneity). In this case, Polly^{XT} particle backscatter
594 coefficient profiles coincide with the corresponding Aeolus-like profiles (pink and blue curves are
595 almost overlaid in Fig. 3-ii) since depolarization values are negligible. Under these conditions,
596 ALADIN is capable of reproducing satisfactorily the layer's structure whereas slightly overestimates
597 its intensity with respect to the ground-truth retrievals.

599 6.1.3 Long range transport of fine aerosols on 8th July 2020

603 On 8th July 2020, the broader area of the Antikythera island was under the impact of moderate-
604 to-high aerosol loads, mainly consisting of organic and sulphate particles, in the western and southern
605 sector of the station, based on CAMS simulated AODs (up to 0.5) (Fig. S12-ii). AERONET
606 measurements yield UV AODs up to 0.5 and Ångström exponent higher than 1.5 during early
607 afternoon (Fig. S13) whereas the FMF is higher than 0.75 throughout the day (Fig. S14). MERRA-2
608 AOD patterns (Fig. S12-i) and speciation (strong contribution from marine and sulphate aerosols to
609 the total aerosol load) are different from those of CAMS, without being very consistent with respect
610 to the ground-based sunphotometer observations (Fig. S13, Fig. S14). Air masses originating in
611 northern Balkans and the Black Sea, after crossing metropolitan areas (i.e., Istanbul, Athens), are
612 advected over ANT at altitudes up to 4 km above surface. A second cluster aloft (>5 km) indicates
613 the convergence of air masses from northwest (Fig. S15). In vertical terms, aerosol layers with local
614 backscatter maxima gradually reducing from 3.5 to 1.5 Mm⁻¹ sr⁻¹ are observed up to 4 km based on
615 Polly^{XT} backscatter coefficient profiles (pink curve, Fig. 3-iii) whereas almost identical values are
616 recorded for the Aeolus-like retrievals (blue curve, Fig. 3-iii) under low VLDR levels (Fig. S16). For
617 this specific case, SCA performance reveals an altitude dependency according to the comparison
618 versus Polly^{XT}. From top to bottom, the weak layer extending from 6 to 8 km, observed in the ground-
619 based lidar profiles is partially evident in the SCA retrievals. SCA fails to reproduce the aerosol layer
620 (in terms of structure and backscatter magnitude) seen from the ground-based lidar between 2 and 4
621 km. Below 2 km, the agreement between ALADIN and Polly^{XT} becomes better, particularly for SCA
622 mid-bin, even though the narrow peak recorded at ~1.2 km by Polly^{XT} cannot be reproduced by
623 ALADIN. This might be attributed either to the adjusted RBS at the lowermost bin (1 km thickness)
624 or to the lower accuracy of SCA retrievals near the ground due to the attenuation from the overlying
625 layers (Flament et al., 2021).

627 6.1.4 Stratification of spherical and non-spherical particles on 5th August 2020

628 In the last case, that took place on 5th August 2020, we are investigating the ability of SCA to
629 reproduce adequately the vertical structure of an aerosol layer detected up to 4 km based on Polly^{XT}
630 (Fig. 3-iv; pink curve). The “peculiarity” of this study case, as it is revealed by the Polly^{XT} time-
631 height plots of VLDR (Fig. S17), is that spherical fine particles dominate below 2.5 km whereas the
632 presence of non-spherical coarse aerosols above this layer is evident. This stratification results from
633 the convergence of air masses either originating in central Europe or suspending most of their travel
634 above northwest Africa (Fig. S18). According to MERRA-2 (Fig. S19-i) and CAMS (Fig. S19-ii)
635 reanalysis datasets, AODs fade from west to east while both numerical products indicate the
636 coexistence of carbonaceous, sulphate and mineral particles over the area where ALADIN samples

Deleted: Aeolus

648 the atmosphere (~100 km westwards of Antikythera). During the Aeolus overpass (~04:40 UTC),
649 sunphotometer columnar observations are not available (Fig. S20, Fig. S21). However, one hour later,
650 UV AODs up to 0.4 are recorded and remain relatively constant during sunlight hours. At the same
651 time, intermediate Ångström (0.7 – 1) and FMF (~0.5) values, exhibiting weak temporal variation,
652 indicate a mixing state of fine and coarse aerosols.

653 The SCA backscatter retrievals at the regular (i.e., SCA; brown curve; Fig. 3-iv) and the mid-
654 bin (i.e., SCA mid-bin; black curve; Fig. 3-iv) vertical scales suffer from noise and retrieval gaps. As
655 a result, Aeolus possibly (acknowledging the weak signals and the underestimated errors) detects
656 incorrectly an aerosol layer between 5.5 and 8 km under the assumption that clear-sky conditions are
657 appropriately represented in the MSG-SEVIRI imagery and remain constant within the time interval
658 (~6 minutes) of MSG and Aeolus observations. At lower altitudes (2.5 – 4 km), due to the suspension
659 of depolarizing mineral particles, a departure is marked between the pink (linear-derived) and blue
660 (Aeolus-like) Polly^{XT} profiles. Both SCA and SCA mid-bin fail to reproduce the backscatter levels
661 of this aerosol layer captured from the ground. In the lowest troposphere (< 2km), SCA overestimates
662 significantly the backscatter coefficient but reproduces satisfactorily the aerosol layer structure at the
663 mid-bin vertical scale (i.e., SCA mid-bin; black curve; Fig. 3-iv), in contrast to the regular scale (i.e.,
664 SCA; brown curve; Fig. 3-iv).

665 A general remark that should be made, is that for the cases analyzed, between the ground-
666 based and spaceborne profiles there is an inconsistency in the vertical representativeness within the
667 lowermost Aeolus bin. Under the absence of the near-field receivers (not considered in our study)
668 Polly^{XT} profiles are reported above ~800 m where the overlap between the laser beam and the receiver
669 telescope field of view is expected to be full. However, the base altitude of the near-surface Aeolus
670 bin is at ~200 m. This can interpret, at some degree, the large positive ALADIN-Polly^{XT} departures
671 at altitudes below 1 km, which are possibly further strengthened by an inappropriate RBS (i.e., low
672 SNR) in the SCA retrievals.

673 6.2 Overall assessment and dependencies

675 In the second part of the analysis, an overall assessment of the Aeolus SCA retrievals is
676 performed by processing all the identified cases (43 in total; see Section 5). Due to the very limited
677 availability of ground-based extinction profiles, only the Aeolus SCA backscatter observations are
678 evaluated. It must be clarified that the evaluation of the Aeolus satellite (SAT) backscatter coefficient
679 is conducted without any conversion (i.e., from total linear to circular co-polar) of the ground-based
680 lidar (GRD) profiles. This has been decided since many of the SAT-GRD collocated samples are
681 derived from the Thessaloniki station. Due to technical issues (related to the polarization purity of the

Deleted: L2A

687 emitted laser beam and the performance of the telescope lenses) no calibrated depolarizing
688 measurements, necessary to derive the Aeolus-like products (Paschou et al., 2022), are available for
689 the study period. Nevertheless, we are not expecting that this consideration, acknowledging that it is
690 imperfect, will affect substantially the robustness of our findings since in most of the study cases the
691 contribution of depolarizing particles is quite low based on the ancillary datasets/products. It is also
692 clarified that the Aeolus QA flags are not taken into account in the current study, since their validity
693 is not yet reliable (Reitebuch et al., 2020) as it has been demonstrated in Abril-Gago et al. (2022).
694 The discussion in the current section is divided in two parts. First, the vertically resolved evaluation
695 metrics are presented separately for the two Aeolus vertical scales, both for the unfiltered and the
696 filtered (cloud-free) profiles (Section 6.2.1). The same analysis format (i.e., SCA vs SCA mid-bin,
697 unfiltered vs filtered) is kept in the second sub-section (Section 6.2.2) where the evaluation results
698 are presented as a function of various dependencies.

Deleted: 1

700 6.2.1 Vertically resolved evaluation metrics

701 In Figure 4, the vertically resolved bias (SAT-GRD; upper panel) and root mean square error
702 (RMSE; bottom panel) metrics are depicted for the unfiltered (cloud and aerosol backscatter) Aeolus
703 SCA backscatter retrievals, reported at the regular (left column) and the mid-bin (right column)
704 vertical scales. Bias and RMSE metrics (Wilks, 2019) are used in a complementary way in order to
705 avoid any misleading interpretation of the former score attributed to counterbalancing negative and
706 positive SAT-GRD deviations. For the calculation of the evaluation scores, the GRD profiles have
707 been rescaled to match Aeolus vertical product resolution. To realize, we are calculating the averaged
708 values of the ground-based retrievals residing within the altitude margins of each Aeolus BRC. Note
709 that in the SAT-GRD pairs, all BRCs from all cases are included (right y-axis in Figure 4), satisfying
710 the defined collocation criteria (see Section 5), and they are treated individually. It is reminded that
711 Aeolus L2A data are provided vertically at a constant number of range bins (i.e., 24 for SCA and 23
712 for SCA mid-bin) but their base altitude and their thickness vary along the orbit and from orbit-to-
713 orbit and they are defined dynamically (depending on the optimum SNR). Therefore, since the GRD
714 and SAT profiles are not interpolated in a common predefined grid, we are using as reference the
715 reverse index (with respect to those considered in the SCA retrieval algorithm in which 1 corresponds
716 to the top-most bin) of Aeolus SCA (from 1 to 24; left y-axis in Figs 4 i-a and ii-a) and SCA mid-bin
717 (from 1 to 23; left y-axis in Figs 4 i-b and ii-b) vertical scales.

Deleted: L2A

718 According to our results for the unfiltered SCA backscatter profiles (Fig. 4), positive biases
719 (up to $3.5 \text{ Mm}^{-1} \text{ sr}^{-1}$; red bars) are evident, at both vertical scales, at the first three bins (below 2 km).
720 For altitude ranges spanning from 2 to 8 km (bins 4 – 12), mainly positive SAT-GRD biases (up to

Deleted: Aeolus

724 $\sim 1.5 \text{ Mm}^{-1} \text{ sr}^{-1}$) are recorded for SCA mid-bin whereas for SCA reach up to $\sim 1 \text{ Mm}^{-1} \text{ sr}^{-1}$ in absolute
725 terms. Similar tendencies are evident at the highest altitudes ($> 8 \text{ km}$) but the magnitude of the SAT-
726 GRD offsets becomes lower ($< 0.5 \text{ Mm}^{-1} \text{ sr}^{-1}$). Between the two Aeolus vertical scales, SCA mid-bin
727 RMSE metrics are better than those of SCA up to $\sim 8 \text{ km}$ (bin 12) and similar aloft (bottom panel in
728 Fig. 4). Nevertheless, the most important finding is that SCA is not capable to reproduce satisfactorily
729 the backscatter profiles as it is revealed by the RMSE levels, which are maximized near the ground
730 ($\sim 8 \text{ Mm}^{-1} \text{ sr}^{-1}$), are considerably high (up to $6 \text{ Mm}^{-1} \text{ sr}^{-1}$) in the free troposphere and are minimized
731 ($< 1 \text{ Mm}^{-1} \text{ sr}^{-1}$) at the uppermost bins. Our findings are highly consistent with those presented in
732 Abril-Gago et al. (2022), who performed a validation of Aeolus, SCA particle backscatter coefficient
733 against reference measurements obtained at three ACTRIS/EARLINET sites in the Iberian Peninsula.
734 Several factors contribute to the obtained height-dependent SAT-GRD discrepancies. Near the
735 ground, the observed maximum overestimations are mainly attributed to the: (i) contamination of the
736 ALADIN lidar signal by surface reflectance, (ii) increased noise in the lowermost bins (caused by the
737 non-linear approach retrieving the backscatter coefficient) as it has been pointed out also in the
738 atmospheric simulations cases I and II in Ehlers et al. (2022) and (iii) limited vertical
739 representativeness of the GRD profiles below 1 km. On the contrary, in the free troposphere, the cloud
740 contamination on spaceborne retrievals plays a dominant role on the occurrence of ALADIN
741 backscatter overestimations with respect to the cloud-free ground-based retrievals. From a statistical
742 point of view, it must also be mentioned that the robustness of the bias and RMSE metrics decreases
743 for increasing altitudes due to the reduction of the number of the SAT-GRD matchups (right y-axis
744 in Fig. 4) participating in the calculations.

745 The assessment analysis has been repeated after removing SCA profiles when clouds are
746 detected by MSG-SEVIRI (grey shaded areas in Fig. 1) within a BRC (colored rectangles in Fig. 1).
747 By contrasting Figures 4 and 5 (evaluation metrics for the filtered profiles), an expected improvement
748 of the level of agreement between SAT and GRD is visible. This translates into a drastic reduction of
749 bias and RMSE levels at altitude ranges up to 5-6 km (\sim bin 10). Between bins 2 and 5 slight
750 underestimations (blue bars) and overestimations (red bars) are found for SCA (Fig. 5 i-a). On the
751 contrary, for the SCA mid-bin (Fig. 5 i-b) low positive SAT-GRD offsets are recorded due to the
752 omitted negative backscatter values, as it will be shown in the next section. Above bin 5, SAT-GRD
753 deviations are low in absolute terms, oscillating around zero, for SCA, whereas only positive SAT-
754 GRD biases are recorded for SCA mid-bin, which are maximized ($\sim 0.7 \text{ Mm}^{-1} \text{ sr}^{-1}$) at the highest bins
755 and are associated with limited SAT-GRD matchups (right x-axis in Fig. 5 i-b). The obtained
756 improvements on bias scores become more confident since they are associated with similar strong
757 reductive tendencies on RMSE levels. More specifically, the RMSE spikes of extremely high values

Deleted: performs

Deleted: , as it is shown by the RMSE profiles

Deleted: Aeolus

Deleted: L2A

Deleted: the

Deleted: Aeolus

764 recorded in the unfiltered profiles either disappear or weaken in the case of the Aeolus filtered SCA
765 (Fig. 5 ii-a) and SCA mid-bin (Fig. 5 ii-b) backscatter profiles. However, even though the RMSE
766 values at the lowermost bins (close to the ground) are decreased when cloud contaminated Aeolus
767 profiles are eliminated, still the corresponding levels for the filtered profiles are considerably high
768 attributed to the lower SNR and the possible impact of surface returns.

769

770 6.2.2 Scatterplots

771

772 An alternative approach to assess the performance of Aeolus SCA backscatter is attempted
773 here by reproducing two dimensional histograms for the entire SAT-GRD collocated sample as well
774 as scatterplots resolved based on various dependencies. More specifically, the dependencies under
775 investigation are those of the: (i) station locations, (ii) BRCs and (iii) orbits (dawn vs dusk). The
776 evaluation metrics have been calculated for all possible combinations of vertical scales (SCA vs SCA
777 mid-bin) and SCA profiles (unfiltered vs filtered).

778 Figure 6 depicts the two-dimensional histograms between GRD (x-axis) and SAT (y-axis)
779 backscatter coefficient for the raw (upper panel) and filtered (bottom panel) SCA profiles reported at
780 the SCA (left column) and SCA mid-bin (right column) vertical scales. Note that we have removed
781 SAT-GRD pairs in which SCA backscatter exceeds $20 \text{ Mm}^{-1} \text{ sr}^{-1}$ in order to avoid the “contamination”
782 of extreme outliers in the calculated metrics, possibly attributed to the presence of clouds (Proestakis
783 et al., 2019).

784 Between the SCA and SCA mid-bin unfiltered retrievals, it is found that the correlation
785 coefficients (0.36 and 0.39, respectively) and RMSEs (2.00 and 1.88, respectively) are similar
786 whereas there is an evident difference on the biases ($0.45 \text{ Mm}^{-1} \text{ sr}^{-1}$ and $0.69 \text{ Mm}^{-1} \text{ sr}^{-1}$, respectively).
787 Nevertheless, it is noted that less SAT-GRD pairs are recorded for SCA mid-bin due to the inherent
788 flagging of negative values. After removing cloud-contaminated SCA profiles, the amount of the
789 SAT-GRD matchups is reduced by about 55% and 59% for SCA (from 537 to 239) and SCA mid-
790 bin (from 356 to 147), respectively. Nevertheless, thanks to this filtering procedure, the initially
791 observed overestimations for SCA and SCA mid-bin are reduced by ~25% and ~43%, respectively,
792 whereas the RMSE values drop down to 1.65 (SCA) and 1.00 (SCA mid-bin). The better agreement
793 between SAT and GRD, for the filtered SCA profiles, is further justified by the increase of the R
794 values (from 0.39 to 0.48) for the SCA mid-bin whereas for SCA there is no positive or negative
795 tendency ($R=0.36$). The spread of the points in the two dimensional space reveals many similarities
796 with the corresponding scatterplots presented in Abril-Gago et al. (2022) for the Iberian
797 ACTRIS/EARLINET stations.

Deleted: , aiming to investigate the factors determining the level of agreement between spaceborne and ground-based retrievals

Deleted: Aeolus

Deleted: Aeolus

Deleted: Aeolus

Deleted: Aeolus

Deleted: Aeolus

807 A common feature in all scatterplots, shown in Figure 6, is that most of the positive outliers
808 are found at the lowermost bins (see Figs. 4 and 5). SAT beta can reach up to $20 \text{ Mm}^{-1} \text{ sr}^{-1}$ in contrast
809 to the corresponding GRD levels, which are mainly lower than $2 \text{ Mm}^{-1} \text{ sr}^{-1}$. For SCA (Figs. 6 i-a, 6
810 ii-a), the majority of the negative SAT-GRD pairs are recorded at the highest bins in which, however,
811 both spaceborne and ground-based backscatter coefficients are noisy. Another cluster of SAT-GRD
812 pairs is those where slight negative SCA backscatter values are grouped together with low positive
813 backscatter values retrieved from ground. At the mid-bin vertical scale, for the unfiltered SCA profiles
814 (Fig. 6 i-b), the negative SAT backscatter values are masked out resulting in better evaluation metrics
815 (except the increase of bias due to the removal of the negative SCA backscatter) with respect to the
816 regular vertical scale. Among the four scatterplots, the best agreement between SCA and ground-
817 based retrievals is revealed for the SCA mid-bin filtered profiles (Fig. 6 ii-b) attributed to the
818 coincident elimination of the negative and the extreme positive SCA backscatter coefficient.

819 Figure 7 depicts the overall scatterplot between ground-based and spaceborne retrievals as a
820 function of the three PANACEA sites (colored categories). The associated evaluation scores are
821 summarized in Table 1 and 2 for the unfiltered and filtered SCA profiles, respectively. The majority
822 of the extreme positive outliers of unfiltered SCA retrievals (Fig. 7 i-a) are recorded in Thessaloniki
823 and Athens. According to our results, for SCA, significant biases ($0.73 \text{ Mm}^{-1} \text{ sr}^{-1}$ for ATH and 0.83
824 $\text{Mm}^{-1} \text{ sr}^{-1}$ for THE) and high RMSE values ($2.26 \text{ Mm}^{-1} \text{ sr}^{-1}$ for ATH and $2.60 \text{ Mm}^{-1} \text{ sr}^{-1}$ for THE) are
825 found. At Antikythera island (ANT), the biases are quite low and equal to $0.06 \text{ Mm}^{-1} \text{ sr}^{-1}$ and 13.6%
826 in absolute and relative terms, respectively (Table 1). In all stations, for the unfiltered SCA mid-bin
827 retrievals, the absolute SAT-GRD departures become larger whereas the RMSE decreases in
828 ANT/THE and increases in ATH. Regarding the temporal covariation between SAT and GRD
829 retrievals, a noticeable improvement is evident in ANT (i.e., R increases from 0.49 to 0.57). For the
830 quality-assured SCA profiles (Table 2), all evaluation metrics converge towards the ideal scores for
831 SCA mid-bin whereas mainly positive tendencies (i.e., better agreement) are evident for SCA.
832 Overall, among the three stations the best performance of the SCA retrievals is recorded at the
833 Antikythera island.

834 Between dawn (descending) and dusk (ascending) orbits, better bias and RMSE scores are
835 computed when Aeolus is flying during early morning hours while better R values are found during
836 early afternoon satellite overpasses. However, our orbit-wise results are not robust since the number
837 of Aeolus overpasses is not evenly distributed (about 85% of the SAT-GRD matchups are acquired
838 during dawn orbits). Among the three BRCs (red, blue or magenta), which can satisfy the defined
839 SAT-GRD spatial criterion (see Section 5) the best metrics are found for the red BRC residing most
840 of the cases closer to the station site.

850 7. Discussion on Cal/Val aspects and recommendations

851

852 Throughout this assessment analysis, several critical points have been identified and
853 highlighted that should be addressed adequately towards a comprehensive Cal/Val study of the
854 Aeolus SCA products. These aspects can: (i) serve as guidelines for future relevant studies, (ii)
855 improve our understanding about the advantages/limitations of Aeolus data in terms of their
856 usefulness and applicability in aerosol-related studies and (iii) suggest possible upgrades regarding
857 ALADIN's observational capabilities, the considerations of the applied retrieval algorithms and the
858 content of information in Aeolus SCA data.

Deleted: L2A

859 A fair comparison of Aeolus SCA backscatter versus linear-derived retrievals acquired from
860 ground-based lidars, when depolarizing particles are recorded, requires the conversion of the latter
861 ones to circular co-polar (Aeolus-like) following Paschou et al. (2022). Nevertheless, it should be
862 acknowledged that the theoretical assumptions can be invalid either due to the orientation of the
863 suspended particles (e.g., mineral dust; Ulanowski et al., 2007; Daskalopoulou et al., 2021; Mallios
864 et al., 2021) or due to multiple scattering effects within optically thick aerosol layers (Wandinger et
865 al., 2010). The lack of aerosols/clouds discrimination in Aeolus SCA data forces the synergistic
866 implementation of ancillary data in order to remove cloud contaminated Aeolus profiles from the
867 collocated sample with the cloud-free ground-based profiles. Nevertheless, it should be noted that the
868 cloud removal itself is not perfect. In our case, we are relying on MSG-SEVIRI cloud observations,
869 which are available at high temporal frequency (every 15 min) thus allowing a very good temporal
870 collocation with Aeolus. The indirect cloud-mask filtering applied to our analysis, leads to a
871 substantial improvement of the level of agreement between spaceborne and ground-based retrievals.
872 Despite its success, our proposed approach provides a sufficient and acceptable solution, but
873 undoubtedly cannot be superior to the utility of a descriptive classification scheme on Aeolus retrieval
874 algorithms similarly done in CALIOP-CALIPSO (Liu et al., 2019; Zeng et al., 2019).

Deleted: L2A

Deleted: L2A

Deleted: 1

875 Aeolus retrievals are available at coarse along-track resolution (~90 km). This imposes
876 limitations on their evaluation against point measurements, which are further exacerbated at sites
877 where the heterogeneity of aerosol loads in the surrounding area of the station is pronounced, taking
878 into account that the spatial collocation between spaceborne and ground-based retrievals is not exact.
879 Numerical outputs from reanalysis datasets (e.g., MERRA-2, CAMS) can be utilized as an indicator
880 of aerosols' burden horizontal variation, taking advantage of their complete spatial coverage, their
881 availability at high temporal frequency and their reliability in terms of total AOD (Innes et al., 2019;
882 Gueymard and Yang, 2020). Nevertheless, such data are better to be utilized in a qualitative rather

Deleted: L2A

888 than a quantitative way, particularly in terms of aerosol species, since they cannot be superior of
889 actual aerosol observations. Over areas with a complex terrain, vertical inconsistencies between
890 ground-based and satellite profiles (reported above ground where its height is defined with respect to
891 the WGS 84 ellipsoid), not physically explained, can be recorded. For the derivation of the evaluation
892 scores, it is required a rescaling of the ground-based profiles, acquired at finer vertical resolution, in
893 order to match the dynamically defined Aeolus' range bin settings. Nevertheless, due to this
894 transformation, the shape of the raw ground-based profile can be distorted and the magnitude of the
895 retrieved optical properties can be modified substantially thus affecting the evaluation metrics. This
896 artifact is evident in cases where the vertical structure of the aerosol layers is highly variable thus
897 hindering Aeolus capability to reproduce accurately their geometrical features. Finally, the
898 consideration of backward trajectories can assist the characterization of the probed atmospheric scene
899 by Aeolus. Potentially, they can be also used as an additional criterion for the optimum selection of
900 Aeolus BRC for the collocation with the ground-based measurements. However, possible limitations
901 may arise due to temporal deviations among FLEXPART run, the Aeolus overpass and ground-based
902 retrievals, which might be critical taking into account the strong spatiotemporal variability of aerosol
903 loads across various scales.

904

905 8. Conclusions

906 The limited availability of vertically resolved aerosol products from space constitutes a major
907 deficiency of the Global Observing System (GOS). The launch of the Aeolus ESA satellite was a
908 major step towards this direction whereas the forthcoming EarthCARE satellite mission (Illingworth
909 et al., 2015) will accelerate further these efforts. ALADIN, the single payload of the Aeolus satellite,
910 constitutes the first UV HSRL Doppler lidar ever placed in space and it is optimized to acquire HLOS
911 wind profiles towards advancing numerical weather prediction (Rennie et al., 2021). ALADIN also
912 retrieves independently the extinction and backscatter coefficients of aerosols and clouds (grouped as
913 particulates according to Aeolus' nomenclature) via the implementation of various retrieval
914 algorithms (SCA, MLE, AEL-PRO).

915 The current work focuses on the assessment of the SCA backscatter coefficients versus
916 ground-based retrievals acquired routinely by lidar systems operating in Athens, Thessaloniki, and
917 Antikythera. The aforementioned stations contribute to the PANACEA Greek National Research
918 Infrastructure (Greek ACTRIS component) and to the European Aerosol Research Lidar Network
919 (EARLINET; Pappalardo et al., 2014). Overall, 43 cases are analyzed out of which 12 have been
920 identified in the urban site of Athens, 16 in Thessaloniki and 15 in the remote site of the Antikythera
921 island.

Deleted: the

Deleted: algorithm

924 In the first part of the analysis, focus was given on the assessment of Aeolus SCA particle
925 backscatter coefficient, under specific aerosol scenarios, versus the corresponding measurements
926 obtained at the Antikythera island (southwest Greece). The misdetection of the cross polarized lidar
927 return signals can interpret the lower Aeolus SCA backscatter values (ranging from 13% to 33%)
928 with respect to ground-based retrievals when depolarizing mineral particles are probed (case of 10th
929 July 2019). For the case of 3rd July 2019, when aerosol loads of moderate intensity, consisting mainly
930 of spherical particles, are confined below 4 km and they are homogeneous in the surrounding area of
931 the station, Aeolus' SCA backscatter product is capable in reproducing quite well the ground-based
932 profile in terms of shape and magnitude. For the cases of 8th July 2020 and 5th August 2020, SCA
933 performance in terms of depicting complex stratified aerosol layers (composed of particles of
934 different origin), as these are observed from ground, degrades due to noise in the cross-talk corrected
935 molecular and particulate signals.

936 Our statistical assessment analysis reveals that the removal of cloud contaminated spaceborne
937 profiles, achieved via the synergy with MSG-SEVIRI cloud observations, results in a significant
938 improvement of the product performance. Unfortunately, the poor evaluation metrics at the
939 lowermost bins (attributed to either the surface reflectance or the increased noise levels for the Aeolus
940 retrievals and to the overlap issues for the ground-based profiles) are still evident after the cloud
941 filtering procedure. Between the two Aeolus vertical scales, the computed evaluation metrics do not
942 provide strong evidence of which of them performs better. Among the three stations (ATH, ANT,
943 THE) considered here, the best agreement was found in the remote site of Antikythera island in
944 contrast to the urban sites of Athens and Thessaloniki. All key Cal/Val aspects, serving as guidelines
945 and potential recommendations for future studies, have been discussed thoroughly.

946 In the current work, we emphasized only on the particle backscatter coefficient due to the
947 limited number of ground-based extinction profiles. A wider assessment analysis is ongoing in the
948 framework of the Aeolus L2A Cal/Val study performed within EARLINET. Finally, the best
949 assessment of Aeolus L2A products is expected versus the purpose-built eVe lidar (Paschou et al.,
950 2022). Thanks to its configuration, eVe can mimic Aeolus' observational geometry and test the
951 validity of the theoretical formulas applied for the derivation of the Aeolus-like backscatter from the
952 linearly polarized emission ground-based systems. The first correlative Aeolus-eVe measurements
953 have been performed in the framework of the Joint Aeolus Tropical Atlantic Campaign (JATAC),
954 that took place in Cape Verde in September 2021. Correlative measurements are also acquired during
955 the ESA-ASKOS experimental campaign (Mindelo, Cabo Verde). The geographical location of Cabo
956 Verde, situated on the "corridor" of the Saharan transatlantic transport (Gkikas et al., 2022), is ideal

Deleted: L2A

Deleted: As expected, the misdetection of the cross polarized lidar return signals, induces an underestimation (ranging from 13% to 33%) of Aeolus L2A backscatter when depolarizing mineral particles are probed (case of 10th July 2019).

1740 **Figure 6:** 2D histograms between Aeolus (y-axis) and ground-based (x-axis) backscatter coefficient retrievals. In the
 1741 upper (i) and bottom (ii) panels are depicted the results for the cloud+aerosol backscatter (unfiltered) and cloud-cleared
 1742 backscatter (filtered) Aeolus profiles, respectively. On the left and right columns are illustrated the results corresponding
 1743 to Aeolus regular (24 bins) and mid-bin (23 bins) vertical scales, respectively. Aeolus backscatter values larger than 20
 1744 $\text{Mm}^{-1} \text{sr}^{-1}$ are masked out from the collocated sample.

1749 **Figure 7:** Scatterplots between Aeolus (y-axis) and ground-based (x-axis) backscatter coefficient retrievals resolved
 1750 based on the indices of Aeolus vertical bins (colored circles). In the upper (i) and bottom (ii) panels are depicted the
 1751 results for the unfiltered and filtered Aeolus profiles, respectively. On the left and right columns are illustrated the results
 1752 corresponding to Aeolus regular (24 bins) and mid-bin (23 bins) vertical scales, respectively. Aeolus backscatter values
 1753 larger than $20 \text{ Mm}^{-1} \text{ sr}^{-1}$ are masked out from the collocated sample.
