## Further details on calibration experiments

### *Estimation of lab air humidity*

Some of the follow-up calibration experiments at the University of Washington (UW) laboratories, denoted as set (2) in the main text, used dilution of dry N<sub>2</sub> with lab air (Fig. S2a, and orange circle in Fig. 2). We estimated the relative humidity (RH) of that lab air as 40 (±4) %, based on the temperature of 18 °C and dew point of 7 °C reported at nearby Boeing Field (airport KBFI) at the time, resulting in an RH range from 20% to 36% for the corresponding measurements.

### *Increased sensitivities following instrument startup*

A noteworthy observation during the HI-SCALE deployment was made during sensitivity tests for organic compounds made in the field, before and after research flights. For those tests, a small flow (≤ 10 sccm) of calibrant-containing N<sub>2</sub> from a cylinder (1 ppmv of isoprene, 1 ppmv of  $\alpha$ -pinene and 0.5 ppmv of dimethyl sulfide, ±5% each, in UHP N<sub>2</sub>; Scott-Marrin) was mixed into a large flow of dry N<sub>2</sub> (> 25 L min<sup>-1</sup>) that was directed into the CIMS inlet tip outside the aircraft, while the CIMS sample pump pulled 22 L min<sup>-1</sup> towards the instrument. Invariably, significantly higher sensitivities were obtained before flights than after flights (Fig. S2b). The mechanism behind that remained unresolved, and the only co-varying circumstance was found to be the relative abundance of dimer reagent ion counts, which we expressed as the monomer-to-dimer ratio  $[C_6D_6^+]/[C_6D_6.C_6D_6^+]$ . We speculate that the benzene mixing ratios in the IMR could have been higher pre-flight, which also coincided with the first 1-2 hours after instrument start-up, and responsible for those observations. We could not exclude that these observations are only seen when using dry N<sub>2</sub>, as attempts of mixing calibration gas with ambient air produced inconclusive results for those organics (example shown in Fig. S2c). The calibration experiments for NH<sub>3</sub> never occurred at times of low enough (< ~5) ratios  $[C_6D_6^+]/[C_6D_6.C_6D_6^+]$ , so we could not establish if the response of NH<sub>3</sub>.C<sub>6</sub>D<sub>6</sub><sup>+</sup> was subject to any dependence on that ratio (Fig. S2c).

## Overall NH<sub>3</sub> levels observed during IOP1

An overview of all the mixing ratios obtained during 11 research flights (RF) in May 2016 is presented in Fig. S3. Below ~900 m AMSL (~600 m above the SGP site), the observed NH<sub>3</sub> mixing ratios broadly ranged from 1 to 10 ppbv, and up to 10s of ppbv in plumes. Observations above 900 m covered a larger number of flights and ranged down to 100 pptv, including the flight yielding data from the highest altitude (4200 m AMSL) as well as the lowest average mixing ratios. The observations at the lower end (100-400 pptv) occurred on May 16 (RF14) and 19 (RF16), which were dominated by clouds, and did not include measurements below cloud base. Mixing ratios then remained as low when climbing higher into the free troposphere. Observations of NH<sub>3</sub> mixing ratios of ~1 ppbv or higher are associated with overall sunny days and were made clear of cloud and with good confidence also within the well-mixed boundary layer.

## WRF-Chem model configurations

We used the community regional Weather Research and Forecasting Model coupled to chemistry (WRF-Chem version 4.2) for generating modeling results in this study. Specifically, WRF-Chem was run for the times of RF13, i.e., the afternoon of 14 May 2016. Resulting NH<sub>3</sub> mixing ratios for the full domain are shown in Fig. S7. Figure 6 includes the results for the model cells crossed by the aircraft during RF13.

Our configuration of the WRF-Chem model included a domain covering most of the Midwest, Eastern and Southern parts of the United States at a grid spacing of 12 km. Gas-phase chemistry represented by the SAPRC-99 mechanism was coupled with the MOSAIC (Model for Simulating Aerosol Interaction and Chemistry) aerosol module (Zaveri et al., 2008) and includes aerosol chemistry and secondary organic aerosol updates as described in Shrivastava et al. (2022). We used the NEI 2017 emissions inventory for anthropogenic emissions in the USA, while biomass burning emissions were from the 2014 Quick Fire Emissions Database (QFED v2.5) inventory and were coupled to the Freitas plume rise model (Freitas et al., 2007). WRF-Chem used online biogenic emissions calculated using the Model of Emissions of Gases and Aerosols from Nature (MEGAN v2.1; Guenther et al., 2012) coupled within the land surface scheme of Community Land Model version 4 (CLM4) in WRF-Chem version 4.2. We have recently implemented within WRF-Chem a mechanistic soil NO<sub>x</sub> emission scheme based on that of Rasool et al. (2019), along with NH<sub>3</sub> emissions derived from Dubache et al. (2019). The total NH<sub>3</sub> emissions fluxes simulated in WRF-Chem are a sum of those from NEI 2017 (Fig. S8) and the soil NH<sub>3</sub> emissions (Fig. S9) that we recently implemented.

Additional details are provided in Table S1.

**Table S1:** WRF-Chem model configurations used in this work

WRF domain	12 km horizontal grid resolution with 45 vertical layers
Planetary Boundary layer (PBL)	Yonsei University (YSU) PBL scheme (Hong, 2010)
Land Surface Model	Community Land Model (CLM v4) (Lawrence et al., 2011)
Cloud microphysics	Morrison double moments (Morrison et al., 2009)
Radiation	RRTMG scheme (longwave + shortwave) (Iacono et al., 2008)
Convective parametrization	Grell and Freitas (2014). Grid-scale wet removal: Easter et al. (2004)
Aerosol-Cloud interactions	Aerosol activation based on the parameterization by Abdul-Razzak and Ghan (2002)
Emissions	NEI 2017 for anthropogenic aerosol and trace gas emissions, QFED v2.5 for biomass burning emissions, biogenic emissions from MEGAN2.1 (Guenther et al., 2012)
Gas-phase photochemistry	SAPRC-99
Aerosol chemistry	MOSAIC for inorganic aerosols, secondary organic aerosol treatments as described in Shrivastava et al. (2022)
Boundary conditions	0.25-degree GFS final analysis (FNL) for meteorology and CAM-Chem global model simulations for aerosols and trace gases

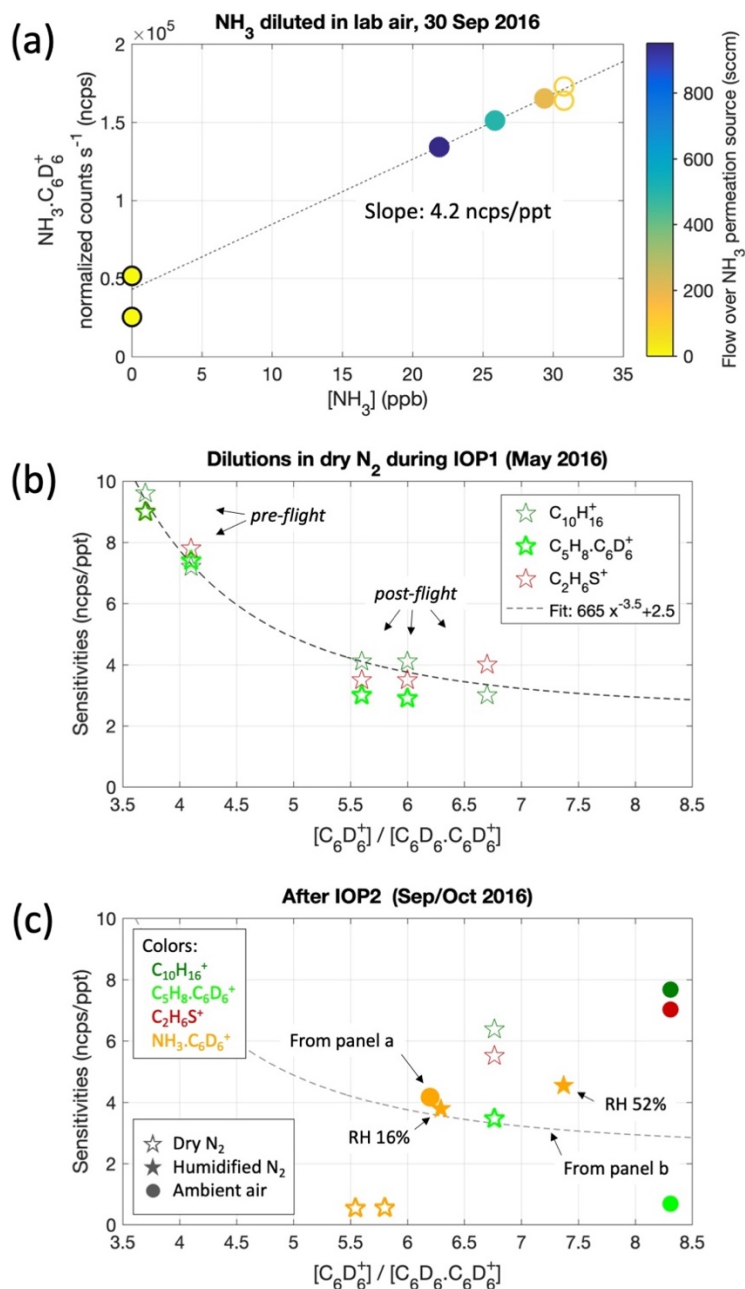

## Wavelet power spectra for temperature measurements

Figure S6 includes power spectra for ambient temperature ( $T$ ) measured by either the AIMMS or the Rosemount sensor. Turbulence was captured well by the  $w$  measurements up to highest frequencies, whereas the Rosemount's 1-Hz  $T$  measurements were somewhat attenuated at frequencies  $> 0.3$  Hz. Interestingly, the power spectra for the AIMMS  $T$  measurements, nominally at 20 Hz, did not reveal any attenuation, even though visual comparisons of the two  $T$  time series suggested that the Rosemount sensor reacted considerably faster to  $T$  changes. Also, sensible heat flux calculations, prepared for a separate publication, produced more reasonable results when using the Rosemount data. The high spectral power of the AIMMS  $T$  measurements beyond  $\sim 0.3$  Hz may instead be due to instrument noise.

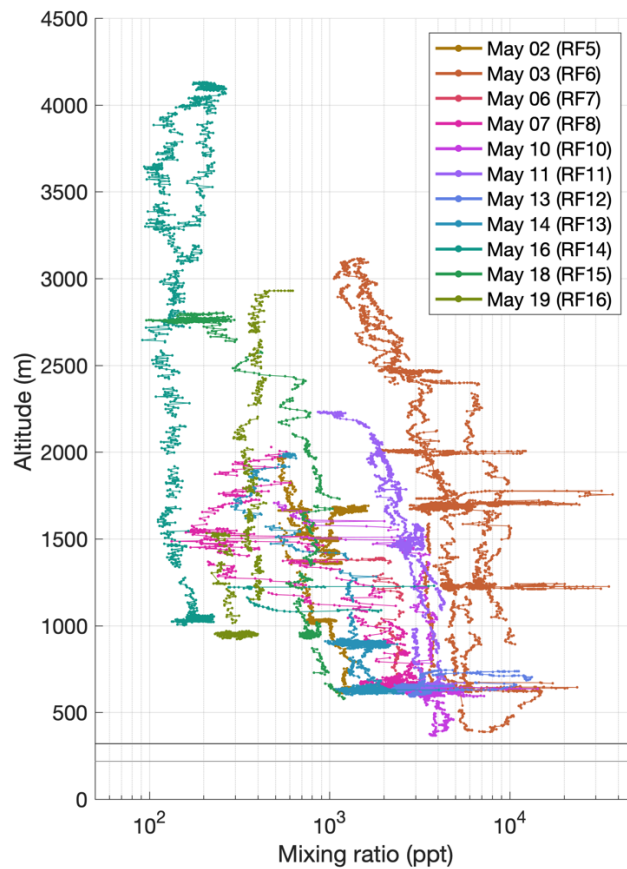

## Figures S1-S9

**Fig. S1:** Portions of flight tracks of the research flights 5-8 and 10-16 when operating in benzene-CI (positive polarity) mode. These flights took place during the intensive operating period of HI-SCALE in spring 2016 (IOP1), specifically May 2, 3, 6, 7, 10, 11, 13, 14, 16, 18 and 19, respectively. Each flight has the same separate color as used in the vertical  $\text{NH}_3$  mixing ratio profiles shown in Fig. S3.

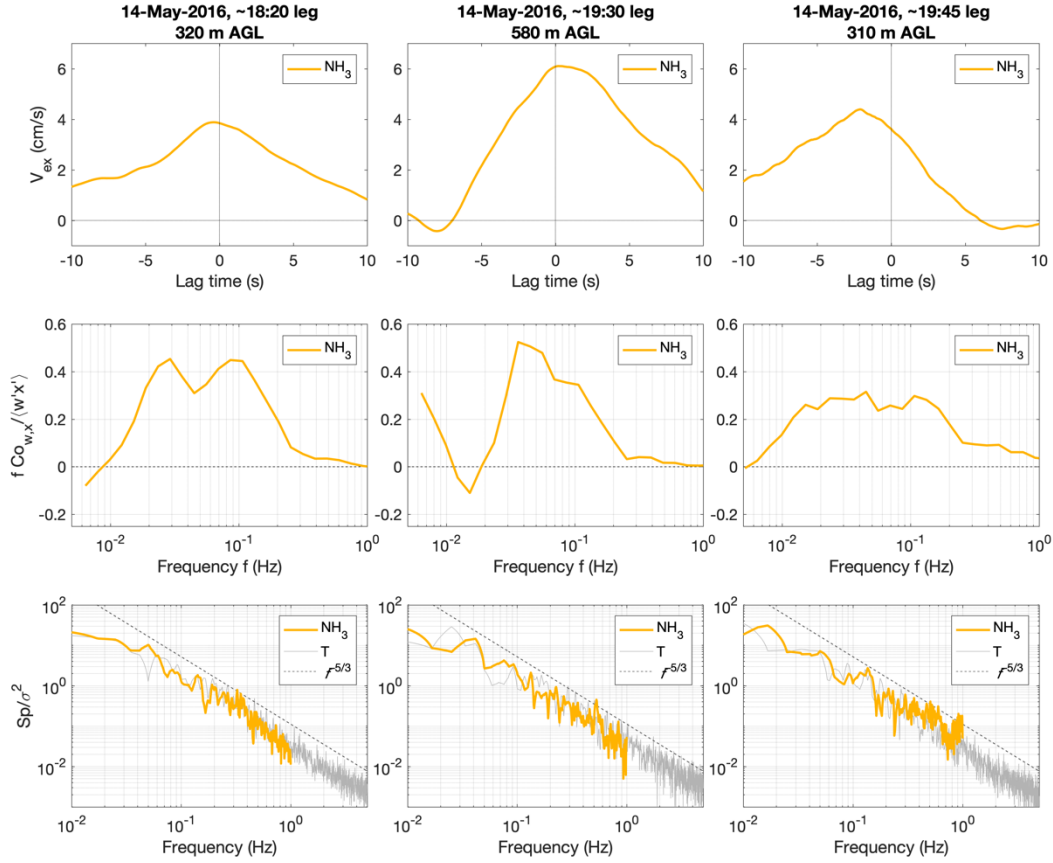

**Fig. S2:** Results of various calibration experiments. **(a)** Response of normalized  $\text{NH}_3 \cdot \text{C}_6\text{D}_6^+$  count rate to  $\text{NH}_3$  mixing ratios obtained from diluting a permeation device output with room air, yielding a sensitivity of 4.2 ncps/pptv. Results with permeation source flows < 150 sccm (open circles) produced less reproducible results. Background counts (black-rimmed yellow) are from both before (lower counts) and after delivering  $\text{NH}_3$ . **(b)** Sensitivities obtained for isoprene ( $\text{C}_5\text{H}_8$ , light green),  $\alpha$ -pinene ( $\text{C}_{10}\text{H}_{16}$ , dark green) and dimethyl sulfide ( $\text{C}_2\text{H}_6\text{S}$ , red) in dry  $\text{N}_2$  during calibration experiments in the field, as a function of the ratio of reagent ion mono- and dimer count rates. **(c)** Various sensitivity calibration results obtained shortly after HI-SCALE, including results in ambient (i.e., humid) air (circles) and for  $\text{NH}_3$  (orange).

**Fig. S3:** Overview of  $\text{NH}_3$  mixing ratios (pptv) retrieved during 11 flights (research flights 5-8 and 10-16) in May 2016, as a function of altitude (m above mean sea level). These are all results obtained from CIMS in standard benzene-CI mode during IOP1 of HI-SCALE. Each color corresponds to a separate flight, using the same color coding as in Fig. S1.

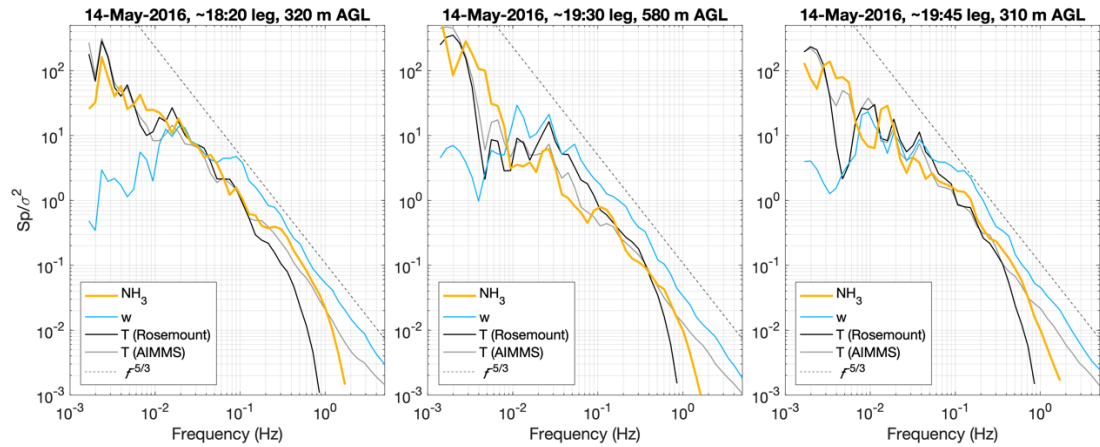

**Fig. S4:** Metrics of eddy-covariance analysis using the ensemble-average method for the three legs in Fig. 6. Shown, for each leg, are averages of all 2-min time intervals (blue in Fig. 6) that fulfill the quality criteria, in particular including stationarity. The top row shows normalized covariance (i.e., exchange velocity,  $V_{ex}$ ) as a function of time lag. Covariance typically maximized when accounting for a  $\sim 1$ -s delay relative to the wind data; consequently, a lag of  $-0.9$  s was used for this flight. The center row shows frequency-weighted and flux-normalized co-spectra for  $x = [\text{NH}_3]$  and  $w$ . The bottom row presents variance-normalized power spectra for  $[\text{NH}_3]$  and temperature, exhibiting the  $-5/3$  decay expected for the inertial subrange (dashed line) and indicating negligible high-frequency attenuation.

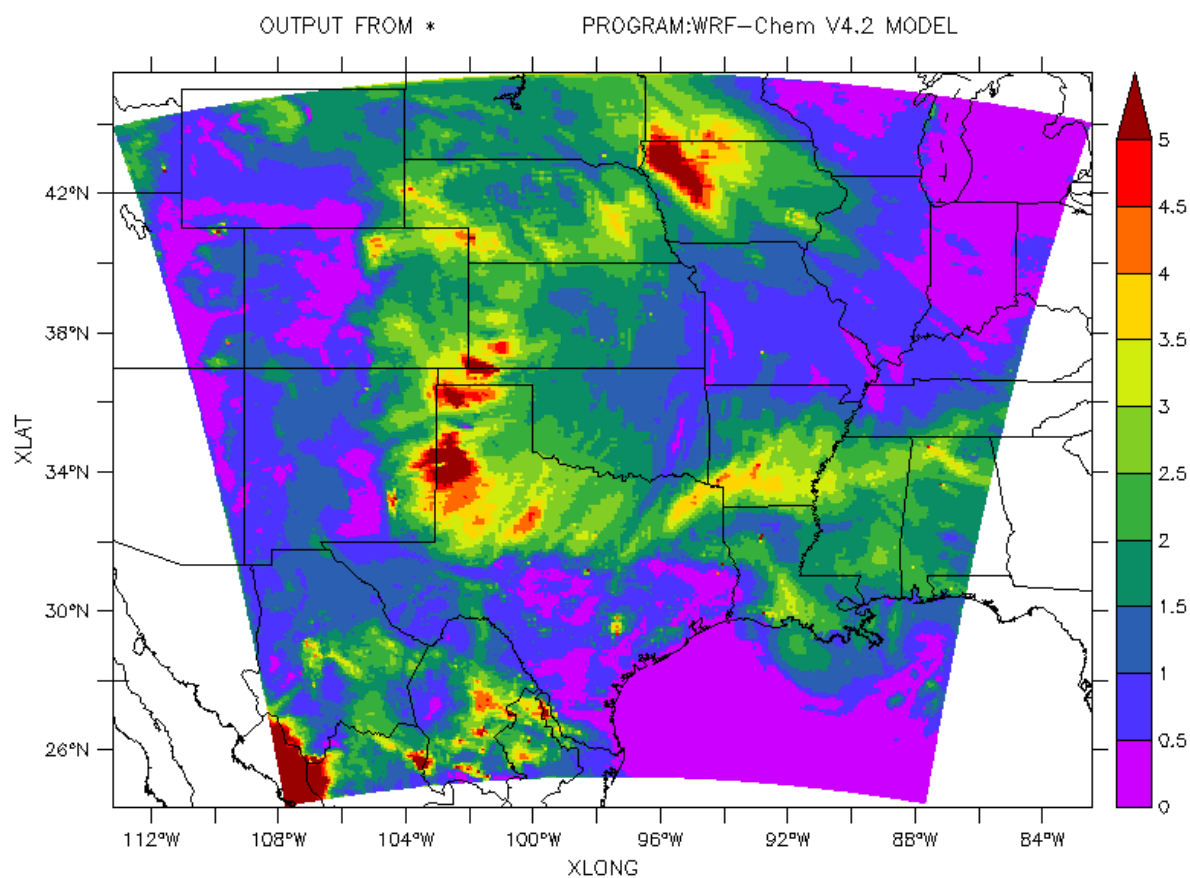

**Fig. S5:** Frequency-weighted co-spectra for  $x = [\text{NH}_3]$  and  $w$  for the three legs in Figs. 6-7, calculated by time-averaging the CWT co-spectra (thick lines) and by fast Fourier transform of the same period (thin lines).

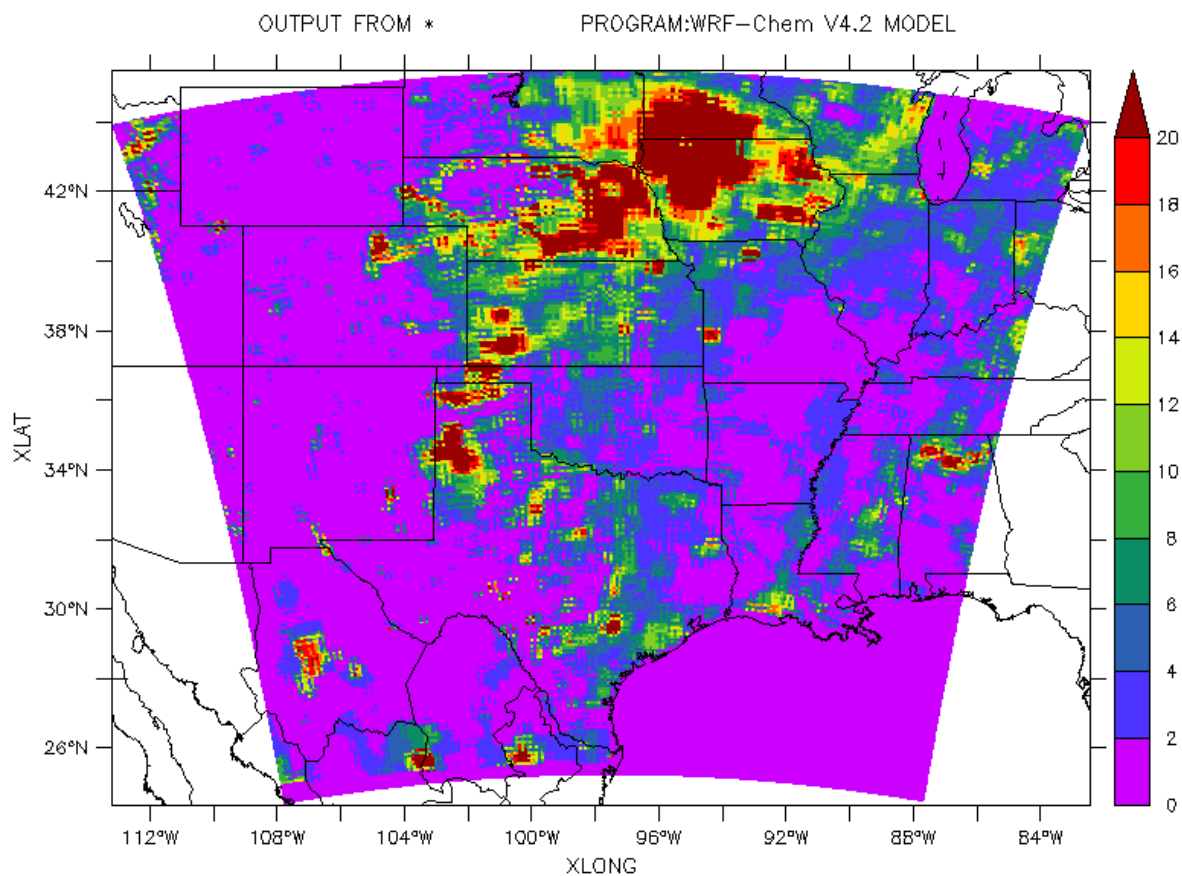

**Fig. S6:** Variance-normalized CWT power spectra for the three legs in Figs. 6-7, exhibiting the  $-5/3$  decay expected for the inertial subrange (dashed line) and indicating negligible high-frequency attenuation, at least up the Nyquist frequencies (1 Hz for  $\text{NH}_3$ , 0.5 Hz for Rosemount, 5 Hz for AIMMS), analogously to the power spectra in Fig. S4 (bottom row).

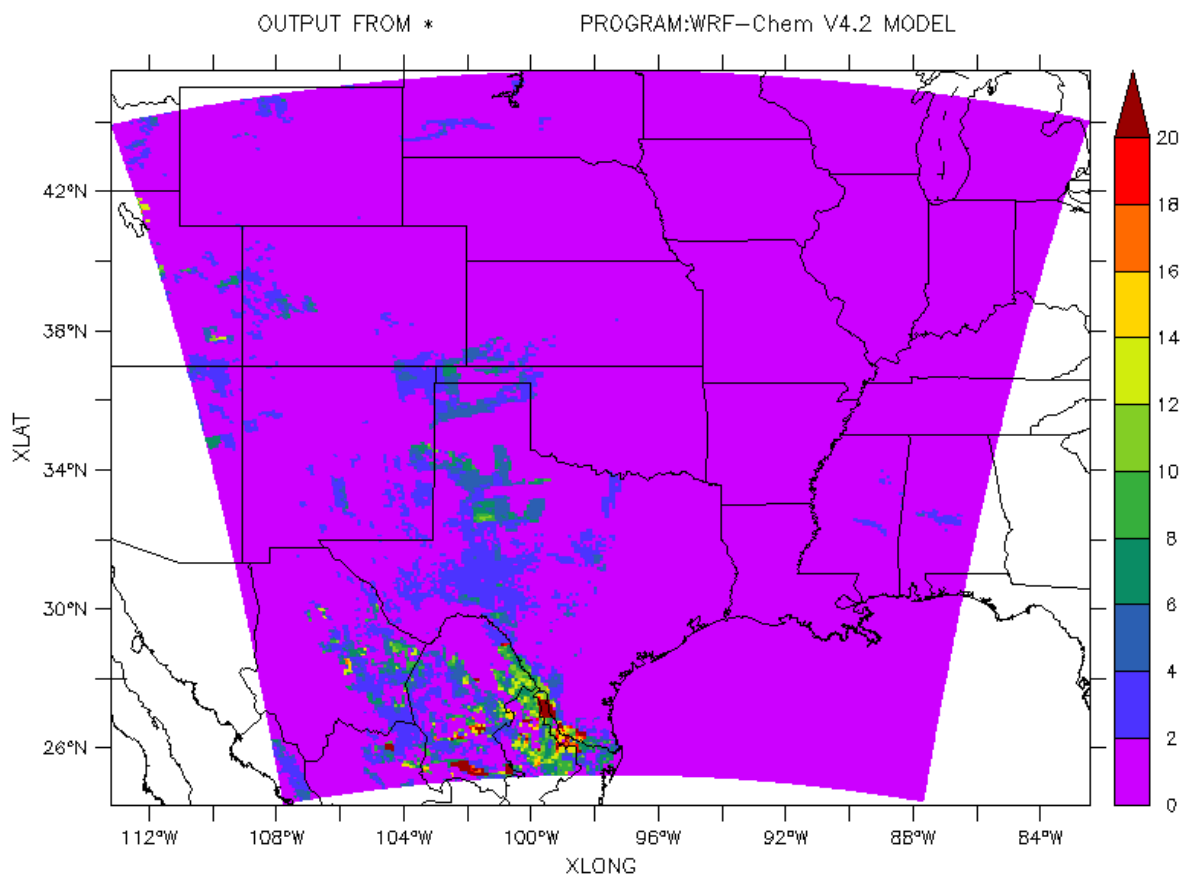

**Fig. S7:**  $\text{NH}_3$  mixing ratios (color scale from 0 to 5 ppbv) resulting from WRF-Chem model simulations for 14 May 2016, 20:00 UTC, i.e., during RF13. The RF 13 flight tracks discussed in the main text (Fig. 6) were centered on the SGP ground site, located at the center of this map (36.61° N, 97.49° W).

**Fig. S8:** Emissions of NH<sub>3</sub> in the National Emissions Inventory (NEI, 2017 data) for 14 May 2016 20:00 UTC. They do not include emissions from soils related to N cycling (Fig. S9), which we additionally included in the WRF-Chem model simulation. The color scale ranges from 0 to 20 mol km<sup>-2</sup> h<sup>-1</sup>. The map is centered on the SGP ground site at 36.61° N, 97.49° W.

**Fig. S9:** Emissions of  $\text{NH}_3$  in the mechanistic soil  $\text{NO}_x$  emission scheme that were added to the NEI emissions in WRF-Chem model simulation. The color scale ranges from 0 to 20  $\text{mol km}^{-2} \text{h}^{-1}$ . The map is centered on the SGP ground site at 36.61° N, 97.49° W. For the area of RF13, and indeed of all flights of HI-SCALE IOP1, the scheme yielded additional  $\text{NH}_3$  emissions below 2  $\text{mol km}^{-2} \text{h}^{-1}$  (purple) for 14 May 2016.
