9 **Abstract.**

10

11 Methane (CH₄) is a strong greenhouse gas that has become the focus of climate mitigation policies in recent years.
12 Ethane/methane ratios can be used to identify and partition the difference sources of methane, especially in areas with
13 natural gas mixed with biogenic methane emissions, such as cities. We assessed the precision, accuracy and selectivity
14 of three commercially available laser-based analyzers that have been marketed as measuring instantaneous dry mole
15 fractions of methane and ethane in ambient air. The Aerodyne SuperDUAL instrument performed best of the three
16 instruments but it requires expertise to operate and space for the large footprint. The Aeris Mira Ultra LDS analyzer
17 also performed well for the price point and small footprint but required characterization of the water vapor dependence
18 of reported concentrations and careful setup for use. The Picarro G2210-i precisely measured methane but it did not
19 detect the 10 ppbv increases in ambient ethane detected by the other two instruments when sampling a plume of
20 incompletely combusted natural gas. For long-term tower deployments or those with large mobile laboratories, the
21 Aerodyne SuperDUAL provides the best precision for methane and ethane. For smaller mobile platforms, the Aeris
22 MIRA is a more compact analyzer, and with careful use, can quantify thermogenic methane sources to sufficient
23 precision for short term deployments in urban or oil and gas areas. We weighed the advantages of each instrument,
24 including size, power requirement, ease of use on mobile platforms, and expertise needed to operate the instrument,
25 and we recommend the Aerodyne SuperDUAL or the Aeris MIRA Ultra LDS depending on the situation.

26

27

28

29 1 Introduction

30 The atmospheric concentrations of methane (CH_4), a strong greenhouse gas, have been rising at an unprecedented rate
31 in recent years, with record breaking growth rates since 2020 (https://gml.noaa.gov/ccgg/trends_ch4/). Methane has
32 an atmospheric lifetime of ~ 10 years compared to ~ 100 years for carbon dioxide (CO_2) and absorbs over 80 times
33 more heat than CO_2 over 20 years (Szopa et al., 2021). Both of these characteristics make the reduction of methane
34 emissions a priority target for short-term reductions in anthropogenic global warming. In recent years, methane has
35 become the target of climate mitigation policies at many levels of government, including international (e.g. founding
36 of the United Nations Environment Programme funded International Methane Emissions Observatory (IMEO) in
37 2022), national (e.g. Inflation Reduction Act, 2022, USA) and local (e.g. New York's Climate Leadership and
38 Community Protection Act, (CLCPA), over 50 cities in the US banning natural gas new construction).

39 Methane sources are categorized as thermogenic (e.g. oil, natural gas, coal mining) or biogenic; which can
40 be both natural (e.g. wetlands) or anthropogenic (e.g. agriculture, landfills, sewage) in origin (Saunio et al., 2020).
41 Each of these methane sources co-emits different trace gas species, which we can use to identify the source of methane.
42 Thermogenic sources of methane, such as natural gas, also contain ethane (C_2H_6) and other hydrocarbons. The
43 incomplete combustion of natural gas can co-emit high concentrations of carbon monoxide (CO) and other Volatile
44 Organic Compounds VOCs. Biogenic sources of methane do not co-emit ethane, but can emit carbon dioxide (CO_2)
45 and more odorous trace gases such as hydrogen sulfide (H_2S). Therefore, ethane can be used to distinguish between
46 thermogenic (methane/ethane co-emitted) and biogenic (no ethane emitted) sources of methane. Many studies have
47 used methane/ethane ratios to identify natural gas leaks in the natural gas production and distribution networks (e.g.
48 review of methods described in (Ravikumar et al., 2019). Methane/ethane observations have also been used for mobile
49 and stationary sampling in urban areas across many countries to identify natural gas leaks separately from biogenically
50 produced methane (e.g. (McKain et al., 2015; Lamb et al., 2016; Maazallahi et al., 2020; Defratyka et al., 2021).

51 Methane monitoring networks are being developed for city, state and national scales with the goal of
52 evaluating the efficacy of methane reduction policies. Many of these networks will need to partition the contribution
53 of methane between thermogenic and biogenic sources. In recent years, commercial analyzers have been developed
54 to measure methane and ethane at ambient concentrations and many of these analyzers are marketed as allowing users
55 to attribute the sources of methane.

56 Here, we evaluated three laser-based spectrometers that are marketed to measure ambient ethane and
57 methane; (i) a cavity enhanced infra-red (IR) absorption spectrometer (Aerodyne Research Inc SuperDual QCI/ICL),
58 (ii) a mid-IR absorption spectrometer (Aeris Technologies Mira Ultra LDS) and (iii) a cavity ring down spectrometer
59 (Picarro G2210-i CRDS). The precision and accuracy of each instrument was evaluated and compared to the advertised
60 performance. We tested the water vapor response and assessed the long-term operation needs of each instrument.
61 Finally, we evaluated the performance of each instrument while sampling urban air at a rooftop site with large natural
62 gas and biogenic emissions in the urban core of New York City in February 2022. We examine the requirements for
63 long-term operation of each analyzer and make recommendations for operation.

64
65

66 2 Methods

67 2.1 Description of Analyzers

68 2.1.1 Aerodyne Research Inc SuperDual

69 Various configurations of Aerodyne laser spectrometers have been used to measure methane and ethane in stationary
70 (McKain et al., 2015), ground-based mobile (Yacovitch et al., 2014) and airborne (Kostinek et al., 2019; Plant et al.,
71 2019) platforms. These spectrometers use a continuous wave interband cascade laser (ICL) based spectrometer to
72 measure methane, ethane and water vapor, often alongside a continuous wave quantum cascade laser (QCL) to
73 measure dry mole fractions of carbon dioxide (CO₂), carbon monoxide (CO), and nitrous oxide (N₂O). Here, we use
74 a SuperDUAL configuration of a two-laser system with a 2L astigmatic Herriott cell (path length 210m) at 50 Torr
75 pressure. The instrument was manufactured in 2015 and refurbished with new lasers in 2020. We use the provided
76 TDLWintel software to fit the absorption spectra and quantify five target gasses and water vapor. The ICL (Laser 1)
77 sweeps from 2988.520 to 2990.625 cm⁻¹ to detect CH₄, C₂H₆ and H₂O. The edge of the ethane absorption feature
78 (2990.081 cm⁻¹) includes a small methane peak (2989.98 cm⁻¹) that is fixed to the value determined from the main fit
79 at 2989.003 cm⁻¹. The QCL (Laser 2) sweeps from 2227.550 to 2228.000 cm⁻¹ and includes absorption features for
80 ¹³CO₂ (2227.605 cm⁻¹), CO (2227.639 cm⁻¹), N₂O (2227.843 cm⁻¹) and H₂O. We use the default water broadening
81 value of 2 for all species except CO, which is 1.45. The analyzer has a large, heavy footprint (56 cm x 77 cm x 64 cm;
82 75kg) and requires an external pump and chiller (to maintain laser temperature stability) that require a stable power
83 source. The instrument has been used extensively and successfully for long-term ground site observations and mobile
84 lab deployments but it is not suitable for smaller/car based mobile sampling. As part of our regular ambient sampling,
85 the Aerodyne SuperDUAL samples nitrogen gas each hour to account for instrument drift for lower concentration
86 species such as ethane. A smooth spline is fitted to the reported zero for each gas species and subtracted from the 1Hz
87 data.

88 2.1.2 Aeris Technologies MIRA Ultra LDS

89 The Aeris Technologies MIRA Ultra LDS (#100209; manufactured July 2021) uses a mid-IR ICL (~3000 cm⁻¹ range)
90 with a multi-pass cell. There are few descriptions of the Aeris MIRA but (Travis et al., 2020) described the portable
91 version of the instrument with an onboard battery (MIRA Pico, not evaluated here). The multi-pass cell (60 cm³) has
92 a path length of 13 m and an internal pump maintains the cell pressure at 180 Torr with a ~380 sccm flow rate. The
93 small footprint of the rackmount configured analyzer (43 cm x 28 cm x 13 cm; 5 kg) makes it ideal for car-based
94 mobile sampling. The current configuration using a small internal pump is not suitable for sampling below ambient
95 pressure and care should be taken when configuring the system when sampling through long lines on towers.

96 2.1.3 Picarro G2210-i

97 The Picarro G2210-i (#3441-RFIDS2010, manufactured Aug 2019) is a Cavity Ring Down Spectrometer that
98 measures CH₄, CO₂, C₂H₆, and δ¹³C-CH₄. The instrument uses an external pump to reach a cell pressure of 148 Torr
99 and flow rate of 24 sccm through a cavity of 35 cm³ with a path length of up to 30 km
100 (https://www.picarro.com/support/library/documents/g2210i_analyzer_datasheet). Methane data from the instrument
101 has been used on mobile (O'Connell et al., 2019) and stationary (Lebel et al., 2020) platforms and is also mentioned

102 in (Defratyka et al., 2021) but none of these studies have discussed or shown the observed ethane concentrations. The
103 datasheet indicates that the instrument is designed to sample ambient air but may have interferences from elevated
104 concentrations of gas species such as hydrogen sulfide (H₂S) or volatile organic compounds (VOCs).
105

106 2.2 Instrument Evaluation Set-up

107 2.2.1 Humidity

108 The humidity of the sample line for the instruments was varied using a Perma Pure Nafion (™) dryer. Nafion dryers
109 have a semi-permeable membrane separating an internal sample gas stream from a counterflow purge gas stream
110 contained within a stainless-steel outer shell. If the partial pressure of water vapor is higher in the purge gas stream,
111 then water is added to the sample gas stream. A counter flow of air was drawn through the Nafion at ~2000 sccm
112 using a vacuum pump and the inlet to the counter flow was alternatively sampling the top of a container of water that
113 was at a temperature slightly warmer than the observatory or dry air-conditioned air in the observatory. To achieve
114 the driest humidity, dry nitrogen was pushed through the Nafion. The flow rate through the Nafion was controlled
115 using a ball valve and allowed for different rates of changes in the humidity. No liquid water was introduced to the
116 sample lines for the instruments. A range of water vapor from 3% to 0.05% was used for all instruments except for
117 the Aeris Mira Ultra LDS ethane data, which was cut off at 1.05% water vapor (for reasons discussed below).
118

119 2.2.2 Calibrations against NOAA standards

120 Each of the instruments was calibrated against two ambient range cylinders calibrated by the Central Calibration
121 Laboratory (CCL) at the National Oceanographic and Atmospheric Administration (NOAA) Global Monitoring
122 Laboratory (GML) in Boulder, CO. CCL maintains the World Meteorological Organization (WMO) methane scale
123 (WMO X2004A) and an internal CCL standard for ethane (C₂H₆-2012). A dry, compressed air cylinder was used to
124 test multi-hour instrument stability.
125

126 2.2.3 Instrument Stability

127 We evaluated the instrument stability by running a calibrated compressed air cylinder for a 4 hour period and
128 calculating Allan-Werle variance and precision. During this time the regular zero for the Aerodyne SuperDUAL was
129 not performed. The Aeris MIRA and Picarro G2210-i were humidified (1.7 - 1.9 % H₂O) to allow the Aeris MIRA to
130 report ethane (see Section 3.1). The Aerodyne SuperDUAL was not humidified and reported less than 0.054 % H₂O
131 for the same tests.

132 2.2.4 Zero-air tests

133 During regular ambient operation, the Aerodyne SuperDUAL samples nitrogen gas each hour to account for
134 instrument drift for lower concentration species such as ethane. We use the boil off from a large liquid nitrogen dewar,
135 which can be refilled on site, and which contains a variable mole fraction of carbon monoxide (~250 ppb/nmol mol⁻¹).
136 Regular zero sampling is not required for long-term either the Picarro G2210-i or the Aeris MIRA but we evaluated

137 each instrument's performance when sampling the hourly zero air addition for dry air and for air humidified to >0.5%
138 water vapor for the Aeris MIRA and Picarro G2210-i.

139 2.3 Site Description and Sampling of ambient urban air

140 The City University of New York (CUNY) Next Generation Environmental Sensor (NGENS) Observatory is on the
141 rooftop of the 56m building in Hamilton Heights in Harlem. The sampling point is ~93m above sea level on a tower
142 at the south end of the building. The Aerodyne SuperDUAL has been operated at the site over a number of years and
143 was running from early January - June 2022. The site samples urban air that has been influenced by natural gas
144 emissions (both pre and post combustion), wastewater treatment plants (North River to the north-west, Ward Island
145 to the east) and sewer street emissions. During the long-term operation of the Aerodyne SuperDual, nitrogen (liquid
146 nitrogen boil off, N₂) is added as a test of the zero drift in the instrument. For the experiments described here, N₂ was
147 used hourly during ambient sampling and prior to and after the compressed air tank test runs. When the Aerodyne
148 SuperDUAL is operated independently, air is drawn through ~10 m of ½" Synflex tubing at 20 L min⁻¹ using a
149 diaphragm pump before being sub-sampled by the Aerodyne SuperDUAL (flow rate 1.7 L min⁻¹). The use of a separate
150 pump to increase the total flow rate and reduce instrument response times is commonly used for ground operation
151 with longer tubing (e.g. towers). However, the pump also reduces the pressure within the tubing to below ambient
152 pressure, which was a problem when sampling with the smaller pump capacity of the Aeris MIRA. For the work
153 described here, the external pump was removed and the response time through the tubing was reduced to 30s. Each
154 instrument sampled from a Swagelok cross fitting using a ~1 m ¼" Synflex tubing.

155 We sampled air from the roof in February, 2022 when ambient air temperatures ranged from below freezing
156 (-9.3°C) to a warm spring day (19°C). The lowest temperatures were also associated with low humidity, which caused
157 problems that were also detected during the humidity testing, so the sample line of the Picarro G2210-i and Aeris
158 MIRA were humidified to >1% water vapor as a work around for these problems.

159 3 Results and Discussion

160 We characterized the laboratory performance of each analyzer with respect to humidity corrections, precision
161 assessment, calibration to NOAA standards and long-term stability, before sampling ambient air in New York City.
162 We used these tests to recommend the best instrument for use in different circumstances.

163 3.1 Characterization of Water Sensitivity

164 All three instruments showed a dependency on water vapor for methane that was statistically significant. Figure 1
165 shows the dependence of the retrieved methane and ethane with the water vapor reported by each instrument for a
166 compressed air cylinder with variable humidity. A linear correction was calculated for methane and ethane for both
167 the Aerodyne SuperDUAL and the Picarro G2210-i but a quadratic dependence was observed for the Aeris MIRA
168 methane. The values of each water vapor correction are shown in Table 1. The Picarro G2210-i needed the smallest
169 absolute correction for methane, and the Aerodyne SuperDUAL reported the smallest correction for ethane. The
170 SuperDUAL was operated with the default water vapor broadening coefficient for methane and ethane of 2.0. This
171 correction is likely too large for methane and moving closer to the value of 1.05 recommended by Kostinek et al.,
172 2019 would reduce the water vapor correction. Here we have applied a linear correction with water vapor to the
173 observed data that results in a 10 ppbv (parts-per-billion by volume; equivalent of nmol mol⁻¹) change in methane but
174 a ~0.08 ppbv change in ethane for 0-2% water vapor.

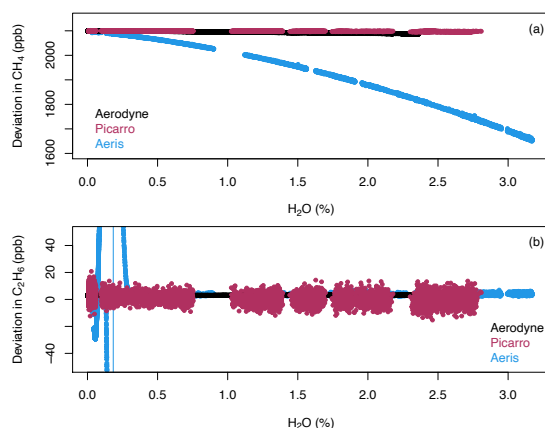

175

176

Table 1: Summary of water vapor corrections derived for each instrument

Instrument	CH ₄ Correction ppbv/% H ₂ O $y = m * [\text{H}_2\text{O}]$	C ₂ H ₆ ppbv/% H ₂ O $y = m * [\text{H}_2\text{O}]$	Notes: Using default water broadening coefficients for all instruments before calibration
Aerodyne SuperDUAL	-5.335 ppbv /% H ₂ O	0.042 ppbv /% H ₂ O	
Aeris MIRA Ultra LDS	-25.53 (% H ₂ O) ² - 59.22 % H ₂ O	0.23 ppbv / % H ₂ O	C ₂ H ₆ only calculated for H ₂ O > 1.05 %
Picarro G2210-i	-1.15 ppbv /% H ₂ O	-0.82 ppbv /% H ₂ O

181

182

We identified two separate, but related, situations with the Aeris MIRA that could prove to be a problem if not accounted for in operation in certain environments and configurations:

183

184

185

186

187

188

189

190

191

192

193

194

195

196

- (i) The wavelength of the laser is tied to the water vapor absorption peak. When running a dry calibration tank, the instrument loses frequency lock and the laser wavelength can drift to the point that the ethane peak can no longer be resolved. The reported ethane concentrations vary between 200 ppbv and -100 ppbv during this dry air sampling, possibly driven by laser wavelength drift. When the water vapor increases again after a calibration, the ethane fit is not immediately recaptured. Noise in the reported ethane and methane concentrations increases significantly below 1.05% water vapor and below 0.5% the ethane fit is completely lost.
- (ii) For most environments, water vapor in the atmosphere absorbs some of the mid-IR laser power and the laser power of the Aeris MIRA is optimized to achieve maximum sensitivity. However, New York City in February is cold and dry, with very low concentrations of ambient water vapor. Without enough water vapor to attenuate the laser power, the detector can be saturated, leading to no ethane detected and a noisy methane retrieval. This problem can be fixed by reducing the laser power slightly (using the procedure recommended by Aeris engineers) or by humidifying the sample line slightly. We opted for the latter fix for this study. At the other extreme, water vapor closer to 3% can also lead to increased noise in the fitted methane and ethane.

197 After losing the ethane peak during either of these circumstances, the Aeris MIRA analyzer will often fail to find the
198 peak again until manually re-connected to the internet. We have not identified a cause for this behavior but it was
199 more likely during (ii) and was not a problem after we humidified the sample flow. Using the GPS receiver provided
200 by Aeris also seemed to mitigate the problem.

201 3.2 Instrument calibration

202 Each instrument was calibrated against two NOAA calibration standards after accounting for the water vapor
203 correction described in Section 3.1. A linear fit (OLS, ordinary least squares) was calculated for each species and the
204 span (slope) and zero correction (intercept) and 95% confidence intervals were calculated (Table 2). The span and
205 offset were then applied to each species. As described above, the Aeris MIRA could not report ethane concentrations
206 when sampling a dry tank so the sample line of both the Aeris MIRA and Picarro G2210-i were humidified to water
207 vapor mole fractions between 1.7-1.9 % H₂O. For methane, all three instruments reported a span correction less than
208 3%, and zero corrections of between 3 and 14 ppbv. All three instruments report very similar methane mole fractions
209 for a compressed air tank after all calibration steps were applied. For ethane, the Aeris MIRA and Aerodyne
210 SuperDUAL reported a span less than 7% and offset of less than 2 ppbv. However, the slope and intercept for the
211 Picarro G2210-i were not successfully resolved for the reported 1 Hz data and a two-point linear fit was calculated for
212 the average values reported over the sampling period (Slope 0.427; intercept 4.275). The resulting correction
213 successfully resolved the target gas mole fractions but with a large standard deviation in the 1 Hz data (Fig S5).

214
215 **Table 2. Calibration span (slope) and zero (intercept) calculated for each instrument reporting at 1 Hz when sampling the**
216 **NOAA calibration standards. **The ethane Picarro G2210-i calibration was calculated from the mean of each cylinder**
217 **measurement (two-point calibration).**

Species (nmol mol ⁻¹)	Slope	Intercept	Slope +/-	Intercept +/-	r ²

Aerodyne; C ₂ H ₆ (ppbv)	1.069	0.064	0.001	0.004	0.9996

218

219 3.3 Instrument precision

220 The precision of each analyzer was evaluated by sampling a calibrated compressed air cylinder for four hours. We
221 calculated an Allan-Werle variance (Fig 2) and the observed precision for methane and ethane for each instrument
222 (Table 3).

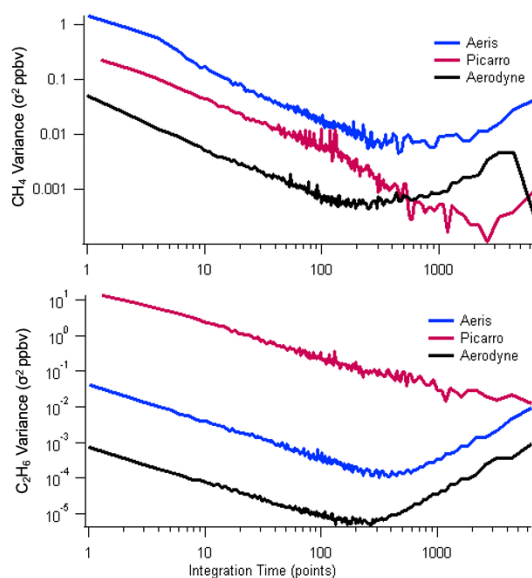

Figure 2. Allan-Werle Variance for (a) methane and (b) ethane for all three instruments when sampling a compressed air cylinder on Feb 17th, 2022 11 am - 3 pm EDT. Each of the tanks was calibrated to NOAA cylinders after water vapor correction. The reported water vapor for the Aerodyne SuperDUAL (black) was below 0.054 %. The Aeris MIRA (blue) and Picarro G2210-i (red) were humidified to water vapor 1.7 – 1.9 %.

 241

For methane, the Aerodyne SuperDUAL had the best 1 Hz (0.227 ppbv) and 10s (0.072 ppbv) precision with a minimum of 0.021 ppbv at 3.2 mins but the variance increased slightly again (but still below 1 ppbv) after about 15 mins. There were no zeros performed for the SuperDUAL during the precision experiment so this increase in variance was not unexpected. The Aerodyne SuperDUAL matched the 100 s precision of (Kostinek et al., 2019) at 0.024 ppbv. At 100s, the Aeris LDS precision was 0.14 ppbv and the Picarro G2210-i precision was 0.08 ppbv, both of which exceeded their quoted precision of 0.5 ppbv (at 1 s) and 0.1 ppbv (at 5 min).

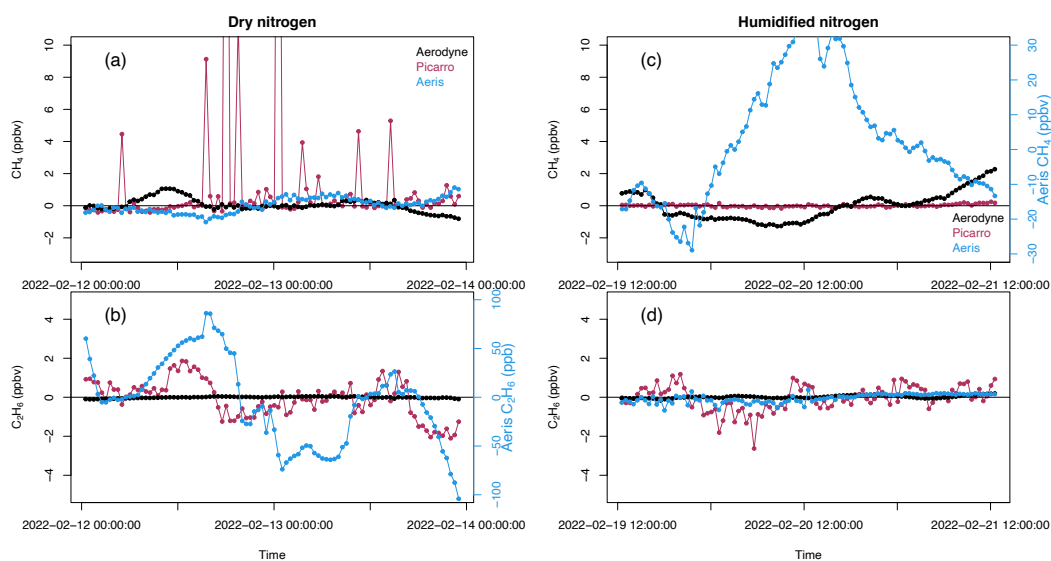

For ethane, the Aerodyne SuperDUAL had the best 1Hz (0.027 ppbv) and 10s (0.008 ppbv) precision with a minimum of 0.002 ppbv at 2.2 mins but the variance increased slightly again (but still below 0.03 ppbv) after about 15 mins. The Aerodyne SuperDUAL matched the 100s precision of (Kostinek et al., 2019) of 0.003 ppbv. At 100s, the Aeris MIRA precision was 0.02 ppbv and the Picarro G2210-i precision was 0.48 ppbv, both of which exceeded

242 their quoted precision of 1 ppb nmol mol⁻¹. The Picarro G2210-i ethane precision is similar to that observed with a
243 Picarro G2201-i analyzer (0.8 ppbv at 1 minute; (Defratyka et al., 2021)).

244 3.4 Long-term instrument stability

245 We evaluated the stability of frequent additions of zero air (gas free of methane, ethane, CO₂, etc.) for all three
246 analyzers. Fig 3 shows the instrument response when sampling dry and humidified nitrogen (methane and ethane free).
247 The Aerodyne SuperDUAL was not humidified for the second period (Fig 3c-d) and the noise was not significantly
248 different for the two periods (C₂H₆ < 0.01 ppbv; CH₄ < 0.95 ppbv; 1σ s.d.).
249

250
251
252
253
254
255

Figure 3: Instrument response when sampling (a-b) dry and (c-d) humidified methane (a, c) and ethane (b, d) in nitrogen. Picarro G2210-i (red) and Aeris MIRA (blue). Note the separate right y-axis for the Aeris (b) ethane and (c) methane. Also note that the Aerodyne SuperDUAL (black) did not sample humidified nitrogen in c-d.

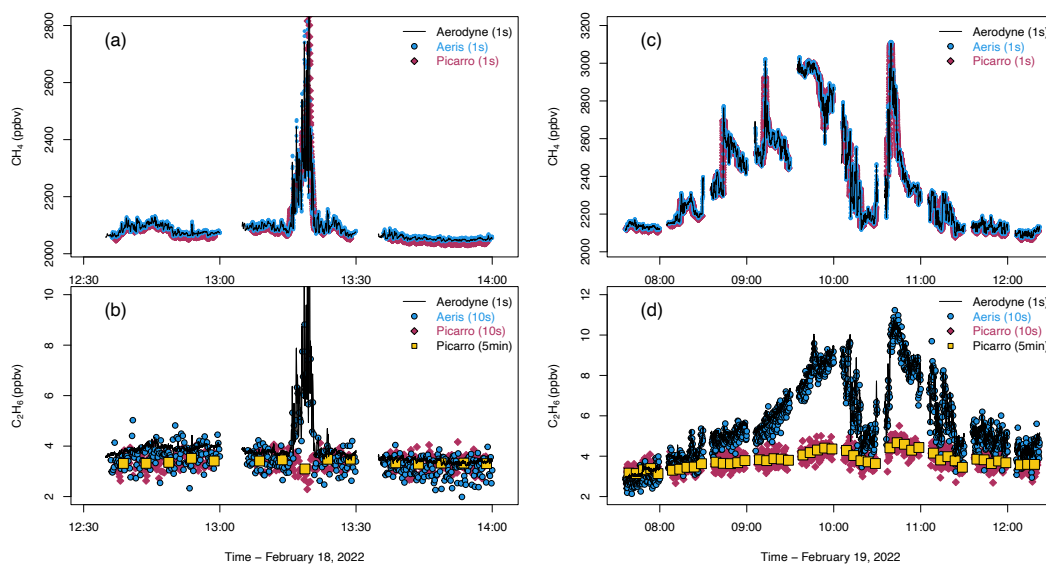

256 The Picarro G2210-i instrument noise is reduced when sampling humidified nitrogen over dry nitrogen (Fig
257 3), especially for outliers in the reported methane (Fig 3a). However increased variability in methane is not evident in
258 Fig 1(a) at low humidity so there may be another driver of this behavior. The reported ethane goes from -0.082 +/-
259 0.95 ppbv (1σ s.d.) when sampling dry nitrogen to -0.03 ± 1.73 ppbv (1σ s.d.) when the nitrogen is humidified to ~1%.
260 The reported methane goes from 1.35 ± 6 ppbv (1σ s.d.) when dry to 0.007 ± 0.08 ppbv (1σ s.d.) when humidified.

261 The Aeris MIRA instrument response is statistically different when sampling dry or humidified nitrogen (Fig
262 3): The reported ethane goes from varying between -100 and 100 ppbv (with a mean of -3.92 ± 43.8 ppbv; 1σ s.d.)
263 when sampling dry nitrogen to -0.05 ± 0.22 ppbv (1σ s.d.) when the nitrogen is humidified to ~1%. However,
264 humidifying the nitrogen also affects the reported methane, which goes from 0.02 ± 0.5 ppbv (1σ s.d.) when dry to 2.5
265 ± 17.5 ppbv (1σ s.d.) when humidified. This is also shown as increased noise on the methane at low humidity in Fig
266 S1.

267 3.5 Ambient sampling

268 In order to test the suitability of each analyzer to report accurate methane and ethane mole fractions in ambient air, we
269 ran all instruments sampling ambient air from the CUNY Observatory in Harlem, NY. In general, air is cold and very
270 dry in New York City in winter and we humidified the Aeris MIRA and Picarro G2210-i sample flows in response to
271 the instrument characterization experiments described above. Figure 4 shows typical examples of the ambient methane
272 and ethane mole fractions observed by all the analyzers when sampling ambient air in February 2022.

281

Figure 4: Ambient sampling for methane (top row) and ethane (bottom row) for (a-b) a short natural gas plume on Feb 18th, 2022 and (c-d) a large scale change in methane and ethane in the nocturnal boundary layer and into the early morning of February 19th, 2022. Times in UTC. Aerodyne SuperDUAL (black line), Aeris MIRA (blue circle), Picarro G2210-i (red diamond) and Picarro G2210-i averaged to 5 minutes in yellow square. All instruments corrected for humidity and calibrated to NOAA calibration scales.

282 On February 18th a large-scale change in air mass resulted in a drop in ambient air temperature from 15°C to
283 7°C (during Fig 4a and b), residential heating increased and a plume of high methane and ethane was intercepted at
284 the observatory for about 10 minutes. The Aerodyne SuperDUAL and Aeris MIRA both responded very similarly;
285 reporting large coincident increases in methane (up to ~2800 ppbv) and ethane (~10 ppbv). The Aerodyne SuperDUAL
286 also reported a large increase in carbon monoxide (CO) up to ~1500 ppbv for the same plume, possibly indicating an
287 incomplete combustion source. The methane reported by the Picarro G2210-i also increased, but with a longer peak
288 duration due to the much slower sampling flow rate (sampling time lags were corrected for previously). However, the
289 ethane surprisingly decreased while sampling the plume.

290 On February 19th ambient air temperatures ranged from -3.7°C at night to -1.2°C in the early morning and
291 wind speeds were low (2-4 m s⁻¹) leading to a build-up of methane and ethane in the nocturnal boundary layer (Fig 4
292 c and d). The prolonged elevated methane (to ~3000 ppbv) and ethane (to ~11 ppbv) was easily observed by the
293 Aerodyne SuperDUAL and the Aeris MIRA. The CO also increased (~700 ppbv) to about half of that seen on February
294 18th. The methane reported by the Picarro G2210-i also increased in line with the other reported methane but, again,

295 the Picarro G2210-i was not able to resolve the large increase in ethane, this time indicating an increase in ethane of
296 1-2 ppbv instead of the 7-8 ppbv seen by the other instruments.

297 The trace gases measured by the Aerodyne SuperDUAL indicate that Fig 4 (a and b) shows a post-meter
298 plume of incompletely combusted natural gas, likely emitted close to the observatory. The nocturnal boundary build-
299 up observed in Fig 4 c and d was coincident with a large increase in other combustion pollutants such as CO. As
300 mentioned in the data sheet for this instrument, it is possible that the co-emitted species of natural gas combustion
301 (such as CO or other volatile organic compounds, VOCs) are acting as an interferent for the Picarro G2210-i ethane
302 retrieval. This result indicates that the Picarro G2210-i should not be used near flares, natural gas power plants or in
303 urban areas that combust natural gas on a large scale. Indeed, care should be taken to ensure that thermogenic sources
304 are not erroneously attributed to biogenic sources with the Picarro G2210-i.

305 **4 Conclusions and Recommendations**

306 We evaluated the performance of three commercially available laser-based ethane analyzers: Aerodyne Inc.
307 SuperDUAL, Aeris Technologies MIRA LDS, Picarro Inc. G2210-i. We assessed the precision, accuracy and
308 interferences of each analyzer. We measured ambient air in a cold urban environment with each analyzer and have
309 made recommendations or analyzers based on performance, ease of use and reliability.

310 Across the month, the Aerodyne SuperDUAL reported with the highest precision of all three instruments but
311 requires regular zero air/nitrogen to maintain accuracy. The large size of the instrument and external chiller and large
312 pump mean that it is more suitable for tower/ground-based or large mobile laboratory operation and is not suitable for
313 car-based sampling. There is a smaller footprint instrument from Aerodyne – the Aerodyne “mini” – which has the
314 methane/ethane accuracy of the SuperDUAL but this also requires an external chiller and large pump. The Aerodyne
315 SuperDUAL also requires expertise to operate and maintain but is the best performing analyzer if the space and
316 expertise are available.

317 The Aeris MIRA was close to the Aerodyne SuperDUAL for precision for methane but was less precise for
318 ethane. The Aeris MIRA pump is small so the analyzer cannot draw against pressures much below ambient pressures,
319 such as those from long sampling lines. Methane required a large water vapor correction. Ethane could only be
320 reported for humidified samples, which affects the calibration protocol most often used in long-term operation. The
321 Aeris MIRA also had some software problems when not connected to the internet, so it requires regular attention.
322 However, overall the Aeris MIRA performed well when sampling plumes of incompletely combusted natural gas and
323 in large-scale ethane increases in a nocturnal urban boundary layer. The small size and internal pump also make the
324 analyzer ideal for sampling from small mobile platforms such as cars and bikes (especially the Aeris MIRA LDS Pico,
325 which is the battery-powered version of the analyzer tested here).

326 While the Picarro G2210-i reported precise methane mole fractions and the analyzer performed adequately
327 in many of the test, it could not detect ambient ethane enhancements of over 5 ppbv observed by the other instruments.
328 When sampling an incompletely combusted natural gas plume, it also reported a reduction in ethane when the other
329 analyzers reported a plume of ~10 ppbv.

330 Overall, we recommend the Aerodyne SuperDUAL or the Aeris MIRA Ultra LDS depending on the situation.
331 For long-term tower deployments or those with large mobile laboratories, the Aerodyne SuperDUAL provides the
332 best precision for methane and ethane. The other reported trace gases in the Aerodyne SuperDUAL, including CO,
333 carbon dioxide (CO₂) and nitrous oxide (N₂O) alongside ethane, also provide a way to more accurately attribute the
334 methane sources. For smaller mobile platforms, the Aeris MIRA is a more compact analyzer, and with careful use,

335 can quantify thermogenic methane sources to sufficient precision for short term deployments in urban or oil and gas
336 areas.

337 Data Availability. A permanent link will be added here once the permanent doi is available after the review process.
338 Currently the data from this study is available at: <https://atmoscomp.ldeo.columbia.edu/content/data-sharing>

339 Author Contributions. RC, AHD and LM designed the study, RC and AHD operated the instruments, AHD conducted
340 the tests, RC and AHD analyzed the data. RC prepared the manuscript with input from AHD and LM. The authors
341 declare that they have no conflict of interest.
