**Abstract.** The measurement of volatile organic compounds (VOCs) can be influenced by ozone (O<sub>3</sub>), resulting in sampling artifacts that corrupt the data obtained. Published literature reports both, positive (false enhancements of signal) and negative (loss of signal) artifacts in VOC data due to ozonolysis occurring in the sample gas. To assure good data quality it is essential to be aware of such artifact inducing processes, characterize them and try to minimize the impact with a suitable sampling setup. Here we present results from experiments with a sodium thiosulfate ozone scrubber (Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>), which is a cost effective and easily applied option for O<sub>3</sub> scavenging during gas phase sampling. Simultaneous measurement of selected organic trace gases using gas chromatography- and proton transfer reaction-mass spectrometry was performed at different ozone levels (0-1 ppm) and different relative humidities (0-80 %). In this way both tropospheric and stratospheric conditions were examined. The measured data show that several carbonyl compounds including acetaldehyde, acetone and propanal show artificial signal enhancement when ozone is present at higher concentrations (>150 ppb) in dry air, while analytes with double bonds like isoprene (measured with GC-MS) and terpenes show lower signals due to reaction with ozone. Both effects can be eliminated or in the case of sesquiterpenes substantially reduced by using Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> impregnated quartz filters in the inlet line. With the chosen scrubbing material, relative humidity (RH) substantially improves the scrubbing efficiency. Under surface conditions between 50-80 % RH, the filter allows accurate measurement of all species examined.

## 1 Introduction

Volatile organic compounds (VOCs) are trace atmospheric constituents usually present at mixing ratios of parts per billion (ppb) or lower in the earth's atmosphere. Nevertheless, they can have a considerable impact on the global air chemistry, climate and influence the health of living organisms on the earth's surface (Crutzen and Lelieveld, 2001; Williams, 2004). Organic trace gases can act as greenhouse gases, contribute to particle formation and take part in photochemical oxidation processes that influence ozone. Additionally many VOCs are also considered to be contaminants of the indoor environment where human exposure to such chemicals can be high (Weschler and Carslaw, 2018). VOC sources can be of natural (plants, phytoplankton, volcanoes, etc.) or anthropogenic origin (e.g. fossil fuel combustion, agriculture, industry) (Koppmann, 2008; McDonald et al., 2018; Weschler and Shields, 1997). To understand the chemical reactions and processes in outdoor as well as indoor environments, it is essential to accurately quantify the VOCs in the air.

Common analytical techniques for sampling organic trace gases are proton-transfer-reaction mass spectrometry (PTR-MS)

and gas chromatography-mass spectrometry (GC-MS). With these measurement techniques a wide range of volatile organic compounds can be covered including aliphatic and aromatic hydrocarbons, oxygenated and halogen containing species (Koppmann, 2008; Warneck and Williams, 2012). However, research has shown that due to the reactivity of some analytes to ozone, measurements can be rendered inaccurate, as already reported by Helmig (1997) more than twenty years ago.

30 Ozone can influence VOC measurements either due to reaction with the target analytes during sampling, which particularly affects techniques with pre-concentration steps prior to analysis (Koppmann et al., 1995; Pollmann et al., 2005; Helmig, 1997), or by generating sampling artifacts in the inlet of an online instrument. Northway et al. (2004) and Apel et al. (2003) reported for example increased values for acetaldehyde in their systems for measurements in the lower stratosphere where ozone levels are high and humidity is low. Ozone and water are omnipresent in the troposphere with mixing ratios between 10 and 200 ppb

35 (ozone) and humidities (10-100 %). Stratospheric O<sub>3</sub> is essential for life on planet earth as it absorbs high energy solar UV radiation. It is formed in the stratosphere through the photolysis of oxygen, which generates mixing ratios between 1-10 ppm. While such processes generate the protective ozone layer in the stratosphere, at ground level this oxidative gas is considered to be a pollutant as it is detrimental to the human respiratory tract and damages plants (Pandis and Seinfeld, 2006). Being present in both the troposphere and stratosphere, albeit at different concentrations, ozone can potentially affect VOC measurements

40 made at the ground and from high flying aircraft. The two instruments examined in this study are regularly installed on an aircraft capable of reaching ca. 15 km which at mid-latitudes gives access to the lower stratosphere. Also in indoor environments where ozone is typically 3-5 times less than outside ambient levels, it may affect the measurement fidelity.

Sodium thiosulfate (Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>) has been reported to have a good ozone scrubbing efficiency for VOC measurements (Lehmpuhl and Birks, 1996; Pollmann et al., 2005) and was therefore chosen as the best test material for O<sub>3</sub> removal in the experiments

45 described here. Like ozone, humidity varies strongly between the dry stratosphere and much more humid conditions of the earth's surface. Humidity is considered an important variable here as it can strongly influence chemistry occurring at surfaces. Measurement conditions were therefore examined that reflect the conditions likely to be met in these two environments. The aim of this study was to investigate the influence of different ozone levels and different relative humidity (RH) on two specific VOC measurement instruments, namely the fast GC-MS "SOFIA" described by Bourtsoukidis et al. (2017) and a PTR-ToF-

50 MS described in Wang et al. (2022). We report on the effect of using the sodium thiosulfate impregnated quartz filters for multiple VOC species including carbonyls, alcohols and non-methane hydrocarbons. Additionally, the lifetime of the scrubber with respect to ozone exposure was determined under tropospheric and stratospheric conditions. This is essential to assure that the scrubber is working correctly when applied in the field, to determine optimum exchange times, and to avoid unnecessary exchange and waste. These results will define operational expectations of using Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> filter in field conditions, to

55 improve organic trace gas measurement techniques, assure good data quality for smaller VOCs and therefore improve the data comparability between different studies.

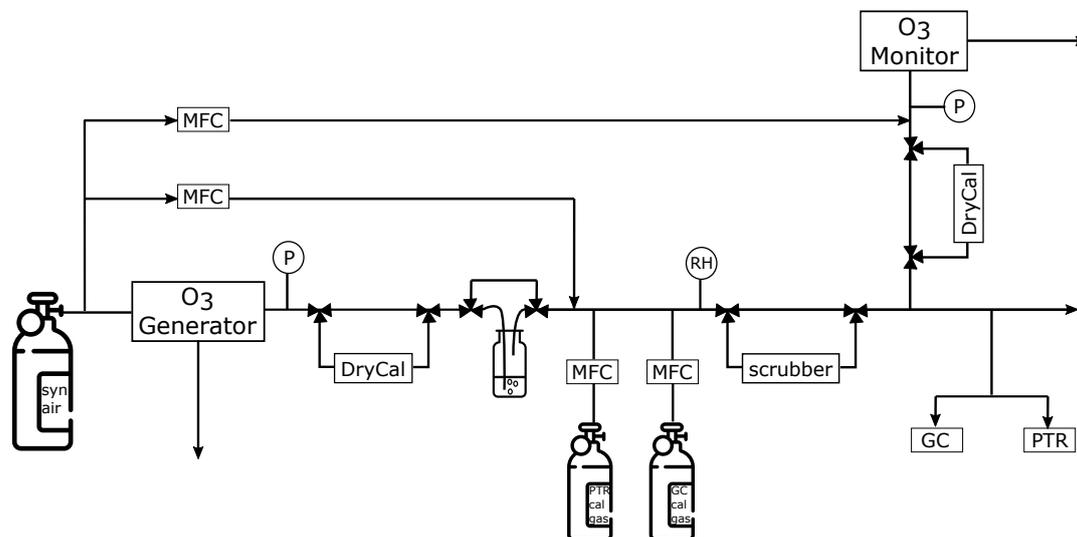

## 2 Materials and methods

The influence of ozone on measurements from an online VOC instrument (PTR-ToF-MS 8000, Ionicon Analytik, Austria) and a custom built quasi-online fast gas chromatograph-mass spectrometer (GC-MS) (Bourtsoukidis et al., 2017) which collects, concentrates and measures within 3 minutes was investigated. Additionally, the effect of an implemented sodium thiosulfate ozone scrubber on those systems as well as the scrubber lifetime was examined at different relative humidity. A list with the measured species is shown in section 3. It includes saturated and unsaturated halocarbons, non-methane hydrocarbons (NMHCs), small oxygenated VOCs (OVOCs), siloxanes and some nitrogen and sulfur containing molecules. Some species could be detected with both instruments simultaneously while other species could only be measured by one machine. Both instruments used fluorinated ethylene propylene (FEP) tubing (outer diameter (OD) 1/4" (0.635 cm)) as inlet line and have an inlet flow of 200 sccm. The tubing was not new, but used previously for airborne measurements aboard a research aircraft. It was flushed with synthetic air for at least one hour prior to the experiments performed.

### 2.1 Experimental setup

The experimental setup includes both PTR-ToF-MS and fast GC-MS as shown in Figure 1. Synthetic air from a gas cylinder (synthetic air, hydrocarbon free, T50, Westfalen, Germany) was connected to the ozone generator which was set to generate O<sub>3</sub> at levels between 25 and 1000 ppb. This corresponds to tropospheric and lower stratospheric levels, similar to those encountered by the HALO aircraft on which the instruments are certified to fly. Thereafter the air stream was led through ultra-pure water for humidification. Two different calibration gas cylinders (40L, Apel Riemer, USA) were connected via t-pieces to the sampling line. These cylinders contained a gravimetrically prepared mixture of VOCs at known mixing ratios, which could be added to the system air. The VOC enriched synthetic air could then be directed through the ozone scrubber or directly to the two mass spectrometers, which both drew circa 200 sccm air from the sampling line each. At the end of the Teflon tubing inlet line the ozone monitor was connected to measure the O<sub>3</sub> concentration after the scrubber. Several exhaust lines and pressure gauges were installed in the setup to ensure a system pressure close to ambient pressure (ca. 1000 mbar). This is required for the operation of the ozone instruments. To make sure that the monitor was always operated within the required flow range, a dilution flow could be added shortly before the instrument. Gas flows were checked regularly with a flow meter (DryCal, Mesalabs, USA) after the ozone generator and monitor. All the lines were made of FEP and heated to approximately 45 °C to avoid condensation in the tubing. This simulates conditions on the research aircraft aboard which the measurement devices have been installed. The total tubing length between ozone generator and scrubber was approximately 2 m, the outer diameter was 1/4", again equivalent to the aircraft set-up.

During the ozone experiment series various tests were performed: VOC mixtures were measured at several levels, adding 0, 50 and 1000 ppb of ozone to investigate the measurement performance at ambient background ozone levels on the ground and in the lower stratosphere. Additionally, one VOC level was measured at seven different ozone levels up to 1000 ppb (0, 25, 50, 150, 400, 750, 1000 ppb). The tests also included experiments without added VOCs to see if any of the analytes are produced in the pre-used inlet line. To investigate the influence of sodium thiosulfate impregnated quartz filters as an ozone scrubber,

**Figure 1.** Experimental setup, abbreviations stand for: MFC - mass flow controller; RH - relative humidity sensor; P - pressure gauge; DryCal - flow meter.

90 VOC levels at 0.5 and 2 ppb were measured at different ozone levels (0, 50 and 150 ppb) and different relative humidities (0 %, 50 % and 80 % RH) with and without scrubber in the flow path. For scrubber performance tests, another exhaust line was installed after the ozone generator to reduce the flow through the sodium thiosulfate impregnated quartz filter in order to simulate field conditions. The flow through the filter was set to 200-600 sccm to replicate either typical field measurement conditions or the experiments focusing on the influence on the VOC measurements. For those experiments the flow through  
95 the scrubber was higher to provide enough air for both of the mass spectrometers. Before each single longevity experiment the  $\text{Na}_2\text{S}_2\text{O}_3$  impregnated filter was exchanged and left in the flow path until an abrupt increase in ozone concentration was detected with the  $\text{O}_3$  monitor. This rise marks the end of the scrubber lifetime. Further details on the preparation of the filter scrubber can be found in section 2.3. Scrubber performance was tested under three different ozone concentrations: 50, 150 and 1000 ppb at 0 % RH. These are the same ozone levels used for the experiment focused on the effect of  $\text{O}_3$  on the VOC  
100 measurements, which correspond to ambient ground and lower stratospheric ozone levels. Additionally, the influence of 80 % relative humidity on the scrubber lifetime was tested. This RH level was chosen as an extreme to see whether or not it changes the scrubber performance.

## 2.2 Instrumentation

### 2.2.1 Ozone instruments

105 An ozone generator as well as an ozone monitor (49iQPS and 49iQ, both Thermo Fisher Scientific, USA) were installed in the experimental setup. Each instrument's supply air stream is divided into a reference and a sample gas channel. In the generator

the sample gas flows through an ozonator, while the reference gas of the monitor flows through a scrubber to eliminate existing ambient ozone. Both instruments use a spectroscopic approach to determine the mixing ratio: as the O<sub>3</sub> molecule absorbs UV light of 254 nm the difference of light intensity of this wavelength in both channels is used to calculate the ozone concentration in the sample stream based on Beer's Law (ThermoFisherScientific, 2020a, b).

### 2.2.2 PTR-MS

An Ionicon PTR-ToF-MS with a drift tube pressure of 2.2 mbar, drift temperature 60 °C and E/N 137 Td was operated with H<sub>3</sub>O<sup>+</sup> as primary ions. This is a soft ionization technique and therefore causes little fragmentation of the analytes during the detection process. Identification of the analytes was performed using the exact mass of the most abundant fragment, usually the protonated molecular mass, which does not exclude simultaneous measurement of isomeric compounds. The mass range of the system was 0-500 amu and the mass resolution approximately 3500. The PTR inlet flow was 200 sccm, the distance between ozone scrubber and PTR 2.85 m and limits of detection (LOD) were <0.05 ppb, with a total uncertainty of 15-20 %. Measured species included alkenes, siloxanes and OVOCs. For measurements at RH>0 a humid calibration was applied: The calibration was performed at the same relative humidity as the corresponding experiment.

### 2.2.3 GC-MS

The fast GC-MS system has been described in detail by Bourtsoukidis et al. 2017. In this study it was used to measure halo-carbons, small NMHCs and OVOCs as well as some sulfur containing compounds and small organic nitrates. Due to its chromatographic column it is capable of separating isomeric compounds prior to detection (e.g. acetone and propanal). The custom-built instrument uses a cryogenic three step pre-concentration to collect air samples, followed by gas chromatographic separation in a custom-built oven and detection with a quadrupole mass spectrometer which was operated in selected ion monitoring mode (SIM). With a time resolution of 3 min it is currently not possible to measure high molecular mass compounds (e.g. sesquiterpenes) as those would need more time to elute from the GC-column. Bromoform is the largest analyte detected with the currently applied method. The system's inlet flow was 200 sccm, tubing length between GC inlet and ozone scrubber 2 m, LODs typically <0.03 ppb (acetaldehyde, acetone and acrolein <0.2 ppb) and the total measurement uncertainty approximately 10 %.

## 2.3 Ozone scrubbing

Various materials have been tested to eliminate interferences from ozone on VOC measurements. Helmig (1997) (compiled an overview of widely used O<sub>3</sub> scrubbing techniques for the sampling of atmospheric organic compounds. Several groups have reported satisfactory results of sodium thiosulfate as an ozone scavenger for VOC analysis (Helmig, 1997; Lehmpuhl and Birks, 1996; Pollmann et al., 2005; Strömvall and Petersson, 1992). In this study the scrubbers were prepared by soaking quartz fiber filters (37mm, GE Healthcare Life Sciences, USA) in a 10 % (w/w) aqueous solution for 1 h followed by drying under a nitrogen flow of approximately 100 sccm at room temperature.

**Table 1.** Measured species and effect of ozone. X: no effect; ↓: negative artifact; ↑: positive artifact.

| Analytes and effect of O <sub>3</sub> on measured MR |   |   |                        |   |                    |

## 2.4 Scrubber lifetime calculation

The time that the scrubber remains effective at removing ozone, here termed the scrubber lifetime is important information for field measurement practitioners. In order to improve data quality and keep cost and work load low, the ozone scrubbers need to be exchanged before their efficiency is compromised, while still using them as long as possible. Assuming that the scrubber lifetime is a function of ozone mixing ratio and flow, the data from the scrubber lifetime experiment was plotted and fitted with a power function. Additionally the influence of relative humidity on the scrubber lifetime was tested.

## 3 Results and discussion

### 3.1 Influence of ozone on VOC measurements

For most of the analytes, mainly saturated NMHCs and halocarbons, no ozone interference of the measurement through reactive loss due to ozone was expected. This is because such species do not contain a double bond with which ozone can react, nor do they contain oxygen atoms so are unlikely to be produced by surface oxidation processes. However, due to the different molecular structures and physical properties of some analytes, it was potentially possible to obtain negative artifacts for some unsaturated species like isoprene and terpenes as well as artificial signal enhancement on the aldehyde masses. Table 1 shows whether ozone had an effect on the measured mixing ratio of the VOCs.

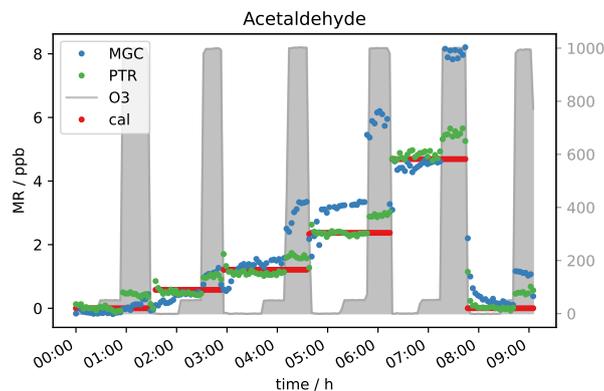

**Figure 2.** Different VOC levels at 0, 50 and 1000 ppb O<sub>3</sub>.

### 3.1.1 No effect on VOC measurements

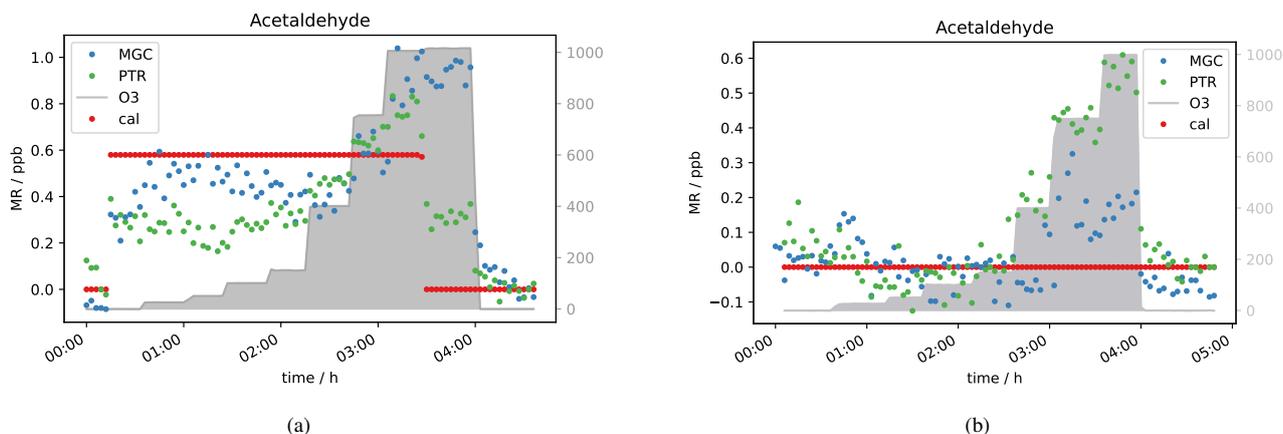

In accordance with the expectations no interference from reactions with ozone were observed for most of the measured species, namely saturated and unsaturated halocarbons, alkanes, aromatics, nitriles, methyl tert butyl ether (MTBE), ethanol, hydroxy-  
155 acetone, methyl ethyl ketone (MEK), isopropyl nitrate, the two sulfur containing species carbon disulfide and dimethyl sulfide (DMS) as well as siloxanes. As an example of the VOCs where ozone did not influence the measurements Figure 2 shows the mixing ratios of chlorobenzene applied and measured by GC- and PTR-MS as well as the ozone mixing ratio. In this experiment no ozone scrubber was applied. The GC result does not match the applied VOC mixing ratio of 2 ppb. Corresponding data was recorded just before the filament of the quadrupole mass spectrometer burnt through. It is likely that due to the end of  
160 the filament lifetime the measurement was not that accurate. After changing to a new filament (06:20 in the plot, 4 ppb standard gas applied), the GC signal was back to normal. Nevertheless, this does not interfere the ozone tests: It is clearly visible, that there is no change in mixing ratio for both instruments, when O<sub>3</sub> increases.

### 3.1.2 Ozone causing positive artifacts

Based on current literature, some carbonyl compounds such as aldehydes and ketones do have the potential to show higher  
165 mixing ratios when ozone is present (Apel et al., 2003; Lehmpuhl and Birks, 1996; Northway et al., 2004). Acetaldehyde measurements in this study under dry conditions agree with the results reported by Northway et al., Lehmpuhl et al. and others. The VOC signal increases with ozone concentration. Both, the PTR- and GC-MS measured higher acetaldehyde mixing ratios when O<sub>3</sub> was above 150 ppb (see Figure 3). This indicates that the interference is not instrument specific but more likely a function of the common inlet tubing exposure to ozone. The higher GC-signals at 2 ppb of calibration gas are again assigned  
170 to the filament degradation already mentioned in the previous section. In Figures 3 and 4a, the acetaldehyde signals rise significantly when 1000 ppb of ozone was present. For the background sample (Figure 4b) the signal rose after increasing

**Figure 3.** Five different standard gas levels between 0 and approx. 4 ppb at ozone mixing ratios of 0, 50 and 1000 ppb.

**Figure 4.** Acetaldehyde mixing ratios at seven different ozone levels between 0 and 1000 ppb and one standard gas level. VOC levels are 0 ppb (a) and 0.5 ppb (b).

ozone from 150 ppb where the effect was negligible to 400 ppb. The acetaldehyde signal increased further between 400 and 1000 ppb O<sub>3</sub> to about 0.4 ppb (GC) to 0.5 ppb (PTR).

Besides acetaldehyde, C<sub>3</sub> and C<sub>4</sub> aldehydes and ketones have also been measured, namely propanal, acetone, butanal and MEK. Unfortunately, for those compounds the results were not as clear as for the C<sub>2</sub> carbonyl described above. The PTR-ToF-MS in H<sub>3</sub>O<sup>+</sup> mode cannot separate the aldehyde from the ketone as they have the same exact mass, i.e. the PTR-ToF-data presented here always shows the sum of propanal and acetone (C<sub>3</sub>) and butanal and MEK (C<sub>4</sub>) respectively and is therefore higher than the GC signals for the separated species. When measuring background air (without added VOCs), measurements of GC and PTR showed an increasing signal for C<sub>3</sub> and C<sub>4</sub> carbonyls when ozone was added, starting at O<sub>3</sub> mixing ratios of 400 ppb, similar to acetaldehyde (cf. Figure 5). While butanal (measured by GC-MS) shows a strong increase, MEK does not show significant increase in the GC data.

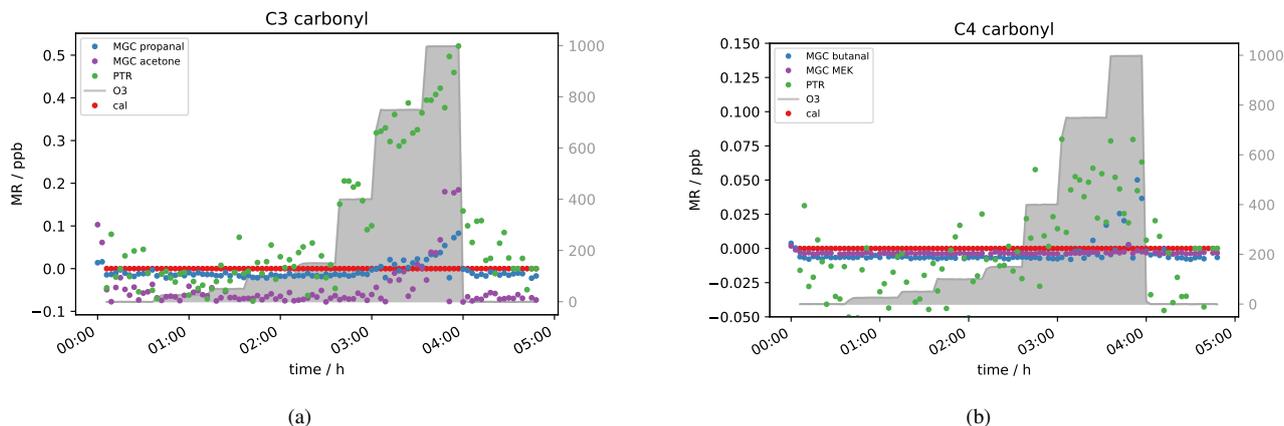

Figure 5. C3- and C4 carbonyl mixing ratios of a background sample at different ozone levels.

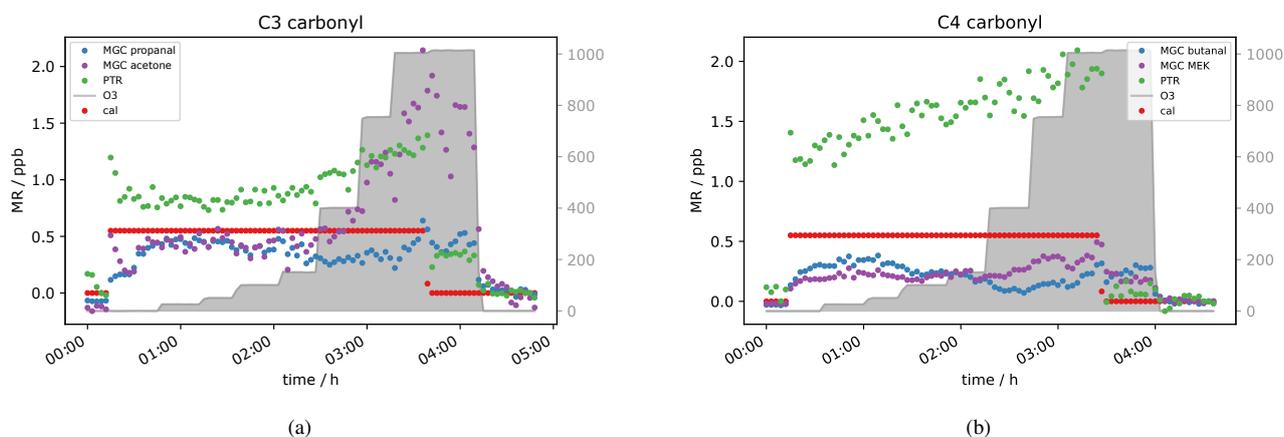

Figure 6. C3- and C4 carbonyl mixing ratios at approximately 0.5 ppb per VOC at different ozone levels.

Interestingly the aldehydes showed slightly decreasing mixing ratio in the GC measurements when the standard gas was added. Figure 6 shows this phenomenon. Propanal and butanal mixing ratios decrease under the same  $O_3$  conditions where they increase in the background measurement, while the sum of C3- and C4 carbonyls (PTR signal) and GC ketones again increase (as in the background measurement). As propanal decreases and acetone increases with ozone, the PTR measurements shows the netto ozone effect on C3 carbonyl. According to the GC data the same could be assumed for C4 carbonyls, but the measurements show an increasing PTR signal already below 200 ppb  $O_3$ . When measuring zero air without added VOCs under 1000 ppb ozone (cf. Figure 6, between 3.5 and 4 h after start of the experiment), not all signals dropped to background levels. They finally drop once ozone was switched off. This is consistent with the results from the background measurement (Figure 5). It shows that exposure of the inlet tubing to high ozone does not rapidly clean the lines of the artifact inducing compounds. Apel et al. reported carbonyl generation in the presence of ozone from the rotor material of VICI valves and a KNF Teflon

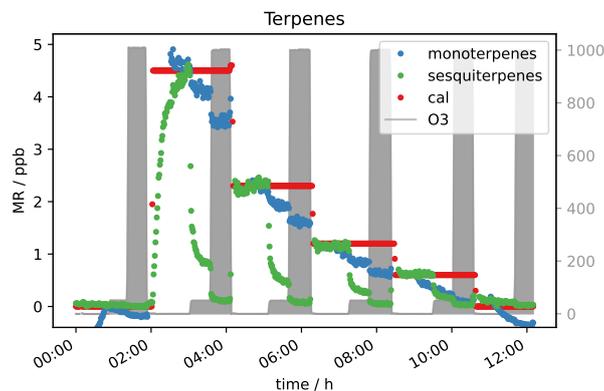

pump included in their system (Apel et al., 2003). Positive artifacts were reported for acetaldehyde, propanal, acetone and butanal, they did not find any interference for MEK. This matches our results. We assume that C2-C4 carbonyl compounds are generated inside the setup inlet tubing and were measured by the GC as otherwise the signal would have dropped when measuring zero air with 1000 ppb O<sub>3</sub>. However, at 0.5 ppb of calibration gas we observed a C3 and C4 aldehyde loss under high ozone exposure in the GC measurements. A possible explanation for this is the effect is due to OH radicals produced via Criegee intermediates from the ozonolysis reaction of alkenes present in the standard gas. OH radicals react preferentially with aldehydes rather than ketones. Apparently, these reactions are faster than the C3 and C4 aldehyde generation within the sampling setup. All the experiments show the same trend: under dry conditions, at tropospheric ozone levels ( $\leq 150$  ppb O<sub>3</sub>), no interference from the oxidant can be observed, while under stratospheric conditions ( $> 400$  ppb O<sub>3</sub>) there is a strong interference. This leads to the conclusion, that both instruments can measure C2 to C4 carbonyls in the troposphere without being restricted by the amount of ozone present. No reliable results can be achieved when ozone is above 150 ppb under dry conditions. Hence, the current setup is not suitable for stratospheric measurements of these oxygenated species.

### 3.1.3 Ozone causing negative artifacts

Due to the presence of reactive double bonds, terpenes (isoprene, alpha pinene and beta caryophyllene) were expected to show a decrease in mixing ratio with increasing ozone concentration. This was indeed observed. In Figure 7 it can be seen that the monoterpene signal at 50 ppb of O<sub>3</sub> is ten to twenty percent lower for each VOC level compared to the signal without ozone present. The signal drops by almost the same percentage when O<sub>3</sub> was increased to 1000 ppb. For sesquiterpenes the effect is even stronger. With 50 ppb O<sub>3</sub>, the signal drops by roughly 80 %, while the signal is close to or below detection limit at an ozone level of 1000 ppb depending on the terpene mixing ratio applied. This behavior can be explained with reference to the different reaction rate constants  $k$  of the mono- and sesquiterpenes in the calibration gas with ozone.  $\alpha$ -pinene, which is the monoterpene included in the standard gas mixture, has a reaction rate constant with ozone of  $9.6 \times 10^{-17} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  while  $k$  for  $\beta$ -caryophyllene is  $1.2 \times 10^{-14} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  (IUPAC, 2021). With a reaction rate more than three orders of magnitude larger, the reaction is fast enough to remove 1 ppb of  $\beta$ -caryophyllene within the short time the sample air needs to travel through the inlet line ( $< 10$  s). Furthermore it can be seen that the sesquiterpene needs quite long (more than an hour) to reach a steady state level in the very beginning, even with lines heated to 45 °C. This could be due to independent absorption of the FEP (fluorinated ethylene propylene) tubing of these less volatile species (Deming et al., 2019). Note that when switching to a new calibration gas level as well as in the first hour of the experiment, there were spikes in the VOC signal. These were judged to be mechanical flow related anomalies and therefore removed to assure better visibility of the mixing ratio in the plots. This experiment was the first one performed and flows were measured every time the VOC level was adjusted. It turned out that some compounds were emitted from the flow meter resulting in elevated terpene masses. The data shown here is data after the spike when the signal was back to steady state. For each condition there are at least 5 min of data.

Another compound which was expected to show a decreasing mixing ratio with increasing ozone concentration due to its double bonds was isoprene. It was measured simultaneously with PTR- and GC-MS. As can be seen in Figure 8, the signal is not measurably affected by adding 50 ppb of O<sub>3</sub>. At an ozone level of 1000 ppb, the GC detects roughly 50 % less isoprene. This

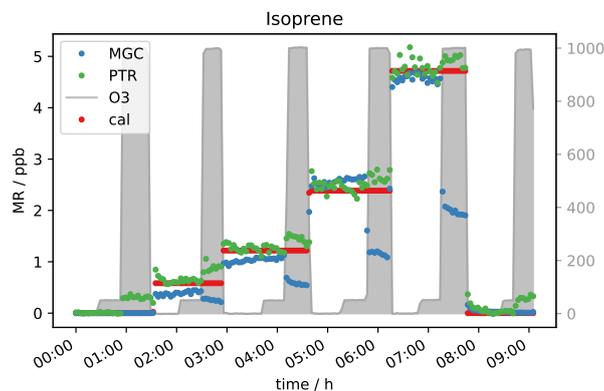

**Figure 7.** Different terpene levels at 0, 50 and 1000 ppb O<sub>3</sub> measured with PTR-MS.

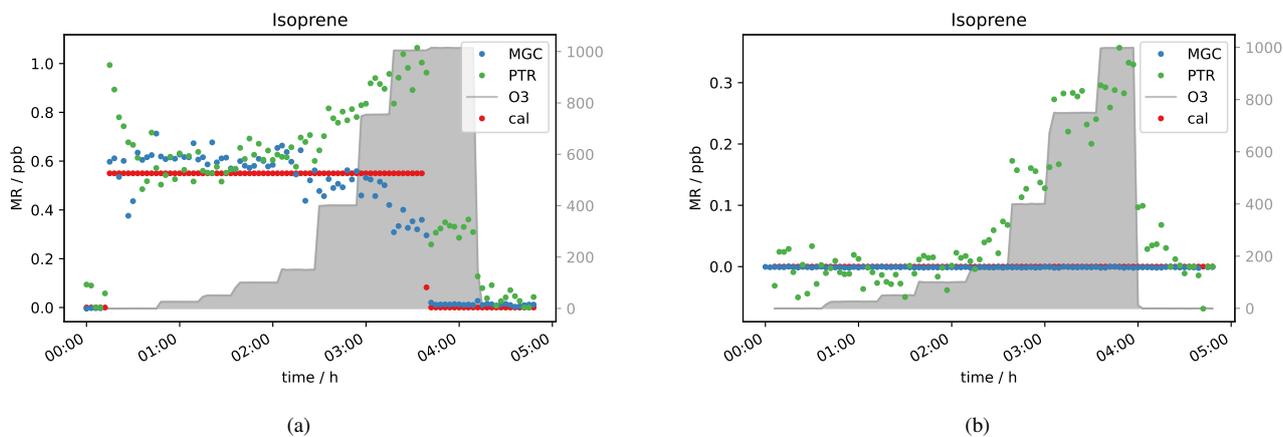

fits with expectations as isoprene ozonolysis is rather slow, the reaction rate coefficient being close to the one for  $\alpha$ -pinene ( $1.3 \times 10^{-17} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ ), which results in only partial depletion of the isoprene present. Interestingly the PTR-ToF shows slightly higher mixing ratios of the isoprene mass ( $m/z$  69). The elevated signal on this mass can be caused by carbonyl compounds present in sample air or inlet line. Literature reports the same exact mass commonly used for isoprene detection in  
230 PTR systems to be a fragment of certain aldehydes (Buhr et al., 2002; Ruzsanyi et al., 2013). For the GC-MS, aldehydes do not interfere as the analytes are separated in the chromatographic system prior to detection. The assumption is supported by the measurement of a background sample (no standard gas added into the system) at different ozone levels (see Figure 9a). The GC does not detect any isoprene in the background sample regardless of the ozone concentration, while the PTR-MS shows an increasing  $m/z$  69 signal at O<sub>3</sub> levels between 150 and 1000 ppb. Apparently the PTR-ToF-MS signal correlates with the  
235 oxidant's concentration. At 150 ppb O<sub>3</sub> the PTR-MS detects approximately 100 ppt of signal at the isoprene mass, at 400 ppb of ozone PTR measurements show around 150 ppt and with the highest tested O<sub>3</sub> concentration (1000 ppb) roughly 350 ppt. Figure 9b shows data obtained from the measurement of one isoprene level ( $\sim 0.6$  ppb) at seven different ozone mixing ratios and without ozone. GC-isoprene is stable until 100 ppb of O<sub>3</sub>. Somewhere between 150 and 400 ppb the isoprene signal starts to decrease until it reaches approximately two thirds of the real value at 1000 ppb O<sub>3</sub>. The PTR-isoprene mass signal is increasing  
240 over the same range as the GC signal decreases. This is in line with the measurement of the background sample, where the two analytical instruments show reverse effects of ozone being present. The signal increase is probably due to fragments of other compounds on the same exact mass. In literature, increased PTR mass 69 signals have been reported in high ozone environments in indoor and outdoor air studies which could not be attributed to isoprene (Colomb et al. (2006), Wang et al. (2022)). Those studies might have been influenced by the same interference we observed.

#### 245 3.1.4 Effect of sodium thiosulfate scrubber on VOC measurements

Generally, when the sodium thiosulfate impregnated quartz filters were added to the sampling system (see Figure 1), no influence on the VOC measurements was seen for the selected VOCs. The literature also reports that this scrubbing material is

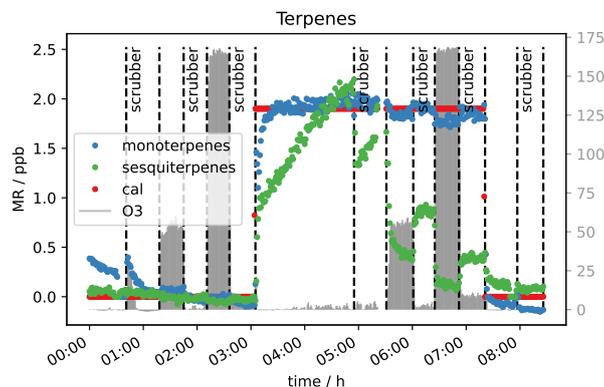

**Figure 8.** Different isoprene levels at 0, 50 and 1000 ppb O<sub>3</sub>.

**Figure 9.** Isoprene mixing ratio at different ozone levels.

suitable for measurement of many VOCs without causing interferences (Helmig, 1997; Pollmann et al., 2005). In Figure 10 the measured terpene mixing ratios 0 and 2 ppb VOC with and without scrubber are shown. It can be seen, that the scrubber performed as expected and removed the ozone effectively.  $\alpha$ -pinene levels reach the same concentration with the scrubber as before ozone was applied. The measurement of this compound is not affected by the sodium thiosulfate filters and if the scrubber is applied, there is no interference on the measurement with up to 170 ppb of ozone. As mentioned before  $\beta$ -caryophyllene again needed a long time to reach steady state when 2 ppb of the VOC were applied to the system (inlet line temperature 45 °C, cf. section 2.1). Steady state is reached after roughly two hours when the scrubber was bypassed. For the 30-40 min when the thiosulfate filters were introduced, steady state is not even reached. Sesquiterpene adsorption by the tubing material would again explain this effect. The scrubber was connected using Teflon tubing and a filter holder of the same material. The first time when the terpene-rich air was directed through the scrubber (50 ppb O<sub>3</sub>, five hours after start of the experiment) the

**Figure 10.** Terpene mixing ratios with and without scrubber at 50 and 170 ppb O<sub>3</sub>.

sesquiterpene mixing ratio increased within half an hour, while later (170 ppb O<sub>3</sub>) this was not the case. In other words, in the first half hour the sesquiterpenes appeared to be absorbed by the tubing, while afterwards the material was conditioned and the concentration could reach steady state. Steady state mixing ratios decrease with increasing O<sub>3</sub> mixing ratio as the scrubber was installed roughly half way between the T-piece where the standard gas was connected and the analytical instruments. Furthermore at the applied flow rate of approximately 650 sccm, there is already about 10 ppb of ozone passing the scrubber (cf. section 3.2) which allows the oxidant to further react with  $\beta$ -caryophyllene on the way to the detector. For all other compounds including isoprene no interference from the scrubber itself could be observed. Furthermore interferences from ozone on the measurements of analytes like isoprene or acetaldehyde could be eliminated with the filter scrubber in line. The effect on sesquiterpenes could probably also be eliminated if the scrubber was placed at the inlet's front end. However, it cannot be excluded that the sesquiterpene signal is affected by the scrubber material. Therefore, a longer time span with the scrubber in the sampling line would be required for the signal to reach steady state and the instrument would be unresponsive to rapid changes.

### 270 3.2 Scrubber performance

Figure 11 shows the O<sub>3</sub> mixing ratio measured with the ozone monitor behind the sodium thiosulfate scrubber under the dry condition at approximately 200 sccm. Results from the experiment at 1000 ppb O<sub>3</sub> can be seen in Figure 11a. The ozone concentration behind the filter never reached 0 ppb, already at the beginning, 100 ppb of the oxidant could pass the scrubber. That means 1000 ppb of ozone result in an overload of the scrubber capacity, and it was not suitable to remove the oxidant completely from the dry sample air - not even for short time periods. The concentration increases slightly in the beginning, while after 15 h a sudden signal rise can be observed where the mixing ratio increases from roughly 200 ppb to 500 ppb. After 55 h no ozone was scavenged anymore, the concentration before the scrubber is the same as after. Despite inefficient scrubbing under these conditions, the scrubber lifetime would be 15 h as after this time period a strong increase in the signal of the ozone monitor can be observed. In total it can be concluded that the sodium thiosulfate impregnated quartz filters made in the way

280 described in the method section are not suitable for measurements at these flow rates and such high ozone levels as encountered  
in the lower stratosphere due to insufficient O<sub>3</sub> removal and relatively fast depletion of the scrubbing material. However, at  
lower flow rates it might be more efficient and effective.

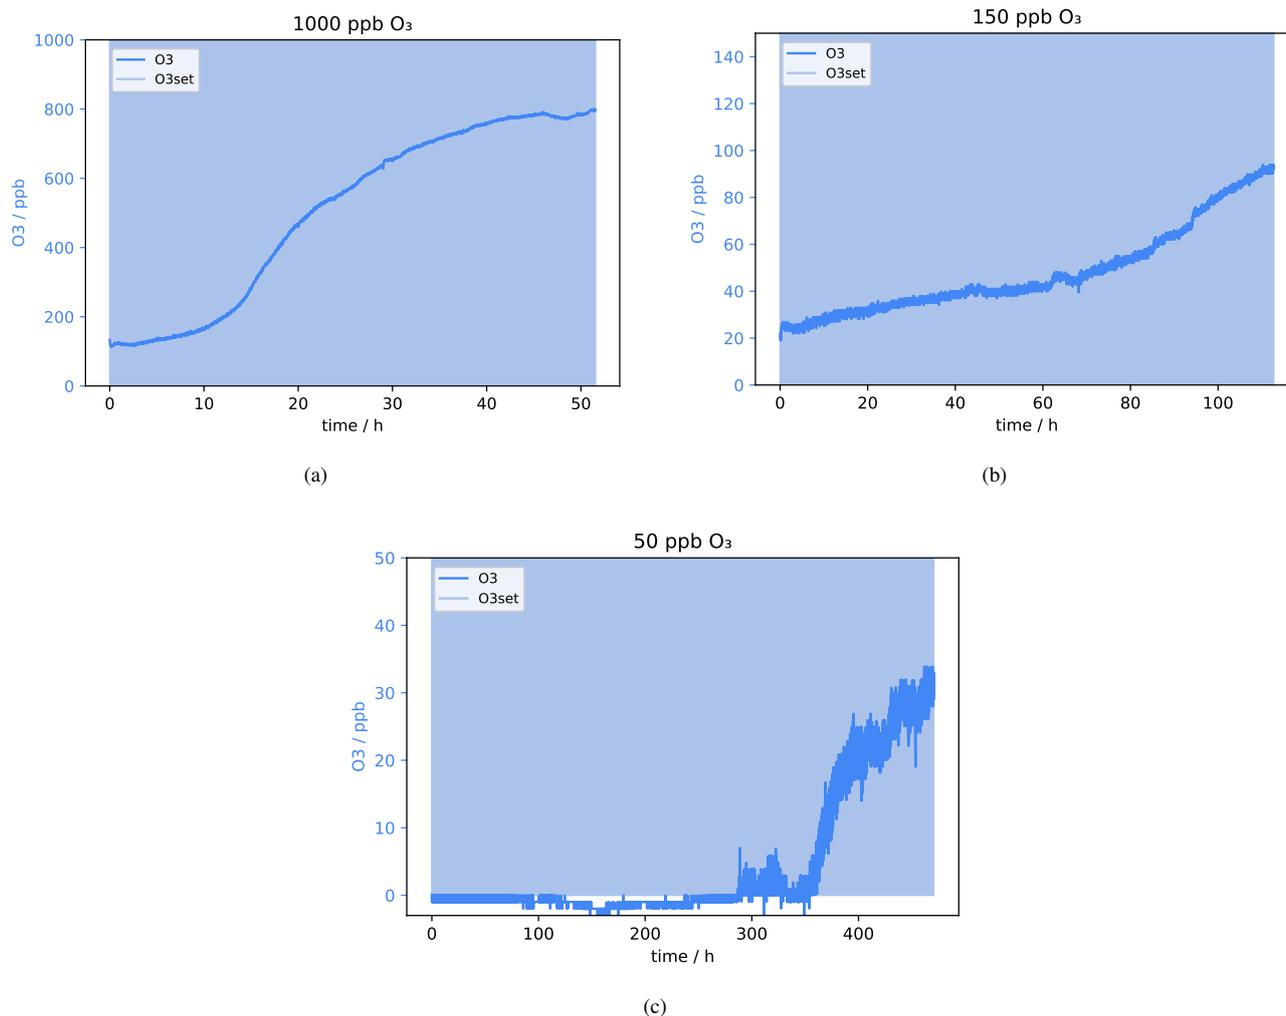

Figure 11b presents the result from a similar experiment but with 150 ppb of ozone applied, which corresponds to high ozone  
levels at ground level, and typical for the upper troposphere. In the very beginning, the O<sub>3</sub> concentration was already 20 ppb.  
285 It can be excluded that the filter is not able to remove the O<sub>3</sub> completely as the experiment was started twice under these  
conditions. The first time the ozone mixing ratio was zero at the beginning, but unfortunately the experiment had to be stopped  
after 50 h, but there was no sudden signal increase visible within that time. This 20 ppb offset during the second experiment  
might be caused by the filter not being perfectly centered in the filter holder. It is possible that a tiny stream of air bypassed  
the filter inside the filter holder as the 37 mm quartz filter was placed under a 47 mm Teflon filter in a Teflon filter holder with  
290 50 mm inner diameter. The smaller quartz filter was selected to avoid leaks at the filter holder previously caused due to the  
thickness of the quartz filter. With 150 ppb of ozone applied, the measured mixing ratio increased by 20 ppb within 40 h and up  
to 50 ppb within 80 h. As previously shown even isoprene was not affected by 50 ppb of ozone. The only compounds affected  
by such low O<sub>3</sub> levels were mono- and sesquiterpenes. Therefore, it is concluded that the ozone scrubber can be used up to  
80 h (3.3 days) at a flow of 255 sccm. The scrubber lifetime test for the lowest ozone concentration used here (50 ppb) took  
295 in total more than 20 days. During the first 300 h (12.5 days) the signal didn't change and was below or close to the limit of  
detection of 0.5 ppb. Around 300 h the measured mixing ratio started to be above detection limit, but still below 5 ppb O<sub>3</sub>. A  
sudden increase occurred after approximately 350 h (14.5 days), where the mixing ratio climbed up to 20 ppb within 1.5 days.  
After the total time of 477 h (almost 20 days) the experiment was stopped, the mixing ratio after the scrubber reached more  
than 30 ppb. The breakthrough point of the Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> impregnated filter after 350 h was determined as the end of the scrubber  
300 lifetime i.e. at background O<sub>3</sub> mixing ratios of 50 ppb the scrubber lasts more than 14 days.

Results of the test at a flow of 550 sccm, which corresponds approximately to the flow used for the experiments to investigate  
the effect of ozone on the VOC measurements (section 3.1) are presented in Figure 12. Please note that for the average and  
minimum scrubber lifetimes only measurements at O<sub>3</sub> levels 150 and 1000 ppb have been included as for 50 ppb there was no  
measurement at approximately 550 sccm. For quality assurance it is considered important to have a real measurement which  
305 can be compared with the calculated results.

The scrubber lifetime is 8 h at 550 sccm and 1000 ppb O<sub>3</sub> according to Figure 12a. At the lower ozone level (150 ppb), the  
actual flow was 620 sccm. From the plot a lifetime of 30 h has been determined.

Scrubber lifetime  $\tau$  highly depends on ozone concentration and flow rate. In Table 2 measured flows and lifetimes can be  
found. The data was fitted with a power function ( $y=ax^b$ , cf. Figure 13) being the best fit with R<sup>2</sup> close to 1. Additionally,  
310 the lifetimes for exactly 200 and 550 sccm were calculated with equation 1 and can be found in Table 3. The factors  $a$  and  $b$   
obtained from the fit were rounded to 3500000 and -1 respectively as small changes are attributed to measurement uncertainties.

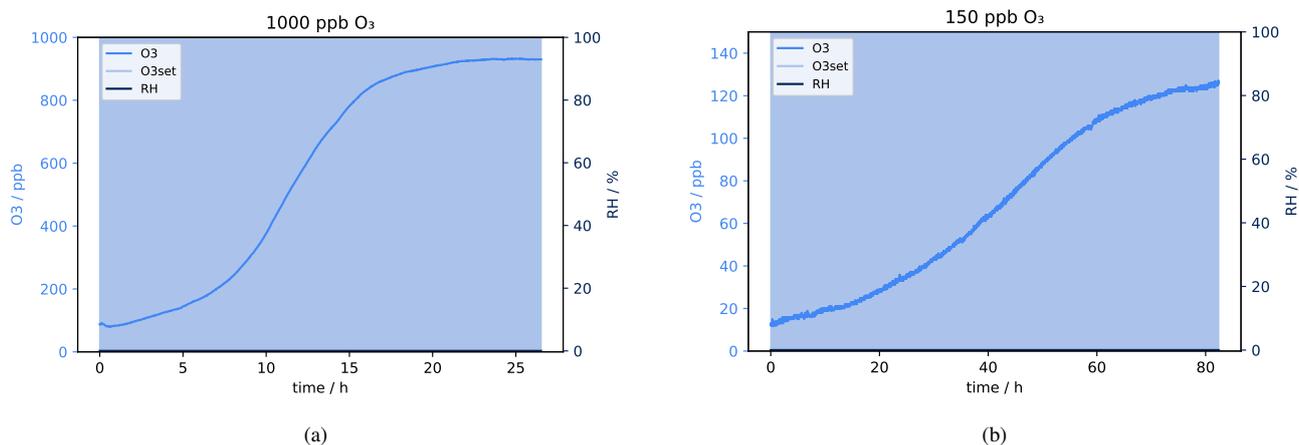

$$\tau = \frac{3500000}{O_3 * flow} \quad (1)$$

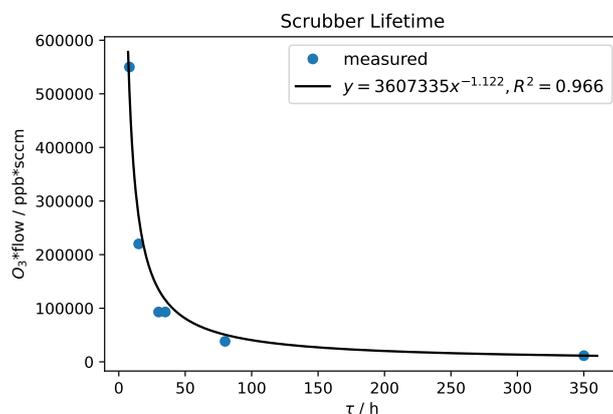

**Figure 11.** O<sub>3</sub> mixing ratio after Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> scrubber at 0 % RH. Flows and O<sub>3</sub> levels before scrubber: (a) 220 sccm, 1000 ppb; (b) 255 sccm, 150 ppb; (c) 230 sccm, 50 ppb.

The ozone levels were chosen to correspond to those experienced in the troposphere (50 and 150 ppb O<sub>3</sub>) and stratosphere (1000 ppb O<sub>3</sub>) so that replacement times of the scrubber under field conditions could be determined. Flows correspond to the  
315 inlet flows of the mass spectrometers (200 sccm) and to the flow used for the experiments described in section 3.1.

The calculated lifetime at 200 sccm and 1000 ppb of ozone is 18 h. Hence, this is the time after which the filter should be exchanged under these conditions if reducing ozone to 100-200 ppb is enough for the compounds of interest. If the back-  
ground ozone mixing ratio does not exceed 150 ppb and the flow is the same as used for the here applied mass spectrometers (200 sccm), the scrubber needs to be replaced after 117 h to avoid interference from ozone for analysis of most VOCs ex-  
320 cept terpenes. However, on many ground based measurement sites in the troposphere the ozone mixing ratio rarely exceeds

**Figure 12.** O<sub>3</sub> mixing ratio after Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> scrubber at 0 % RH. Flows and O<sub>3</sub> levels before scrubber: (a) 550 sccm, 1000 ppb; (b) 620 sccm, 150 ppb.

**Figure 13.** Measured data from the scrubber performance test.

50 ppb, which would result in a scrubber exchange every 14 days to assure efficient ozone removal. The lifetime calculation at 550 sccm and stratospheric ozone concentration results a scrubber lifetime of 6 days and is slightly lower than the measured lifetime (8 days, cf. Figure 12a). With 150 ppb O<sub>3</sub> and the same flow τ would be 42 h and filter replacement due in less than 2 days. The determination of the lifetime is approximate as we use the time at which a sudden increase in ozone concentration after the scrubber was observed. Exchanging the filter earlier does not affect the data quality and is therefore recommended. However, in section 3.1 the presented experiments were all performed in less than one day and the maximum ozone concentration (1000 ppb) was applied for only several hours. Thus, the ozone concentration was stable throughout each experiment.

**Table 2.** Ozone mixing ratio and corresponding flows through the scrubber during scrubber performance tests as well as resulting lifetimes  $\tau$ .

| O <sub>3</sub> / ppb | measured    |            |               |
|----------------------|-------------|------------|---------------|
|                      | flow / sccm | $\tau$ / h | $\tau$ / days |
| 1000                 | 220         | 15         | 0.6           |
| 150                  | 255         | 80         | 3.3           |
| 50                   | 230         | 350        | 14.6          |
| 1000                 | 550         | 8          | 0.3           |
| 150                  | 620         | 35         | 1.5           |

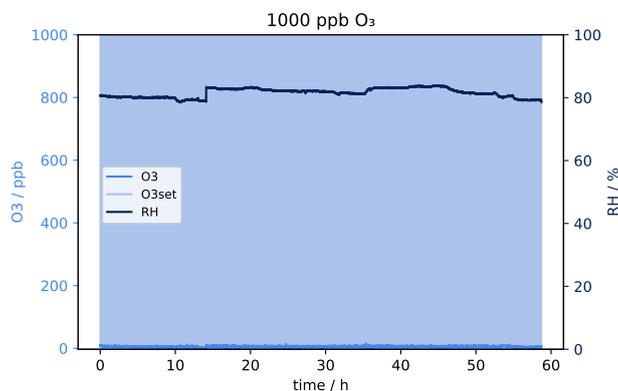

**Table 3.** Calculated scrubber lifetimes  $\tau$  at exactly 200 and 550 sccm.

| O <sub>3</sub> / ppb | calculated  |            |               |
|----------------------|-------------|------------|---------------|
|                      | flow / sccm | $\tau$ / h | $\tau$ / days |
| 1000                 | 200         | 18         | 0.7           |
| 150                  | 200         | 117        | 4.9           |
| 50                   | 200         | 350        | 14.6          |
| 1000                 | 550         | 6          | 0.3           |
| 150                  | 550         | 42         | 1.8           |

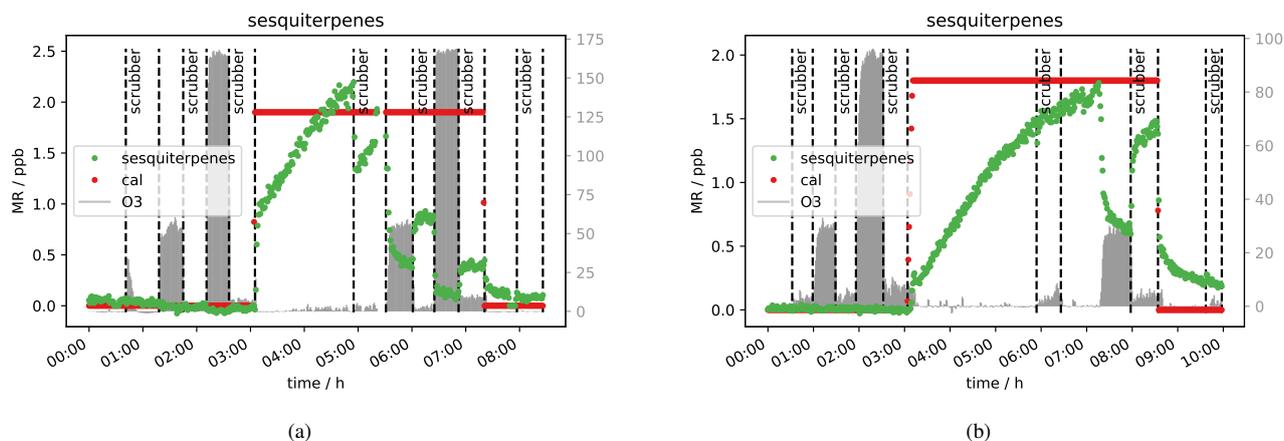

### 3.3 Effect of humidity

330 Field measurements can take place in various locations and environmental conditions. Relative humidity may influence the analysis of water soluble compounds. However, the presence of water may also affect the behaviour of VOC molecules when interacting with surfaces. The scrubber material used here is inorganic and water soluble and has therefore been tested under dry and humid conditions. For the measurements performed within this study, humidity did not have any influence on the GC- and PTR-ToF-MS instrument measurement capability as these dried the air before detection (GC-MS) or used humid 335 calibrations (PTR-ToF-MS). Thus any effects observed can be ascribed to the inlet system. Interestingly, the scrubber lifetime increased dramatically at 80 % relative humidity. The test was done twice to double check the results obtained. Figure 14 shows the ozone mixing ratio and relative humidity measured at 1000 ppb O<sub>3</sub> and a flow of 230 sccm. RH was relatively stable throughout the whole experiment. As mentioned in section 3.2, under similar dry conditions the sodium thiosulfate scrubber was able to remove only 90 % of the ozone and filter performance dropped drastically after 15 h. In contrast, at 80 % RH the 340 ozone could be removed completely from the sample air. The O<sub>3</sub> mixing ratio did not change over 65 h of experiment, it was always below 10 ppb. After 65 h the experiment was stopped.

The only signal that was still influenced by ozone when the filter scrubber was in the sample line, was the sesquiterpene signal. Consequently the corresponding mixing ratio can be used to investigate whether or not relative humidity changes

**Figure 14.** O<sub>3</sub> mixing ratio after Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> scrubber at 80 % RH, 230scm.

**Figure 15.** Sesquiterpene mixing ratio with and without scrubber at 50 ppb O<sub>3</sub> when 2 ppb of sesquiterpenes were introduced to the system; (a) 0 % RH, (b) 50 % RH

the results compared to the dry condition. Figure 15 shows the sesquiterpene mixing ratio under dry (15a) and humid (15b) conditions when ca. 2 ppb standard gas was introduced to the system. In the first plot the signal with scrubber at 50 ppb of ozone (approx. 06:00-06:30) comes back to 50 % of the original signal, while in the second plot it comes back to approx. 80 % (approx. 08:00-09:00) of the original height. This is consistent with the results from the scrubber lifetime tests at 80 % RH and suggest that scrubber performance benefits from increased humidity.

Sodium thiosulfate reacts with ozone to tetrathionate, water and oxygen:

As it is an equilibrium reaction, the equilibrium will shift to the left if there is an excess of water, recovering the thiosulfate from the  $S_4O_6^{2-}$  produced. This could explain why the ozone level during the scrubber performance test at a relative humidity of 80 % was relatively stable throughout the whole measurement time which was almost 3 days and why all the oxidant can be scavenged at an  $O_3$  level of 1000 ppb.

#### 355 4 Conclusions

Most species tested were not affected by ozone being present. Nevertheless, higher mixing ratios were observed for carbonyl compounds indicating an ozone interference. Signals for acetaldehyde, propanal, acetone and butanal increased with ozone levels above 150 ppb in background measurements with GC as well as PTR. Thus it can be concluded, that there are positive artifacts generated in the experimental setup i.e. in the tubing, inside the ozone generator or within both of the mass spectrometers. As we observed the same during stratospheric measurements before, the ozone generator cannot be the only source. When 0.5 ppb of VOC standard gas was measured, the signals for propanal and butanal decreased due to the reaction with the OH radical, generated from ozonolysis of terpenes. For MEK no ozone interference could be observed. Decreasing signals were found for monoterpenes ( $\alpha$ -pinene), sesquiterpenes ( $\beta$ -caryophyllene) and GC-isoprene as expected due to the direct reaction with ozone. The PTR-ToF-MS measured increasing "isoprene" mixing ratios on m/z 69 with increasing ozone concentration due to aldehyde fragments on the same exact mass. Those fragments are most likely ozonolysis products from some adsorbed species inside the FEP tubing or the instrument itself from some former measurements. Therefore caution should be applied when interpreting the isoprene mixing ratios provided by PTR-ToF-MS in high ozone environments. Generally the scrubber lifetime under tropospheric conditions ( $O_3$  mixing ratios between 50 and 150 ppb) and a flow of 200 sccm is between five and fourteen days. The inlet flow of both instruments is the same (200 sccm), therefore the result can directly be used for ground based field measurements with the here employed PTR-ToF-MS and fast GC-MS systems. Sodium thiosulfate impregnated quartz filters are a very convenient means of ozone scavenging as the filters can be prepared in advance easily, at low cost and can be stored in a dry, dark and clean place. The preparation as well as the application are simple and the usage time for the filters is with several days long enough to allow measurement of complete diel cycles without stopping the measurements in between to open the inlet line for scrubber exchange. Nevertheless, the scrubbing technique as applied here is not suitable for sesquiterpene measurement. The observed loss of these analytes could be reduced with a  $Na_2S_2O_3$  scrubber in line, but it could not be eliminated completely. Similar results have been reported earlier. Pollmann et al. (2005) found ozone concentrations in the sampling air reduced to 0.4 % when using a thiosulfate scrubber at an ozone mixing ratio of 100 ppb and 255 sccm. Unfortunately they did not report how long these conditions were measured. Nevertheless, their finding is comparable to that reported here, at 150 ppb  $O_3$  and at the same flow the scrubber could reduce ozone to almost zero while at 50 ppb the oxidant's mixing ratio was below the limit of detection for more than 14 days. The tests have shown that the scrubbing technique used in this study performs well for most ground based operations of the VOC instruments, as inlet flows and ozone levels are usually low enough to stay within range of good performance of the sodium thiosulfate filter scrubber. Nonetheless, it is not possible to completely avoid sesquiterpene loss due to reaction with ozone during sampling. The current setup is not suitable for mea-

385 suring highly ozone reactive compounds such as sesquiterpenes or under high ozone conditions like in the lower stratosphere.  
Fortunately, since sesquiterpenes are emitted from the surface, they are extremely unlikely to be present in the stratosphere.  
In general it can be concluded that higher humidity has a positive influence on the VOC measurements performed here with  
a sodium thiosulfate filter scrubber, when ozone was present and no interference from the humidity on the gas analysis itself  
could be observed. Still, the O<sub>3</sub> removal is not sufficient to measure sesquiterpenes when ozone is present, not even at low  
390 mixing ratio such as 50 ppb. Implementing a stable humidification to the measurement system is non-trivial and additional  
effects for other analytes could develop. It is important to continue the development and characterization of reliable techniques  
which are cheap and easy to implement for lab as well as field experiments.

*Data availability.* The data are published at <https://doi.org/10.5281/zenodo.7191001> (Ernle and Ringsdorf, 2022).

*Author contributions.* LE and MAR designed the experiment; LE and MAR performed the measurements; LE and MAR analyzed the data;  
LE wrote the manuscript draft; MAR and JW reviewed and edited the manuscript
