Abstract

High-quality, long-term measurements of terrestrial trace gas emissions are important for investigations of atmospheric, geophysical and biological processes to help mitigate climate change, protect the environment, and the health of citizens. High-frequency terrestrial fluxes of the radioactive noble gas ²²²Rn, in particular, are useful for validating radon flux maps, used to evaluate the performance of regional atmospheric models, to improve greenhouse gas emission inventories (by the Radon Tracer Method) and to determine Radon Priority Areas for radiation protection goals.

A new automatic radon flux system (the *Autoflux*) was developed as a Transfer Standard (TS) to assist with establishing a traceability chain for field-based radon flux measurements. The operational characteristics and features of the system were optimized based on a literature review of existing flux measurement systems. To characterize and calibrate the *Autoflux* a bespoke radon Exhalation Bed (EB) facility was also constructed with the intended purpose of providing a constant radon ~~exhalation~~emanation under a specific set of controlled laboratory conditions. The calibrated *Autoflux* was then used to transfer the derived calibration to a second continuous radon flux system under laboratory conditions, both instruments were then tested in the field and compared with modeled fluxes.

This paper presents: i) a literature review of state-of-the-art radon flux systems and EB facilities; ii) the design, characterization and calibration of a reference radon EB facility; iii) the design, characterization and calibration of the *Autoflux* system; iv) the calibration of a second radon flux system (*INTE_Flux*) using the EB and *Autoflux*, with a total uncertainty of 9% ($k=1$) for an average radon flux of ~ 1800 mBq m⁻² s⁻¹ under controlled laboratory conditions; and iv) an example application of the calibrated TS and *INTE_Flux* systems for in situ radon flux measurements which are then compared with simulated radon fluxes. Calibration of the TS under different environmental conditions and at lower reference fluxes will be the subject of a separate future investigation.

1 Introduction

The noble, radioactive, noble gas radon (²²²Rn) contributes over half of the total public radiation dose from natural sources (WHO, 2009). However, due to its short half-life (3.8 days) and chemical inertness, radon is also widely used as an environmental tracer for atmospheric and geophysical processes (Grossi et al., 2012; Vargas et al., 2015, Chambers et al., 2016; Chambers et al., 2018; Zhang et al., 2021). In particular, climate scientists are using co-located measurements of atmospheric radon and greenhouse gas (GHG) concentrations to apply the so-called Radon Tracer Method (RTM) for estimating local- to regional-scale GHG emissions (Grossi et al., 2018; Levin et al., 2021).

These applications require information, at high temporal resolution and low uncertainty, about: i) the quantity of radon emitted per unit area and time from a surface of interest (the radon flux, F , or exhalation rate; usually expressed in mBq m⁻² s⁻¹); and ii) the atmospheric radon activity concentration (SI units Bq m⁻³).

Terrestrial radon exhalation is the result of ²²²Rn escape from soil pore spaces to the atmosphere after its formation by ²²⁶Ra decay (Nazaroff, 1992). ²²²Rn exhalation rates are primarily driven by diffusion processes and depend strongly on the soil ²²⁶Ra content and soil properties (porosity, tortuosity, soil humidity, etc.). Consequently,

Formatted: Spanish (Spain)

56 the ²³⁸U content and parameters influencing diffusive transport in the soil need to be known to properly estimate
57 the spatial and temporal variability of ²²²Rn exhalation rates (Schüßler, 1996; Lopez-Coto et al., 2013; Karstens et
58 al., 2015). Furthermore, the emanation factor of radon from the soil grains to the pore spaces is influenced by soil
59 humidity (Nazaroff, 1992; Zhuo et al., 2006; Zhuo et al., 2008).

60 Although diffusion is the primary transport mechanism of radon in soils, driven by the strong vertical concentration
61 gradient (Karstens et al., 2015), advective transport can also occur, but this has not been thoroughly investigated
62 and is likely to be highly site specific. Advective transport typically results from local pressure gradients, changing
63 wind speed and direction, etc. Consequently, advective processes could influence radon flux measurements
64 (Gutiérrez-Álvarez et al. 2020a). Other factors including soil type, atmospheric pressure, rainfall (related to soil
65 moisture), and soil temperature can affect the radon flux. However, complex dependencies between these factors
66 makes it difficult to quantify changes in radon flux due to any one of these factors in isolation (e.g., a precipitation
67 event is often also associated with a drop in pressure and temperature).

68 To date, most radon flux studies have been based on random sampling and short temporal measurement data, due
69 to the lack of robust continuous radon flux systems. Unfortunately, these kinds of datasets are not sufficient to
70 clarify relationships between radon flux and environmental factors. This is also a contributing factor to why some
71 studies reach contradictory conclusions about the influence of individual parameters on the radon flux.

72 Long-term, reliable radon flux measurements are needed in conjunction with corresponding environmental
73 observations in the soil and lower atmosphere (McLaughlin, 2011; Yang et al., 2017). To ensure reliable
74 measurements it is important to characterize and calibrate the operational radon flux systems, which requires: i) a
75 ²²²Rn Exhalation Bed (EB) facility, to provide reference radon fluxes under controlled laboratory conditions; ii) a
76 Transfer Standard (TS) instrument to be calibrated using the EB and used as a reference monitor for calibrating
77 other new or existing monitors, or to be used directly for in situ measurement campaigns; and iii) planned field-
78 based inter-comparison campaigns of different radon flux systems under in situ environmental conditions.

79 The need of an EB facility is justified because, despite the fact that the response of the radon monitors itself can
80 be previously studied within a STAR (System for Test Atmospheres with Radon) by comparison with a known
81 reference radon concentration, and that geometries of external volumes making the radon flux systems could be
82 measured separately with their own uncertainties, the total tubes and internal volumes estimation could lead to
83 high uncertainties. Thus, comparing the radon flux systems response with reference exhalation bed will allow to
84 characterize the effective height of the systems, needed for the flux calculation, with the minimum uncertainty.

85 ~~The response of the radon monitor itself is previously calibrated within a STAR (System for Test Atmospheres
86 with Radon) at a known reference radon concentration. In addition, all the tubes and volumes making the radon
87 flux system are measured separately with their own uncertainties. However, this is not sufficient to calibrate the
88 response of the radon flux system. In fact, when the accumulation chamber is installed on the soil and the system
89 starts working, the measured radon flux may be affected by several factors such the depth of the chamber
90 installation into the soil (Gutierrez-Alvarez et. al., 2019), the environmental conditions of the soil (Yang et al.,
91 2019), etc. A reference exhalation bed, used as primary standard, with a constant and know radon flux, is needed
92 to calibrate radon flux systems and their response under different environmental conditions and to ensure a robust
93 metrology chain.~~

94
95
96

97 One of the main aims of the EMPIR 19ENV01 project (henceforth traceRadon), which started in June 2020, was
98 to provide the necessary measurement infrastructure and transfer standards to enable traceable radon flux and
99 atmospheric radon activity concentration measurements. These goals are being achieved in collaboration with,
100 among other research groups, the Integrated Carbon Observation System (ICOS, www.icos-cp.eu) network, whose
101 researchers are interested in introducing traceable radon flux and atmospheric radon concentration measurements
102 to sites within this network for RTM applications.

103 The specific contributions of this study to the overall traceRadon objectives are to offer a calibrated and
104 characterized continuous TS system, ~~equipped with~~^{provided with} soil and atmosphere sensors, that can be used to
105 carry out radon flux campaigns at different sites to help improve and evaluate the performance of contemporary

Formatted: Font color: Text 1

106 radon flux maps and models (Szegevary et al., 2009; Karstens et al., 2015), as well as be used to calibrate other
107 radon flux systems under laboratory or field conditions.

108 The remainder of this manuscript is arranged in the following way: first, a review is made of state-of-the-art EB
109 facilities, including a description of the one newly designed, built and characterized by Cantabria University for
110 the traceRadon project; next, a review is presented of contemporary, available state-of-the-art radon flux systems,
111 including a description of the new automated system (*AutoFlux*) designed, characterized and calibrated by the
112 Australian Nuclear Science and Technology Organization (ANSTO) and the Universitat Politècnica de Catalunya
113 (UPC); next, the protocol applied to calibrate another automatic radon flux system (*INTE_Flux*), designed by the
114 Institute of Energy Technologies of the UPC, using the *AutoFlux* and the UC EB facility is described. Finally, both
115 radon flux systems are tested during a field-based intercomparison campaign and the results compared with
116 previous tests of these systems and with radon flux model outputs available at the ICOS Carbon Portal ([www.icos-
117 cp.eu/](http://www.icos-cp.eu/)).

118

119 2 Materials and Methods

120

121 2.1. Overview of theoretical radon flux estimation

122

123 A review of relevant literature found that radon flux studies have historically been carried out using a theoretical
124 value as a reference. IAEA (1992) suggested that radon flux systems should be calibrated using a thin layer model,
125 under the assumption of ‘pure’ diffusion and a soil with well characterized ²²⁶Ra activity concentration, depth
126 (thickness), porosity, and radon emanation characteristics (UNSCEAR, 1988; Rogers & Nielson, 1991; Nazaroff,
127 1992; Porstendörfer, 1994). In contrast, most contemporary radon flux studies have been based on the experimental
128 accumulation chamber method (Hassan et al., 2009), resulting in a standard method reflected in the ISO 11665-
129 7:2012: *Accumulation method for estimating surface exhalation rate*. In these cases, the reference value used for
130 calibration of the radon flux system, and method of flux measurement, is based on the results of an exponential fit
131 of the increasing radon activity concentration inside a chamber of known volume, or in a STAR ~~{System for Test
132 Atmospheres with Radon}~~ (ISO, 2009), during several days.

133 The theoretical approach enables calculation of the radon flux (F) by the diffusion equation (Porstendörfer, 1994):

$$F = \varepsilon \cdot C_{Ra} \cdot \rho \cdot L \cdot \lambda \cdot \tanh\left(\frac{z}{L}\right) \quad (1)$$

134 where ε is the radon emanation factor, C_{Ra} is the ²²⁶Ra activity of the soil (Bq kg⁻¹), ρ the dry bulk density (kg m⁻³)
135 of the soil, L the radon diffusion length in the soil (m), z is the soil thickness (m) and λ is the radon decay
136 constant (2.0993·10⁻⁶ s⁻¹ following Morawska, 1989).

137 Within Eq. 1, the emanation factor is defined to be the fraction of radon atoms produced by radium disintegration
138 that escape into the soil pore space. Its value varies between 0, when radon does not escape the ²²⁶Ra-containing
139 soil grain, and 1, when all radon escapes. This factor depends on many things, including: grain size and shape,
140 moisture content, porosity, permeability, and the distribution of ²²⁶Ra atoms in the mineral grains (Baskaran, 2016).

141 Considering a soil sample of a determinate mass, ~~where the sample is has to be sufficiently well distributed to
142 ensure that all radon atoms successfully entering the pore spaces of the sample will eventually escape to the air
143 volume and be measured.~~ the emanation factor ε can be defined as:

$$\varepsilon = \frac{A_{Rn}}{A_{Ra}} \quad (2)$$

144 where A_{Ra} is the total radium activity of the sample, and A_{Rn} , the radon activity that escapes from the sample. The
145 radium activity is usually measured by gamma spectrometric analysis of the soil sample (i.e., Quindos et al., 1994).
146 To determine the radon activity that escapes from the sample, an airtight stainless-steel container of known volume
147 is commonly used, and the rate of escape is determined by the increase in radon concentration inside (i.e., Stoulos
148 et al., 2004). ~~The sample has to be sufficiently well distributed to ensure that all radon atoms successfully entering
149 the pore spaces of the sample will eventually escape to the air volume and be measured.~~

Commented [CS1]: This was already defined before

150 The bulk density, ρ , can be calculated from the sample weight and volume of the dry soil (Hosoda, 2007). When
 151 the soil thickness is much smaller than the radon diffusion length (i.e., $z \ll L$), as is the case for the Exhalation
 152 Bed used in this study, the approximation $\tanh(z/L) \approx z/L$ can be used. Thus, the final equation will be (Lopez-
 153 Coto et al., 2009):

$$F = \varepsilon \cdot C_{Ra} \cdot \rho \cdot \lambda \cdot z \quad (3)$$

154 In order to prove the applicability of Eq. 3, the diffusion length L has to be evaluated and compared with z . L can
 155 be estimated as:

$$L = \sqrt{D/\lambda} \quad (4)$$

156 where D is the effective diffusion coefficient of the trace gas in the soil air (hereafter also named effective
 157 diffusivity). D is assumed to be constant with depth (Karstens et al., 2015), and can be estimated from water
 158 saturation w_s and porosity p using the following expression (Rogers and Nielson, 1991; Prasad et al., 2012):

$$D = D_{air} \cdot p \cdot \exp(-6w_s p - 6w_s^{14p}) \quad (5)$$

159 where D_{air} is the radon diffusion coefficient in air ($1.1 \cdot 10^{-5} \text{ m}^2\text{s}^{-1}$).

160 Karstens et al., (2015) made reference to Jin and Jury (1996) and Millington and Quirk (1960) who proposed, and
 161 verified, another experimental estimation of the effective diffusivity:

$$D = D_{air} \cdot \frac{(p-w_v)^2}{p^{2/3}} \quad (5a)$$

162 where w_v (m^3/m^3) is the Volume Water Content (VWC) of the soil. Equations 5 and 5a were both derived
 163 empirically and are quite consistent with each other, mainly for dry soils, as will be shown in the following sections.

164 The porosity and water saturation w_s (m^3/m^3) (Idoria et al., 2020; IAEA, 2013) are given by:

$$p = 1 - \frac{\rho}{\rho_g} \quad (6)$$

165 where ρ_g is the grain density, and:

$$w_s = \frac{\rho \cdot w_c}{p \cdot \rho_w} \quad (7)$$

166 where w_c (kg/kg) is the mass water content of the soil sample and ρ_w is the water density ($1000 \text{ kg}/\text{m}^3$). Karstens
 167 et al., (2015) reported that the temperature dependence of ^{222}Rn diffusivity could also be estimated according to
 168 Schery and Wasiolek (1998):

$$D(T) = D_0 \left(\frac{T}{T_0} \right)^{3/2} \quad (8)$$

171 where T is the mean soil temperature in Kelvin and D_0 the effective diffusivity at the reference temperature $T_0 =$
 172 273 K.

173 The experimental approach allows the flux of a given soil surface to be calculated from the increase in radon
 174 activity concentration $C_{Rn}(t)$ within a chamber of known volume during a time t , as described by Eq. 9:

$$C_{Rn}(t) = C_0 e^{-\lambda_{eff} t} + \frac{F \cdot A}{V_{eff} \cdot \lambda_{eff}} (1 - e^{-\lambda_{eff} t}) \quad (9)$$

175 where the effective decay constant, λ_{eff} , is the sum of the radon decay constant (λ), possible radon lost due to system
 176 leakages (λ_i), and radon concentration reabsorbed by the ground (λ_r), as described by Grossi et al., (2011). C_0 is
 177 the initial radon activity concentration within the volume, V_{eff} is the effective volume where the radon is free to
 178 accumulate, and A is the area of the exhaling surface.

181 2.2. State of the art Exhalation Bed facilities

184 Table S1 in the supplementary material presents a summary of EB facilities found in the literature. The Canadian
185 Mining Institute (CANMET) built a national reference standard flux bed for calibrating flux monitoring
186 instrumentation. This 5 m diameter bed consisted of a 5.5 cm thick layer of uranium bearing material from uranium
187 tailings and provided a radon flux of $285 \pm 41 \text{ mBq m}^{-2} \text{ s}^{-1}$ (Stieff et al., 1996). In the University of South China
188 Radon Laboratory a standard facility simulating radon exhalation from soil was built in 2001 (Tan & Xiao, 2011).
189 It consisted of a radon source located at the bottom of a conical volume. The middle cylindrical part was made of
190 a plaster and spumy board that simulates the soil or sand porosity. Finally, in the upper part, there is powdery
191 calcium carbonate to maintain the radon concentration in the conical volume. The reference flux for this system is
192 $1482 \pm 50 \text{ mBq m}^{-2} \text{ s}^{-1}$, which was measured using an activated charcoal box and Lucas cells. It is still operating,
193 and some studies continue to use it (Tan & Xiao, 2013; Tan et al., 2020). Oak Ridge Associated Universities
194 (Tennessee, USA) constructed a multilayer exhalation bed. It consists of a base layer of uranium ore spread over
195 the bottom of a rectangular Hardigg polyethylene case of dimensions $84 \text{ cm} \times 53 \text{ cm}$. The base has a 10 cm
196 covering layer of dirt to create a uniform flux at the top surface. The reference exhalation rate of this system was
197 determined by the accumulation method, using a continuous radon monitor, and by using activated charcoal
198 canisters and electrets. The range of values obtained varied from approximately $80 \text{ mBq m}^{-2} \text{ s}^{-1}$ to $430 \text{ mBq m}^{-2} \text{ s}^{-1}$
199 (Altic, 2014). Onishchenko et al. (2015), from the Institute of Industrial Ecology UB RAS (Ekaterinburg, Russia),
200 designed a calibration system to test radon flux measurement devices. It was constructed from a 200 L metal drum
201 filled with quartz sand (radium concentration less than 2.5 Bq/kg) with a calibrated ^{226}Ra source in the bottom
202 space of the system. The reference exhalation rate obtained by the accumulation method and charcoal canisters
203 was $700 \pm 80 \text{ mBq m}^{-2} \text{ s}^{-1}$.

204 Gutiérrez-Álvarez et al. (2020a; 2020b) performed an experimental characterization of a soil exhalation rate using
205 the accumulation method (Eq. 9). Two reference exhalation soils were prepared using phosphogypsum in
206 rectangular polypropylene boxes with 6.0 cm and 13.0 cm soil thicknesses, respectively. ~~Means of the~~
207 ~~experimental result estimates of the bed exhalation rates were of $13.3 \pm 0.42 \text{ mBq m}^{-2} \text{ s}^{-1}$ and $23.4 \pm 0.53 \text{ mBq}$~~
208 ~~$\text{m}^{-2} \text{ s}^{-1}$ with an uncertainty for $\sigma=1$ of 2%-3% were determined.~~ These ~~previous values results~~ were compared to
209 exhalation rates determined by applying the theoretical approach (Eq. 3) ~~which gave values of $12 \text{ mBq m}^{-2} \text{ s}^{-1}$ and~~
210 ~~$23 \text{ mBq m}^{-2} \text{ s}^{-1}$, respectively for the two exhalation beds, with a total uncertainty of about 20%. and no statistical~~
211 ~~difference was noted between the two methodologies used.~~

212

213 2.3. Design of a Reference Radon Exhalation Bed

214

215 In the framework of traceRadon, and using information from the previous section, a radon EB was designed and
216 built at the University of Cantabria (UC) following Gutiérrez-Álvarez et al. (2020a; 2020b). The EB structure
217 consisted of five stainless steel plates, welded in the shape of a box, open at the top. In this configuration it is
218 important to minimize air leakages through the plates that may lead to the loss of radon activity. The intended
219 purpose of this EB was to provide a constant, well characterized, radon emanation rate under a specific set of
220 controlled laboratory conditions. Since soil moisture influences on the radon emanation were not of specific
221 interest in this case, a relatively shallow soil matrix was sufficient for the EB aims.

222 The EB structure was filled with a high ^{226}Ra content soil, extracted from a former Spanish uranium mine in
223 Saelices el Chico (Spain), managed by the Spanish National Uranium Company ENUSA. A total soil mass of
224 around 400 kg was collected. The material was then transported to UC laboratory and distributed over a 30 m^2
225 plastic surface in a layer of thickness of approximately 1 cm to be dried and homogenized. Soil homogenization
226 was performed according to technical document 1415 (IAEA, 2004) following these steps: i) the material was
227 manually homogenized using a stainless-steel rake; and ii) it was sieved with a 2 mm aperture sieve (the device
228 has a woven wire mesh in accordance with DIN ISO 3310-1). For the sieving process, soil was taken randomly in
229 5 kg amounts. Finally, the homogenized soil was placed into the EB container.

230 The EB facility was installed in the basement of the UC Faculty of Medicine, in the Laboratory of Environmental
231 Radioactivity (LaRUC). Sensors were installed to continuously monitor temperature, pressure and soil moisture.
232 Two thermometers (Testo, Model 175T2) measured the soil temperature and air temperature inside the
233 accumulation chambers. Soil moisture was measured with an ODYSSEY (Xtreem) probe, and all environmental
234 parameters were recorded by a data logger every minute. ~~Error! Reference source not found, Table S2 of the~~
235 ~~supplementary material summarizes the main characteristics of the selected sensors.~~

236 The EB radon flux was estimated theoretically and experimentally using the approaches presented in Section 2.1.
 237 To apply Eq. 3, the various soil parameters were measured and/or calculated as explained in Section 3. The
 238 experimental derivation of the EB's radon flux was performed using Eq. 9 as by Gutiérrez-Álvarez et al. (2020a).
 239 For this, the whole surface of the EB was covered with a stainless-steel container of known volume (Figure S1 of
 240 the supplementary material). Three radon monitors, an RTM 2200 (Sarad GmbH), a Radon Scout (Sarad GmbH)
 241 and an AlphaE (Bertin Instruments), were used simultaneously to measure the increase of radon concentration
 242 within the effective accumulation volume. Please note that the sum of the volumes occupied by the solid
 243 components of the three monitors were lower than 1% of the total available volume of the ~~used~~-accumulation
 244 chamber. In addition, several small air samples were also taken using the grab sampling technique and analysed
 245 with the ionization chamber IK-250 (RADON v.o.s.).

246

247 2.4. State of the art in Radon Flux Systems

248

249 A literature review carried out in the framework of traceRadon found that radon monitors employed in flux
 250 measurement systems mainly fall into two categories: active or passive. Active monitors analyze the air in real
 251 time, whereas passive monitors (i.e., charcoal canisters) rely on the progressive accumulation of radon by
 252 diffusion. The accumulated radon is then measured using a separate system (e.g., by gamma spectroscopy or
 253 ionization chamber) (McLaughlin, 2011). Due to the need of radon flux systems capable of high-frequency
 254 measurements (capable of resolving diurnal variability), only active systems will be presented and discussed here.

255 Generally, radon flux systems are comprised of two main parts: a continuous radon monitor and an accumulation
 256 volume to be placed on the soil surface. The radon flux (or exhalation rate), is then calculated by Eq. 9 using the
 257 measured increase of radon within the known volume. However, Eq. 9 can only be solved if the exhalation rate F
 258 and the total system leakage λ_{eff} remain constant over the designated time period. This condition is hard to satisfy
 259 for long-term radon flux measurements under field conditions, making it difficult to apply the ISO suggested
 260 exponential fit. Variability of environmental parameters, in the soil and/or atmosphere, may force changes in the
 261 quantity of radon exhaled from the surface. Furthermore, gradients of temperature and/or pressure between
 262 internal and external air of the accumulation chamber may ~~change the increase~~ the leakage of the system (λ_{eff}).
 263 ~~To minimize such problems, it is advisable to perform short radon flux measurements. This is also important when~~
 264 ~~using measurements to validate radon flux models.~~ For short measurement periods, $\lambda_{eff} \cdot t \ll 1$ and the initial
 265 concentration within the accumulation chamber is relatively close to the atmospheric value, which is usually small
 266 ($C_0 \approx 0$). Thus, Eq. 9 can be substituted with a Taylor series of the exponential truncated to the first order as:

$$C_{Rn}(t) = C_0 e^{-\lambda_{eff} t} + \frac{F \cdot A}{V_{eff} \cdot \lambda_{eff}} (1 - e^{-\lambda_{eff} t}) \approx \frac{F \cdot A}{V_{eff} \cdot \lambda_{eff}} \cdot \lambda_{eff} t = \frac{F}{h_{eff}} \cdot t = b \cdot t \quad (10)$$

267

268 where $h_{eff} = V_{eff}/A$ is referred to as the effective height of the system (Morawska, 1989). ~~Thus, to minimize radon~~
 269 ~~flux and/or λ_{eff} effective lambda variability during the measurements, it is advisable to perform short radon flux~~
 270 ~~measurements which are also important validate radon flux models.~~

271 The main characteristics of radon flux systems in the literature based on continuous radon monitors are
 272 summarized here (see Table S3 and Figure S2 of the supplement material for more detail). System 1 was designed
 273 and built by ANSTO. While not a commercial system, it is based on a commercial AlphaGUARD (AG) monitor
 274 and has a drum-like accumulation chamber with a lid that can be automatically opened and closed. A separate
 275 pump is used to circulate air from the accumulation chamber to the AG in a closed loop. No monitoring of the air
 276 inside the accumulation chamber is performed by this system. System 2 (the *emanometer*), also designed and built
 277 by ANSTO, is the predecessor of the System 1 and is based on the flow-through accumulation method. In this case
 278 the accumulation volume is permanently closed and to perform a measurement the edges of the accumulation
 279 chamber are buried in soil to make a reasonable seal with the emanating surface (Zahorowski and Whittlestone,
 280 1996). The system has two detection volumes (scintillation cells) separated in the flow path by approximately 5
 281 minutes to enable separate radon and thoron (^{220}Rn) flux estimation (more details in Zahorowski and Whittlestone,
 282 1996). System 3 is a commercial accumulation chamber designed and built by LI-COR (www.licor.com). To date,
 283 this chamber is only sold together with an 8100-401 Chamber Control Kit for the purpose of automatic CO_2 flux
 284 measurements. So far it has never been coupled with any commercial radon monitor. Systems 4, 5 and 6 are
 285 research products, each using different radon monitors and types of accumulation chambers, some of which can

Formatted: Font: Italic, Subscript

286 be opened and closed automatically. System 6, in particular, developed at the Helmholtz Zentrum München
287 (Institute of radiation protection), Neuherberg, Germany, allows radon flux measurements to be made at different
288 sites around a circular path, using a mechanical arm (Yang et al., 2017). Unfortunately, system 6 is no longer
289 available due to the discontinuation of the research group. Systems 7 and 8, built by INTE-UPC and UC
290 respectively, are based on radon monitors (DOSEman and AlphaE) operating in diffusion mode. Radon monitors
291 operating in diffusion mode can influence the flux instrument's response time, as well as the subsequent fit
292 calculation for estimating the flux, as will be shown in Section 3. Both systems have accumulation chambers that
293 can only be opened manually, but air is refreshed by an external pump.

294 The importance of the accumulation chamber characteristics when measuring soil gas fluxes should not be
295 underestimated. An inherent challenge in flux chamber design is minimizing the influence that the chamber may
296 have on the measurements, especially for long-term observations. Based on our literature review, the main
297 characteristics required for radon flux systems (monitors and accumulation chambers) are listed and have been
298 taken into account when developing a radon flux system suitable for use as a Transfer Standard.

299 For a system capable of making radon flux measurements at high temporal resolution, which minimizes the
300 disturbance of flux estimates by changing environmental parameters inside the accumulation chamber, the main
301 requirements are:

- 302 - to use a continuous direct radon monitor that measures activity concentration in flow mode (not diffusion
303 mode) at a high temporal resolution (e.g., 1 min - 10 min), and with a minimum detectable radon
304 activity concentration low enough to measure short term radon increases within the accumulation
305 chamber with below 100 Bq m⁻³ a statistical uncertainty lower than 20%, allowing radon flux
306 measurements to be obtained using Eq. 10.
- 307 - the accumulation chamber needs to open completely and automatically after each measurement period,
308 to establish the initial condition of C_0 equal to the ambient radon concentration.
- 309 - environmental sensors are needed inside and outside the accumulation chamber.
- 310 - the accumulation chamber needs to have a smooth internal geometry to avoid inhomogeneous internal
311 concentration distribution.
- 312 - the accumulation chamber should be painted gloss white, to minimize the temperature difference between
313 air inside and outside of the chamber when the chamber is in direct sunlight.
- 314 - the chamber should have a matching collar to attach to (via an easy to clean and seal flange), which can
315 be firmly seated in the soil (to a depth of 2 cm – 10 cm, depending on soil type / texture) to minimize
316 radon losses (Gutiérrez-Álvarez et al., 2020b).

317

318 2.5. Design of a new Radon Flux Transfer Standard (TS) System

319

320 Based on the monitor requirements described in section 2.4 an automatic and low maintenance radon flux
321 measurement system was designed and built at ANSTO in September 2020 as an alternative implementation of
322 System 1, described previously. This new system was implemented in collaboration with the UPC, and
323 subsequently fully characterized by UPC in collaboration with UC, in the framework of traceRadon. UPC also
324 implemented the means to remotely control the system for data download during the experiments and improved
325 the scripts for the flux calculations and analysis.

326 This instrument enables 8 automatic flux measurements to be performed each day, every 3 hours. The *AutoFlux* is
327 comprised of an AG PQ2000 PRO (Saphymo) radon monitor (working in 10 min flow mode), an accumulation
328 chamber (drum) with automatic lid, and several environmental sensors installed within the soil, inside the drum,
329 and outside the drum at 50 cm above ground level. An internal lip near the bottom of the accumulation chamber
330 allows the chamber to be pushed 5 cm into the soil to make a good seal with the surface. The radon flux is estimated
331 by performing linear fit of the radon concentration increase within the closed drum every 10 min over a 1-hour
332 period using Eq. 10. The drum's hinged lid is opened and closed using a 150 lb 4" classic rod linear actuator. The
333 actuator is fitted with an external limit switch kit, powered by a 4 x 12V DC relay card and controlled by a CSI
334 CR1000 datalogger (<https://www.campbellsci.es/cr1000>). The opening (default 2h) and closing (default 1h) times
335 of the accumulation chamber are adjustable and controlled by the program in the datalogger.

336 The novelty of this system is that the diurnal and seasonal variability of soil radon fluxes can be observed and
337 studied in parallel with measurements of soil properties and meteorological conditions. The *AutoFlux*

338 system was constructed in such a way that it can perform long-term measurements of radon flux and environmental
 339 parameters with almost zero maintenance requirements. Unfortunately, this system does not provide a movable
 340 arm to allow a periodic change of the measurement spot. Consequently, the positioning of the lid, even when fully
 341 open, can sometimes partially shelter the measurement surface from the rainfall that the surrounding surface is
 342 receiving. To best match conditions inside and outside of the chamber when open, the accumulation chamber
 343 should be positioned such that the lid opens into the direction of the sun at midday, to maximise the sunlight
 344 received by the surface inside.

345 Figure 1 shows the *AutoFlux* system during a typical radon flux field measurement. Figure S3 of the supplementary
 346 material presents a simplified scheme of the actual state of the *AutoFlux* system.

347

348

349 **Figure 1. Image of the *AutoFlux* system running in the field. The radon activity concentration, internal air temperature,
 350 differential pressure and soil characteristics are measured within the white drum. Ambient temperature, humidity,
 351 pressure and rainfall are measured on the side of the transport case (~50 cm a.g.l.), and the main system components
 352 are located inside the waterproof transport case.**

353 The air exhaled from the soil, rich in radon and thoron (^{220}Rn), enters the accumulation nominal volume $V_D =$
 354 0.042885 m^3 and is pumped at $Q = (1 \pm 0.1) \text{ L min}^{-1}$ first through a filter (PALL Acro 50) and then through a
 355 Permapure PD gas dryer, intended to maintain humidity levels below saturation conditions within the AG monitor.
 356 The low humidity air stream then enters a delay volume ($V_{Th} = 6 \cdot 10^{-3} \text{ m}^3$) within which the ambient thoron decays.
 357 Next, the air passes into the detection volume of the AG ($V_{AG} = 0.62 \cdot 10^{-3} \text{ m}^3$) where the radon concentration is
 358 measured with a 10-minute temporal resolution. The total volume of the circuit tubes is $V_{Tubes} \approx 0.3 \cdot 10^{-3} \text{ m}^3$. The
 359 area of the exhaling surface is $A = 0.126 \text{ m}^2$. Considering the total volume where the radon concentration will be
 360 accumulating V_{eff} will be in this case equal to $V_{tot} = V_D + V_{Th} + V_{AG} + V_{Tubes} = 2.658 \cdot 10^{-3} \text{ m}^3$ the effective height
 361 h_{eff} in the Eq. 10 is equal to 0.204 m.

362 The drum and soil sensors are installed directly into the soil. All sensor outputs are read by a CR1000 datalogger.
 363 A Raspberry Pi 4 (RPI) enables scheduled data downloads from both the CR1000 datalogger and AG via a RS232
 364 serial port and serial to USB FTDI adapter. The RPi, AG, datalogger, PD and all electronic components of the
 365 *AutoFlux* system are safety located within a sturdy, waterproof transport case. External sensors are installed on the
 366 outer walls of the blue transport case. Table 1 summarizes the sensors installed within the *AutoFlux* system. Data
 367 stored on the RPi, which are downloaded from the AG and datalogger hourly, can be transferred to a notebook
 368 computer by connecting the RPi with an Ethernet cable, assuming a Bitwise SSh Client is installed.

369 Figure S4 of the supplementary material shows the accumulation chamber of the *AutoFlux* system in its closed
 370 state (left side) and opened state (right side) during a typical radon flux measurement.

2.6. Calibration of a secondary Radon Flux System using the *AutoFlux* and the UC EB facility

377 After the characterization of the EB (see Section 3.1), and the calibration of the TS under stable laboratory
378 conditions with a constant reference radon flux (see Section 3.2), they were used together to calibrate a second
379 radon flux system (*INTE_flux*, system 6 of Section 2.3).

380 The *INTE_flux* system also operates continuously and is capable of making 3 radon flux measurements per day. It
381 consists of a cylindrical metallic chamber connected to two electro valves and a pump. The electro valves and
382 pump are controlled using a Programmable Logic Controller (PLC) and the system is powered via a 30 m water-
383 proof cable. To measure a radon flux with this system, the ²²²Rn concentration in the chamber exhaled from the
384 soil surface is continuously measured using a DOSEman monitor in diffusion mode, which was previously

385 calibrated at the Radon Reference Chamber (secondary) of the INTE-UPC in agreement with the IEC 61577-4.
386 The DOSEman monitor is powered by an internal battery that lasts 15 days.

387 A typical calibration experiment setup, as carried out at the UC EB facility, is shown in Figure 2, where the
388 *INTE_Flux* and TS were installed on the EB between the 29th of June 2021 and 1st of July 2021.

389
390 **Figure 2. Typical calibration experiment carried out at the UC laboratory: the *INTE_Flux* system is installed together**
391 **with the TS system on the EB facility.**
392

393 3 Results

394

395 3.1. Characterization of the Radon Exhalation Bed (EB) facility

396

397 The EB radon flux was determined under laboratory conditions at specific points in time using both theoretical
398 and experimental approaches, as explained in Section 2.1. The necessary parameters to apply Eq. 3 were measured
399 and/or calculated as explained later in this section and are presented in Table 2, along with their respective
400 uncertainties (with $k=1$). Table 2 also presents all variables and parameters measured or calculated for the
401 experimental characterization of the EB within a week of its installation, together with values obtained from the
402 literature (D and λ).

403 3.1.1 Radium activity concentration (C_{Ra})

404

405 The average radium activity concentration of the soil in the EB was obtained by gamma spectrometry analysis of
406 5 separate samples. The samples were extracted from the center and each of the four corners of the EB at a depth
407 of 10-15 cm. Samples were hermetically sealed in a cylindrical container for one month to allow the ^{226}Ra to reach
408 secular equilibrium with its short-lived progeny (^{214}Pb and ^{214}Bi) equilibrium to be reached between radon progeny
409 and the radium activity concentrations. After this time, after which, time the radium activity was determined using
410 the with ^{214}Pb photopeak (351.93 keV) with an a high-resolution gamma HPGe coaxial detector (model GL-
411 2015-7500, Canberra, USA) following Celaya et al., (2018). The mean ^{226}Ra activity concentration was $19130 \pm$
412 350 Bq kg^{-1} .

413 3.1.2 Emanation factor (ϵ)

414

415 The initial emanation factor, ϵ_0 , of the EB soil was obtained by measuring the ratio between the from the soil
416 radium activity concentration and the radon activity (A_{Rn}) within the pores of a small, and thin (< 5mm) soil
417 sample and its radium activity (A_{Ra}) that escapes to the pore spaces (Eq. 2). A_{Rn} The radon activity in a $M = 100 \text{ g}$
418 soil sample was measured by Eq. 9 after, hermetically sealing the sample within a volume $V = 0.024 \text{ m}^3$ and
419 making an exponential approximation of the radon concentration increase with time according to Eq. 9. The
420 experiment was repeated $n = 3$ times. To facilitate radon escape to the air volume, the soil sample was distributed
421 in a layer less than 5 mm thick.

Formatted: Subscript

Formatted: Subscript

EachThe experiment was run over a period of 500 hours and was replicated at standard temperature conditions ($T = 298$ K) and with a dried soil sample. in three identical boxes to evaluate the uncertainty of ϵ . The continuous radon monitor (Radon Scout; Sarad GmbH) was used for these tests after being calibrated in the LaRUC radon chamber (Fuente et al., 2018). A final average emanation factor of 0.18 ± 0.03 was obtained as:

$$\epsilon_0 \epsilon = \frac{A_{Rn}}{A_{Ra}} = \frac{\phi}{\lambda_{eff} \cdot C_{Ra} \cdot M} = \frac{0.032 \cdot 0.024}{2.2 \cdot 10^{-6} \cdot 19130 \cdot 0.1} = 0.18 \quad (11)$$

with ϕ the activity rate of radon (Bq s^{-1}) obtained as the mean value of the three exponential fits and $\lambda_{eff} = (2.2 \pm 0.3) \cdot 10^{-6} \text{ s}^{-1}$, the effective decay constant of the system. These values are obtained from the average of the three experiments. It can be observed that $\lambda_{eff} \approx \lambda$. The estimated uncertainty of the mean of the initial emanation factor for each experiment was determined from the standard deviation of the three experiments and it was equal to 0.03, divided by the square root of 3 in three identical boxes to evaluate the uncertainty of ϵ . It can be observed that $\lambda_{eff} \approx \lambda$, the decay constant of radon, ensuring negligible leakages within the system. A typical measurement experiment result is shown in Figure S65 of the supplementary material.

As mentioned in the introduction, the emanation factor could vary is not constant over time because – apart from the grain size – it also depends on the moisture content and temperature of the material. Zhuo et al., (2006) and Zhuo et al., (2008) investigated the relationship between the emanation factor variability with soil moisture and soil temperature, and derived the following empirical relationship Eq. 12:

$$\epsilon = \epsilon_0 \cdot [1 + a(1 - e^{-bw_s})] \cdot [1 + c(T - 298)] \quad (12)$$

where ϵ is the radon emanation factor estimated for a given temperature T , and ϵ_0 is the radon emanation factor measured at a temperature of $T = 298$ K for dried soil (see Eq. 11). w_s is the water saturation fraction and a , b , c are parameters calculated for different types of soil textures and declared by Zhuo et al., (2008).

3.1.3 Bulk density (ρ)

The soil bulk density ρ was calculated by measuring the mass, M , with a calibrated balance, and dividing this by its volume, V_s . The volume was measured from an undisturbed soil sample using a test tube manufactured according to ISO 4788. A value of $1645 \pm 2 \text{ kg m}^{-3}$ was calculated.

3.1.4 Radon diffusion length (L)

As explained in Section 2, to simplify Eq. 1 to Eq. 3 the soil thickness z of the EB needs to be much smaller than the radon diffusion length L in the material. Equations 4 to 7 had to be applied after measuring and/or calculating the required soil parameters for these equations: water saturation (w_s) and porosity (p) of the soil. In addition, to apply Eq. 6 and 7 the grain density and water content of the soil sample had to be measured. The mass water content w_c (kg/kg) can be measured as the ratio of the mass of water and the mass of dry soil. It is measured by weighing a soil sample, m_{wet} , then drying the sample to remove the water and weighing it again, m_{dry} :

$$w_c = \frac{m_{wet} - m_{dry}}{m_{dry}} \quad (13)$$

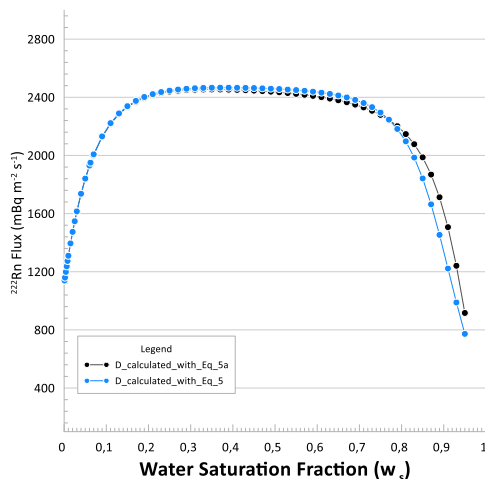

The grain density ρ_g is the ratio of the mass of a dry sample and its volume after eliminating the contribution of the interparticulate interparticle void volume. It can be calculated from the sample weight m_{dry} and the volume V_{dry} of dry soil from:

$$\rho_g = \frac{m_{dry}}{V_{dry}} \quad (14)$$

The diffusion coefficient D and the diffusion length L can now be calculated using Eq. 4 and 5 and L is equal to $(1.286 \pm 0.015) \text{ m}$. The measured EB thickness is equal to $(0.165 \pm 0.005) \text{ m}$, thus the hypothesis $z \ll L$ is verified. Using all the previous parameters the radon flux from the EB can be theoretically estimated by Eq. 3 and it is $F_{Th,EB} = 1918 \pm 278 \text{ mBq m}^{-2} \text{ s}^{-1}$.

Figure 3 shows the theoretical radon flux of the EB calculated using Eq. 1 assuming that the emanation factor varies according to Eq. 11 of Zhuo et al., (2008). The two versions of radon flux presented in Figure 3 represent changes in the adopted diffusion coefficient D . In one case the flux has been calculated using D from Eq. 5 (blue

465 dots) and the other, D from Eq. 5a (black dots). It is evident that no significant difference in EB flux estimate was
 466 observed between these methods in the range of water saturation values for which the EB characterization was
 467 performed.

468
 469 **Figure 3. Variability of EB ^{222}Rn flux calculated using Eq. 1 where the emanation factor variability follows Eq. 11 and**
 470 **the diffusion coefficient D was estimated using both Eq. 5 (black dots) and Eq. 5a (blue dots).**
 471

472 As explained in the Methods section, an empirical evaluation of the EB radon flux was also undertaken by
 473 enclosing the whole exhaling surface with a cover of known volume. The experiments were performed using
 474 different radon monitors inside the closed volume to monitor the radon buildup. Figure S56 of the supplementary
 475 material shows the results of a typical accumulation experiment to estimate the EB radon exhalation rate. The
 476 experiment was repeated several times to confirm its reliability. The response time of the RTM device was set to
 477 1 minute, while it was 10 minutes for the Radon Scout and AlphaE. Air samples were also collected from the
 478 enclosed volume every 15 minutes for independent analysis. Radon concentrations inside the volume reached
 479 values of about 130 kBq m^{-3} after only 5 hours. The diffusion mode of operation for the AlphaE and Radon Scout
 480 monitors (green and orange dots, respectively in Figure S6) is not capable of correctly representing the temporal
 481 variability of radon within the volume, so data from these devices were not used to estimate the EB radon
 482 exhalation rate.

483
 484 The radon exhalation rate was obtained by applying the calculated according to Eq. 10, using calculated or
 485 measured values and parameters summarised in Table 2 (bottom sidepart). Mean values observed reported by the
 486 environmental sensors of the EB facility during the experiments are also reported. The mean of the experimental
 487 radon flux resulting empirical flux estimate was $F_{\text{exp,EB}} = 1757 \pm 67 \text{ mBq m}^{-2} \text{ s}^{-1}$.

488

492

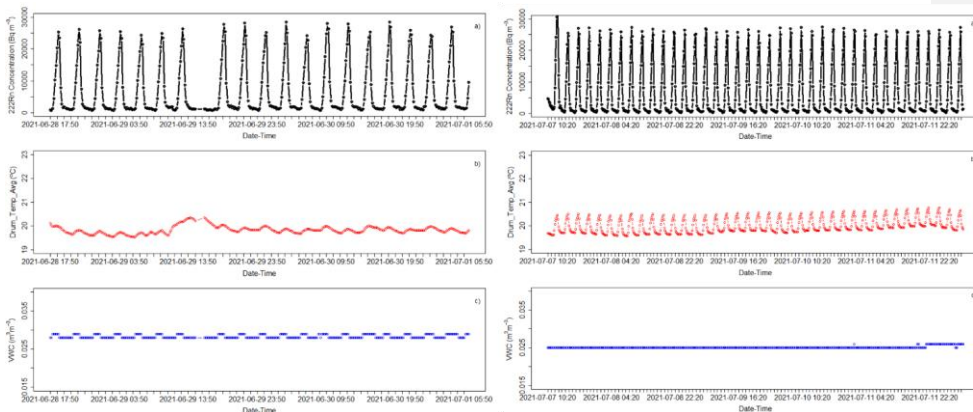

493 3.2 Characterization of the Radon Flux Transfer Standard (TS) System

494

495 The *AutoFlux* was characterized and calibrated under controlled laboratory conditions using the EB facility as
 496 described previously. Figure S7 of the supplementary material shows the *AutoFlux* setup for a typical laboratory
 497 measurement at UC. Two laboratory experiments were performed at standard environmental conditions: i) from
 498 the 28th of June 2021 to the 1st of July 2021 (19 radon flux measurements); and ii) from the 7th to the 12th of July
 499 2021 (39 radon flux measurements). Figure 4 shows the radon activity concentrations (upper panels) measured by
 500 the *AutoFlux*'s AG during the two continuous experiment periods for each accumulation hour. The bottom panels
 501 of Figure 4 show the soil Volume Water Content (VWC) time series measured by the CSI CS655 Water Content
 502 Reflectometer and the air temperature inside the drum measured by the SDI-12 (Unidata 6508A) sensor during
 503 these experiments. A constant increase of around $28 \cdot 10^3 \text{ Bq m}^{-3}$ of radon and of $1 \text{ }^\circ\text{C}$ of temperature was measured
 504 during the 1 h accumulation phase within the system. The Volume Water Content (VWC) measured during the
 505 two experiments ranged between $0.025 \text{ m}^3/\text{m}^3$ and $0.029 \text{ m}^3/\text{m}^3$.

506

507

508

509 **Figure 4.** Radon activity concentrations (black dotted lines in panel *a*) measured by the *AutoFlux*'s AG during the two
 510 calibration experiments. The bottom panels show the time series of the soil VWC (blue dotted lines in panel *c*) and air
 511 temperature inside the drum (red dotted lines in panel *b*) during the experiments.

512 An example of the increase in radon activity concentration measured by the *AutoFlux*'s AG during a typical 1h
513 accumulation period for a single flux measurement is shown in Figure 5. It is evident that the first two values after
514 the chamber closes (0 and 1 in Fig. 5) do not follow the expected theoretical linear increase from Eq. 10. Including
515 these values in the slope calculation could lead to an underestimation of the flux. To better understand the process
516 going on within the drum during a measurement, it is important to note that the 10-minute AG data are
517 representative of the mean radon activity concentration measured over that period, and that the timestamp assigned
518 to each recorded value is at the end of each measurement period. Consequently, the first output value after the
519 chamber is closed (0 in Fig. 5) actually represents the mean radon concentration measured over the 10-minute
520 period leading up to the point of closure. This value has therefore not been considered for the experimental linear
521 fit analysis.

522 A box model (Eq. 15, 16 and 17 and Figure S8 of the supplementary material) can be used to better understand the
523 behavior of radon activity concentrations in the *AutoFlux* system [during the hour of accumulation](#). Figure S8 shows
524 the three main volumes of the system: V_{AG} is the AlphaGUARD detection volume; V_D is the drum (accumulation
525 chamber) volume and V_u is the total volume of all tubing (V_{tubes}) plus the thoron delay volume (V_{Th}). The change
526 in radon concentration with time in each volume of the system components can be described by the following set
527 of differential Equations:

$$\frac{dC_D(t)}{dt} = \frac{F \cdot A}{V_D} - C_D(t) \cdot \frac{Q}{V_D} + C_{AG}(t) \cdot \frac{Q}{V_{AG}} \quad (15)$$

$$\frac{dC_u(t)}{dt} = C_D(t) \cdot \frac{Q}{V_D} + C_u(t) \cdot \frac{Q}{V_u} \quad (16)$$

$$\frac{dC_{AG}(t)}{dt} = C_u(t) \cdot \frac{Q}{V_u} + C_{AG}(t) \cdot \frac{Q}{V_{AG}} \quad (17)$$

532 [Equations 15, 16 and 17 do not take into account the decay of the radon within these volumes because its will be](#)
533 [negligible during the 1h accumulation experiment length](#). Figure S9 of the supplementary material shows the
534 theoretical increase of radon concentration with time in each of the respective volumes C_D (drum concentration),
535 C_u (concentration in thoron delay and tubes) and C_{AG} (concentration in the AG) during the first hour of system
536 closure, obtained through the analytical solution of Eq. 15, 16 and 17 with the software Mathematica (Wolfram
537 Mathematica). The observed increase in radon within the AG becomes parallel to the radon increase within the
538 accumulation chamber only after 700 sec (≈ 12 minutes). Therefore, the second value measured by the AG after
539 the accumulation volume is closed (point 1 in Figure 5) also can't be considered as part of the experimental linear
540 fit analysis due to the system response time delay.

541 Looking at Figure 5, the slope of the experimental data (black dotted line) during the accumulation hour, ignoring
542 the first two points (0 and 1) for the reasons mentioned above, gives a radon flux of (1899 ± 60) mBq $m^{-2} s^{-1}$
543 according to Eq. 10, where the associated uncertainty is calculated from the residual standard error (rse) of the
544 linear fit. These data were measured with a mean volume water content w_v of $0.025 m^3/m^3$, equal to a soil water
545 saturation $w_s = 0.069 m^3/m^3$ that, according to Eq. 1 and 11, gives a theoretical radon flux of (1974 ± 277) mBq
546 $m^{-2} s^{-1}$. Finally, the [experimental data \(black dotted line in Figure 5\) were fitted with](#) theoretical data (blue dotted
547 [line in Figure 5\)](#) obtained by solving differential equations 15, 16 and 17 [were calculated](#) with a radon flux of
548 about $(F_{Th_AF} = 1871 \pm 187)$ mBq $m^{-2} s^{-1}$ where the uncertainty of 10% ($k=1$) is due to the volume estimations and
549 flow variability during the accumulation hour. All of these results are consistent if the associated uncertainties are
550 taken into account and support the understanding of the system response.

551 Radon concentration time series obtained by exposing the *AutoFlux* system to the UC EB facility (Experiments I
552 and II in Figure 4) were analyzed and Eq. 10 was used to calculate the radon fluxes for each measurement, using
553 only points 2, 3, 4, 5 and 6 of the accumulation phase. This resulted in a mean radon flux of $F_{Exp_AF} = 1856$ mBq
554 $m^{-2} s^{-1}$ with a standard deviation of $\sigma_{Autoflux} = 86.5$ mBq $m^{-2} s^{-1}$ over a total of $n = 58$ radon flux measurements.

555 The error of the mean of the flux measured experimentally by the *Autoflux* monitor will be $u_{Autoflux} = \frac{\sigma_{Autoflux}}{\sqrt{n}} =$
556 11.4 mBq $m^{-2} s^{-1}$. All results are consistent within their respective uncertainties. Finally, Table 3 summarizes the
557 mean radon flux measured by the *AutoFlux* system during experiments I and II at the UC EB facility in October

558 2021. The means and standard deviations of the variables measured by the *AutoFlux* environmental sensors are
 559 also reported.

560

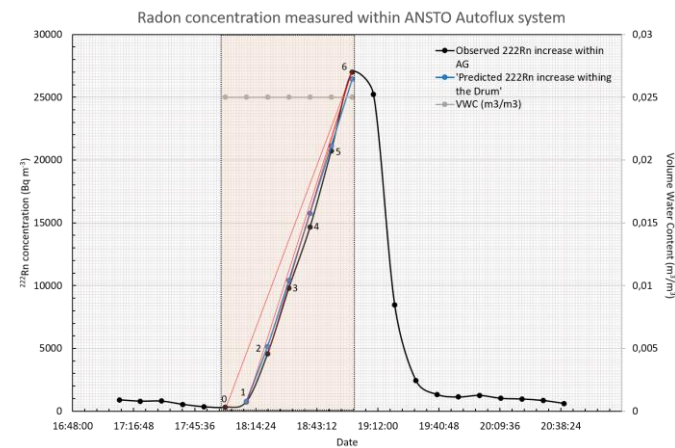

561 **Table 3. Results of ^{222}Rn fluxes and environmental parameters calculated and/or measured using the *AutoFlux* system**
 562 **during experiments I and II carried out at the UC facility in October 2021 (Grey shaded values have been calculated**
 563 **using Eq. 10 and 15-16-17).**

Variable	Mean	St. Dev.
$F_{Exp_AF} (mBq\ m^{-2}\ s^{-1})$	1856	86.5
$F_{Th_AF} (mBq\ m^{-2}\ s^{-1})$	1871	187
Flow ($L\ min^{-1}$)	0.91	0.01
VWC (m^3/m^3)	0.025	0.002
AirTemp ($^{\circ}C$)	19.92	0.095
RH (%)	69.91	1.58
AtmPress (mbar)	1015.3	2.5
DrumTemp ($^{\circ}C$)	20.04	0.11

564

565

566

567 **Figure 5. Increase in radon activity concentration within the *Autoflux*'s accumulation chamber during a typical radon**
 568 **flux measurement (black dotted line). Blue dotted line represents the theoretical value calculated within the AG volume.**

569 The grey dots indicate the VWC measured in the soil at the same time. Red lines show different slopes obtained when
570 considering different values.

571

572 Considering the agreement between the theoretical and experimental results of the mean radon flux values obtained
573 directly from the EB (F_{Th_EB} and F_{Exp_EB}) or using the *AutoFlux* on the EB (F_{Th_AF} and F_{Exp_AF}), the calibration factor
574 of the *AutoFlux* monitor can be now calculated as $F_{Cal_AutoFlux} = F_{Exp_EB}/F_{Exp_AF} = 0.95$. The uncertainty of the
575 calibration factor $u_{Cal_AutoFlux} = 0.07$, calculated following the 'Guide to the Expression of Uncertainty in
576 Measurement' (JCGM 100) by Eq. 18:

577

$$\left(\frac{u_{Cal_AutoFlux}}{F_{Cal_AutoFlux}}\right)^2 = \left(\frac{u_{AutoFlux}}{F_{AutoFlux}}\right)^2 + \left(\frac{u_{Exp_EB}}{F_{Exp_EB}}\right)^2 + \left(\frac{u_{F_Corr}}{F_{Corr}}\right)^2 \quad (18)$$

578 It should be noted that F_{Exp_EB} and F_{Exp_AF} were measured within a 1% of variability of the water saturation
579 condition of the emanating soil, which could induce up to a 6% of variability on the measured flux. This possible
580 variability should be considered within the calculation of the uncertainty of the calibration factor of the Transfer
581 Standard monitor, including a correction factor $F_{Corr} = 1$ with an uncertainty $u_{F_Corr} = 0.06$.

582

583 3.3. Calibration of the INTE_Flux system using the TS and the EB facility

584

585 The upper panel of Figure 6 shows the radon concentration time series measured at the same time by the DOSEman
586 included within the accumulation chamber of the *INTE_Flux* system and by the AG used for the *AutoFlux* system.
587 The slope b in Eq. 10 can be calculated for each radon accumulation period of the *INTE_Flux* and it has been
588 reported in Table 4, together with the radon fluxes measured by the *INTE_Flux* when a nominal $h_{eff} = 0.15$ m is
589 applied. The mean value of the radon flux calculated using the *INTE_Flux* system was $F_{Client} = 1332$ mBq m⁻² s⁻¹
590 with a standard deviation of $\sigma_{Client} = 140$ mBq m⁻² s⁻¹ and the standard error of the mean $u_{Client} = \frac{\sigma_{Client}}{\sqrt{n}} = 63$ mBq
591 m⁻² s⁻¹, where $n = 5$, the number of radon flux measurements carried out with the *INTE_Flux* system. The mean of
592 the radon flux measured by the TS instrument (*AutoFlux*) during the same period was $F_{Ref} = 1868$ mBq m⁻² s⁻¹ with
593 a standard deviation of $\sigma_{Ref} = 137$ mBq m⁻² s⁻¹ and a standard error of the mean $u_{Ref} = 39.5$ mBq m⁻² s⁻¹ ($n_{Ref} = 12$).
594 The calibration factor of the *INTE_Flux* system can be estimated as $F_{Cal} = F_{Ref_Cal}/F_{Client} = 1.33$, where $F_{Ref_Cal} =$
595 $F_{Ref} \cdot F_{Cal_AutoFlux}$ represents the calibrated radon flux value obtained by the ANSTO *AutoFlux* system over the
596 experiment.

597

598

599

600
601
602 **Figure 6. Upper Panel:** Time series of radon concentrations measured by the DOSEman (output each 30 min) in the
603 *INTE_Flux* system accumulation chamber and by the AG (output each 10 min) used for the *AutoFlux* on the EB facility
604 of the Cantabria University during the accumulation and ventilation phases of both instruments. Lower panel: Time
605 series of the radon fluxes obtained with the *AutoFlux* system (black dotted line), by the *INTE_Flux* system (*Client*)
606 before the calibration factor being applied (red dotted line) and after its application (green dotted line).

607
608 **Table 4. Slope and Fluxes obtained by Eq. 10 for the *INTE_Flux* system.**

<i>Slope b</i> (Bq m ⁻³ h ⁻¹)	<i>F_{Client}</i> (mBq m ⁻² s ⁻¹)
37239	1553
30325	1265
29629	1235
33301	1389
29209	1218
Mean ± Standard Deviation (1332 ± 140) mBq m⁻² s⁻¹	

609
610 To estimate the total uncertainty (u_{cal}) of the calibration factor F_{Cal} in agreement with the ‘Guide to the Expression
611 of Uncertainty in Measurement’ (JCGM 100) was used Eq. 19:

612

$$\left(\frac{u_{Cal}}{F_{Cal}}\right)^2 = \left(\frac{u_{Client}}{F_{Client}}\right)^2 + \left(\frac{u_{ref}}{F_{ref}}\right)^2 + \left(\frac{u_{Cal_AutoFlux}}{F_{Cal_AutoFlux}}\right)^2 \quad (19)$$

613 Thus, the calibration factor F_{Cal} value will be obtained with a total associated uncertainty equal to $u_{Cal} = 0.12$ which
 614 corresponds to 9% of the calibration factor. To ensure a confidence level of 95% the Welch–Satterthwaite equation
 615 was used to calculate an approximation to the effective degrees of freedom of the u_{Cal} variable and to select the
 616 corresponding t-student coverage factor. A total expanded uncertainty $U_{Cal} = 0.24$ ($k=2$) was calculated.

617

618 3.4 Short field comparison between TS, *INTE_Flux* and modeled radon fluxes

619

620 The calibrated *Autoflux* and *INTE_Flux* systems were used during two intercomparison campaigns presented by
 621 Rabago et al., 2022. Figure 7 shows time series of radon concentrations measured within both systems at a low
 622 radium content area campaign between the 23rd and the 28th of October, 2021 in Esles de Cayón, Spain (lat.: 43.28,
 623 long.: -3.80). Time series of measured VWC and drum temperature from the *Autoflux* are also shown. It can be
 624 noted that temperature cycles are mostly related with day/night atmospheric condition where the soil moisture
 625 shows a generally decreasing trend over the duration of the campaign. The reader should take into account that the
 626 higher radon concentrations measured by the *INTE_Flux* system are inversely proportional to its smaller volume.

627

628

629

630 **Figure 7. (a) Time series of radon concentrations measured by the *Autoflux*'s AG every 10 minutes (black dotted line)**
 631 **and the *INTE_Flux*'s DOSEman every 30 minutes (red dotted line), (b) drum temperature (red dotted line), and (c)**
 632 **VWC (black dotted line) measured by *Autoflux* sensors.**

633 Daily mean radon fluxes measured by the *Autoflux* and *INTE_Flux* systems throughout the campaign are shown
 634 in Figure 8c together with:

- 635 i) Data from the traceRadon daily radon flux maps for Europe 2021 (Figure 8a) based on ERA5-Land
 636 and on GLDAS-Noah v2.1 soil moisture reanalysis data (Figure 8b), respectively, available at the
 637 ICOS Carbon Portal (Karstens, U. and Levin, I., 2022). Radon fluxes are calculated following
 638 Karstens et al., 2015 and including the calculation of the emanation factor proposed by Zhuo et al.,
 639 2008 but taking into account only half of the temperature influence ($c/2$ in Eq. 12). The soil uranium
 640 content and the soil properties needed to apply Eq. 1 within these maps were extracted by EANR,
 641 2019 and ESDB, Hiederer, 2013, respectively.

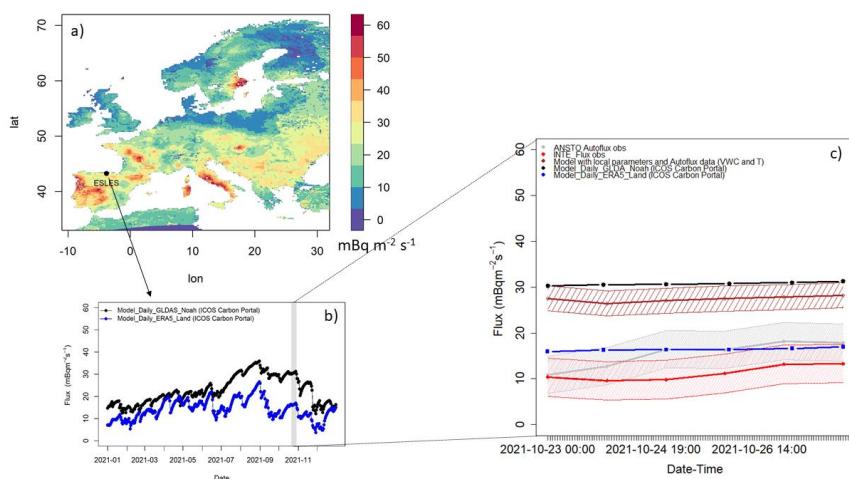

642 ii) Radon fluxes calculated applying the model by Karstens et al., 2015 and the complete emanation
643 factor proposed by Zhuo et al., 2008 with soil temperature and soil moisture values measured by
644 *Autoflux* sensors during the measurement campaign. Uranium content of the soil and soil parameters
645 to apply Eq. 1 were directly measured in the laboratory on soil samples extracted at the measurement
646 site.

647

648 It can be observed that radon fluxes measured by the two calibrated systems are in agreement during the field
649 measurements and they increase throughout the campaign in accordance with the decrease in soil water content
650 (Figure 7c). Output of the model based on ERA5_Land and GLDAS_Noah data does not show any increase over
651 the measurement period, but they are in agreement with the observed data. Radon fluxes modeled using
652 GLDAS_Noah reanalysis data or local measured parameters seem to be twice as high as experimental other values
653 and ERA5_Land radon flux based data. This might be related to a better estimation of the ERA5_Land soil water
654 content and to an underestimation of the soil water content measured by the one-point sensor of the saturation data
655 by the *Autoflux* and of the or by GLDAS_Noah data for these days.

662

663 Conclusions

664 **Conclusions**
665
666 Reliable long-term radon flux observations are important to validate radon flux maps used for radiation protection
667 and climate [goalsproposes](#).

668 In the present study a new automatic radon flux system, which allows 3-hourly measurement of radon fluxes
669 together with environmental parameters in the soil and ambient air, has been characterized and calibrated for being
670 used as Transfer Standard to enable traceable radon flux measurements. This was done using a bespoke exhalation
671 bed built and characterized for this purpose. The new radon flux system (*Autoflux*) was then used to calibrate a
672 second radon flux monitor (*INTE_Flux*). Both calibrated monitors were tested during a short in situ measurement
673 campaign and results were compared with ones obtained from available radon flux maps using soil proprieties

674 from European datasets (traceRadon daily radon flux maps for Europe 2021 based on ERA5-Land and on GLDAS-
675 Noah v2.1 soil moisture reanalysis data, respectively, available at the ICOS Carbon Portal) or local measurements.

676 [The exhalation bed, designed and built as primary standard, was characterized both theoretically and](#)
677 [experimentally to check its reliability and to better understand how the variability of some soil conditions, such as](#)
678 [the water content, could influence the measured radon exhalation. The experimental approach allows a significant](#)
679 [reduction of the uncertainty of the radon exhalation rate.](#)

680 Based on the results so far, the ~~authomatic~~automatic *AutoFlux* system appears to be a reasonable option for a
681 Transfer Standard, however further studies of this kind should be carried out at lower reference radon exhalation
682 rates (in the order of tens mBq m⁻² s⁻¹) and under extreme environmental conditions of soil moisture and
683 temperature to better understand sub daily timescale variability of measured fluxes [and to quantify the increase of](#)
684 [the total flux value uncertainty for these cases. In addition, the *AutoFlux* system, for low radon flux soils, may be](#)
685 [used with a continuous radon monitor with a faster response and an higher sensitivity in to allow to observe the](#)
686 [linear increase of the radon concentration within the accumulation chamber with the smallest possible standard](#)
687 [deviation.](#)

688 Daily radon flux observations during the short field intercomparison campaign carried out in northern Spain from
689 the two calibrated systems are coherent, within their daily standard deviations, and in agreement with the daily
690 radon fluxes modeled using ERA5_Land reanalysis. Daily radon fluxes modeled using local measured parameters
691 and variable or GDAS_Noah reanalysis data show higher values. This last result shows the importance to validate
692 the input parameters (porosity, bulk density, etc.) and variable (i.e. volume water content and temperature in the
693 soil) used within the model and to perform long-term measurements at different soils and under different
694 meteorological conditions.

695 **Author Contributions**

696
697 C. Grossi, D. Rabago, S. Chambers, R. Curcoll and A. Vargas led the data analysis and the writing of the
698 manuscript. D. Rabago, C. Sáinz and L. Quindos carried out the literature study and the design, building and
699 characterization of the Exhalation Bed facility. P. PS. Otáhale and E. Fialová led the literature study of the radon
700 flux systems. C. Grossi, A. Vargas and D. Rabago carried out the experimental and theoretical characterization of
701 the *Autoflux* system. All authors participated in the discussion of the results and the writing of the manuscript.

702

703 **Acknowledgments**

704 Authors declare do not have any conflict of interest.

705 This study has been possible thanks to the project 19ENV01 traceRadon. The project 19ENV01 traceRadon has
706 received funding from the EMPIR programme co-financed by the Participating States and from the European
707 Union's Horizon 2020 research and innovation programme. 19ENV01 traceRadon denotes the EMPIR project
708 reference.

709 Authors want to thank the work of Sylvester Werczynski, previously employed at ANSTO, who worked on the
710 design and control software of the *Autoflux* system and of Ute Kartsens who made available the radon fluxes
711 model data.

712 **Code and data availability**

713 The data and the codes from this study are available from the corresponding author and at the following link:
714 https://github.com/ClauGro/GRL_Data. Scripts of the software R v. 3.6.2 (with Rstudio) and Python v. 3.8 (with
715 Spyder) were used and are also shared in the github repository.
