Abstract

32
33 The narrow cross-section of cloud and aerosol properties retrieved by L2-algorithms that operate
34 on data from EarthCARE's nadir-pointing sensors gets "broadened" across-track by an algorithm
35 that is described and demonstrated here. This *Scene Construction Algorithm* (SCA) consists of four
36 components. At its core is a radiance-matching procedure that works with measurements made by
37 EarthCARE's Multi-Spectral Imager (MSI). In essence, an off-nadir pixel gets filled with retrieved
38 profiles that are associated with a (nearby) nadir pixel whose MSI radiances best match those of
39 the off-nadir pixel. The SCA constructs a 3D array of cloud and aerosol (and surface) properties
40 for entire *frames* that measure ~6,000 km along-track by 150 km across-track (i.e., the MSI's full
41 swath). Constructed domains out to ~15 km across-track on both sides of nadir are used explicitly
42 downstream as input for 3D radiative transfer models that predict top-of-atmosphere (TOA) broad-
43 band solar and thermal fluxes and radiances. These quantities are compared to commensurate meas-
44 urements made by EarthCARE's BroadBand Radiometer (BBR), thus facilitating a continuous clo-
45 sure assessment of the retrievals. Three 6,000 km x 200 km frames of synthetic EarthCARE obser-
46 vations were used to demonstrate the SCA. The main conclusion is that errors in modelled TOA
47 fluxes that stem from use of 3D domains produced by the SCA are expected to be less than ± 5 W
48 m^{-2} and rarely larger than ± 10 W m^{-2} . As such, the SCA, as purveyor of information needed to run
49 3D radiative transfer models, should help more than hinder the radiative closure assessment of
50 EarthCARE's L2 retrievals.

51

52

53

54 **1. Introduction**

55 The objective of the EarthCARE satellite mission is to help improve numerical predictions of
56 weather, air quality, and climatic change via application of synergistic L2-retrieval algorithms to
57 observational data from its cloud-profiling radar (CPR), backscattering lidar (ATLID), and passive
58 multi-spectral imager (MSI) (Illingworth et al. 2015). EarthCARE’s overarching scientific goal
59 (ESA 2001) is to retrieve cloud and aerosol properties with enough accuracy that when used to
60 initialize atmospheric radiative transfer (RT) models, simulated top-of-atmosphere (TOA) broad-
61 band radiative fluxes, for domains covering $\sim 100 \text{ km}^2$, agree with their observational-based coun-
62 terparts to within $\pm 10 \text{ W m}^{-2}$ *more often than not*. “Observed” TOA fluxes derive from radiances
63 measured by EarthCARE’s multi-angle broadband radiometer (BBR). As the latter are not used by
64 retrieval algorithms, comparing them to modelled values, obtained by RT models operating on
65 retrieved quantities, affects a “moderately stringent” verification of the retrievals (Barker et al.
66 2023); “moderately stringent” because BBR radiances consist, in part, of photons that share the
67 same gaseous pathlength and number of cloud-aerosol-surface scattering event distributions as
68 those that constitute MSI radiances. These imperfections aside, this radiative closure verification
69 is a well-defined and cost-effective final stage in EarthCARE’s formal processing chain (Eisinger
70 et al. 2023).

71 In light of EarthCARE’s ambitious goal of limiting differences between measured and modelled
72 TOA fluxes to $\pm 10 \text{ W m}^{-2}$ when averaged over “assessment domains” that measure $\sim 5 \text{ km}$ across-
73 track by $\sim 21 \text{ km}$ along-track, the usefulness of its radiative closure programme depends much on
74 reducing errors and uncertainties in: BBR measurements; variables needed by RT models that are
75 not provided by EarthCARE observations; and RT models. Included in this are issues of observa-
76 tional geometry that face use of BBR data for EarthCARE’s closure assessment. First, L2-retrieved

77 profiles are ~ 1 km in diameter, while the BBR was designed to perform best for footprints of ~ 10
78 x 10 km. For this configuration, fluxes and radiances computed for sequences of retrieved profiles
79 contribute only $\sim 10\%$ of the signal to each BBR footprint (or pixel). Second, at only ~ 1 km wide,
80 net horizontal fluxes for each retrieved column, and sequences of them, will rarely be close to zero
81 (e.g., Barker and Li 1997; Marshak et al. 1998). This implies that 3D RT models, as opposed to
82 their ubiquitous 1D counterparts, will be required to make EarthCARE's radiative closure assess-
83 ment fruitful (Illingworth et al. 2015). Hence the need for 3D arrays of data that describe the Earth-
84 atmosphere system adjacent to the ~ 1 km-wide retrieved L2-cross-section.

85 Fortunately, BBR data are not bound to 10 km resolution, as point-spread function widths of its
86 native radiances are ~ 0.7 km. This offers much flexibility to the design of the closure assessment
87 (e.g., Tornow et al. 2018). The extreme case is to use a single along-track line of BBR radiances
88 that overlap, at best approximately, the ~ 1 km wide curtain of L2-retrieved profiles, referred to
89 hereinafter as the L2-plane. This would, however, degrade BBR performance, via reduced signal-
90 to-noise ratio and pointing accuracy, and thus weaken closure assessments. Alternatively, one
91 could attempt an across-track "broadening" of the L2-plane so as to cover as many BBR native
92 radiances as deemed necessary. Regardless of the route taken and the size of domains over which
93 closure assessments are to be performed, there is the ever-present related issue of lateral flow of
94 photons both within assessment domains *and* between assessment domains and their adjacent areas.
95 Taking these issues together, EarthCARE's science team opted for its closure assessment experi-
96 ment to use 3D RT models applied to assessment domains centred on the L2-plane with across-
97 track widths appreciably greater than 1 km (Illingworth et al. 2015).

98 The method for approximating 3D geophysical variables adjacent to the L2-plane, in order to
99 safely use both 3D RT models and BBR data, is the radiance-matching *Scene Construction Algo-*
100 *rithm* (SCA) (Barker et al. 2011), which forms the basis of the ACM-3D processor. The purpose
101 of the current paper is to recap, in section 2, the SCA, present several operational details associated
102 with it, and demonstrate, in section 3, its overall performance using simulated observations for a
103 virtual Earth-observation system (Qu et al. 2023; Donovan et al. 2023). Application of RT models
104 to SCA products and subsequent radiative closure assessments for the same virtual environments
105 are discussed by Cole et al. (2023) and Barker et al. (2023). A brief discussion is given in section
106 4.

107 **2. 3D Atmosphere-Surface Scene Construction Algorithm**

108 To begin, EarthCARE’s products are partitioned into $\sim 6,565$ km long “frames”, which makes six
109 frames / orbit. Position in a frame is defined by the Joint Standard Grid (JSG). Each frame contains
110 N_{JSG} L2-retrieved columns along-track. Frame widths are 150 km as defined by the MSI’s swath;
111 35 km to the right and 115 km to the left of the L2-plane (relative to the satellite’s direction of
112 motion). Some algorithms require data beyond nadir, and so each frame’s files also contain n_ϵ
113 swaths of data from neighbouring frames. JSG coordinates are denoted as (i, j) , with i running
114 along-track from $1 - n_\epsilon$ to $N_{JSG} + n_\epsilon$, and j running perpendicular to the L2-plane, which is located
115 at $j = 0$.

116 As documented by Cole et al. (2023), EarthCARE’s radiative products are produced by 1D and
117 3D broadband RT models. Some of these products are used to perform radiative closure assess-
118 ments of L2-retrievals (see Barker et al. 2023). While 1D RT models are applied, in ACM-RT (see

119 Cole et al. 2023), to all non-corrupt columns in the L2-plane, their results are averaged over small
120 domains D , in processor ACMB-DF where radiative closure is assessed, referred to hereinafter as
121 *assessment domains*, whose along-track centres, at $j = 0$, are the L2-plane. Conversely, 3D RT
122 models operate directly on D and domain-average results are computed in ACM-RT and used in
123 ACMB-DF. The structure of D for $j \neq 0$ is defined by the *3D Scene Construction Algorithm*
124 (SCA), which is explained in the following subsections. Along-track lengths of D , in terms of JSG
125 cells, are n_{assess} columns(pixels), while their across-track half-widths are m_{assess} , making full across-
126 track widths $2m_{\text{assess}} + 1$ columns(pixels). The initial plan is to fix m_{assess} and n_{assess} at 2 and 21,
127 respectively. Thus, D are $\sim 5 \times 21$ km, so their areal extents, regardless of location, are ~ 100 km²,
128 which is what the BBR was designed to operate at (see Illingworth et al. 2015).

129 The operational SCA is made up of several sub-algorithms. At its core is definition of D at
130 $(i, j \neq 0)$ via MSI radiance-matching (Barker et al. 2011). Other crucial components include: def-
131 inition of buffer-zones around D , as required by the 3D RT models; screening and ranking of D
132 in an attempt to maximize the usefulness of the radiative closure assessment process; and estima-
133 tion of errors for TOA fluxes and radiances that stem from the radiance-matching algorithm. To
134 improve readability of the main text, many details of these sub-algorithms are presented in Appen-
135 dices. General results are shown and discussed in Section 3.

136

137 **Figure 1:** Schematic showing solar zenith angle θ_0 , solar azimuth angle relative to north φ_0 , sat-
 138 ellite-tracking vectors relative to north φ_s , solar azimuth angle relative to satellite-tracking direc-
 139 tion φ_r , and the BBR's two off-nadir zenith angles θ_v .

140

141 2.1. Radiance matching

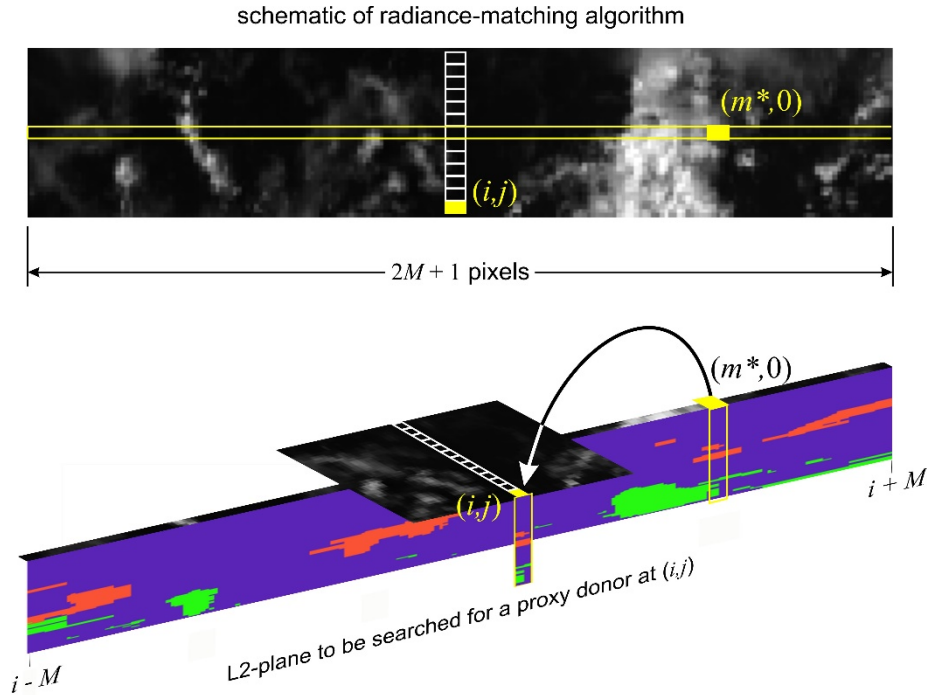

142 The core of the SCA, and thus the ACM-3D processor, is passive narrowband radiance-matching
 143 of an off-nadir MSI pixel's spectral radiances with their nadir counterparts along the L2-plane
 144 (Barker et al. 2011). As this methodology has been described and used elsewhere (Barker et al.
 145 2011; 2012; 2014; Sun et al. 2016), it is recapped briefly here, with details reiterated in Appendix
 146 A. Note that all independent variables referred to here are available to the ACM-3D processor from
 147 other EarthCARE processors; all of which are reported on in this special issue.

148 Let $r_k(i, j)$ be MSI radiances, for the k^{th} channel, where values at position $(i, j = 0)$ align along the
 149 L2-plane and have geophysical profiles associated with them. When seeking to populate an off-nadir
 150 *recipient* column at $(i, j \neq 0)$ with a suitable *donor* from the L2-plane, the algorithm quantifies
 151 how well $r_k(i, j \neq 0)$ match $r_k(m, j = 0)$ for all $m \in [i - M, i + M]$; M being the number of JSG

152 pixels, forward and backward, along the L2-plane one is prepared to allow the algorithm to search.
153 While M could depend on a host of variables, a default value of 200 has been used thus far. As
154 explained in Appendix A, for a nadir pixel to be a potential donor, the recipient's and donor's
155 surface types (land, sea, and snow/ice) must match, and cosine of solar zenith angles μ_0 and azi-
156 muth angles between Sun and satellite tracking direction φ_r must differ by less than specified
157 amounts. Figure 1 shows a schematic of solar-satellite geometry. While the recipient and L2-donor
158 pixels could be required to have the same cloud phase, the intention all along has been for the
159 algorithm to rely just on radiances, not other algorithms.

160 Of those L2-plane pixels whose MSI radiances best resemble those at $(i, j \neq 0)$, the one lying
161 physically closest to $(i, j \neq 0)$ becomes the donor, and its profiles of geophysical information get
162 replicated at $(i, j \neq 0)$. This procedure is performed for all $(i, j \neq 0)$ across the MSI's swath; pixels
163 at $(i, 0)$ donate to themselves. The result is *construction* of a 3D atmosphere-surface domain made-
164 up of profiles from the L2-plane. Correspondingly, MSI imagery are *reconstructed*, too. Figure 2
165 shows a schematic of the radiance-matching procedure. Hereinafter, values at (i, j) that are based
166 on the SCA are indexed as $(m^*(i, j), 0)$, which ties them back to the $m^*(i, j)^{\text{th}}$ column/pixel along
167 the L2-plane.

168

169

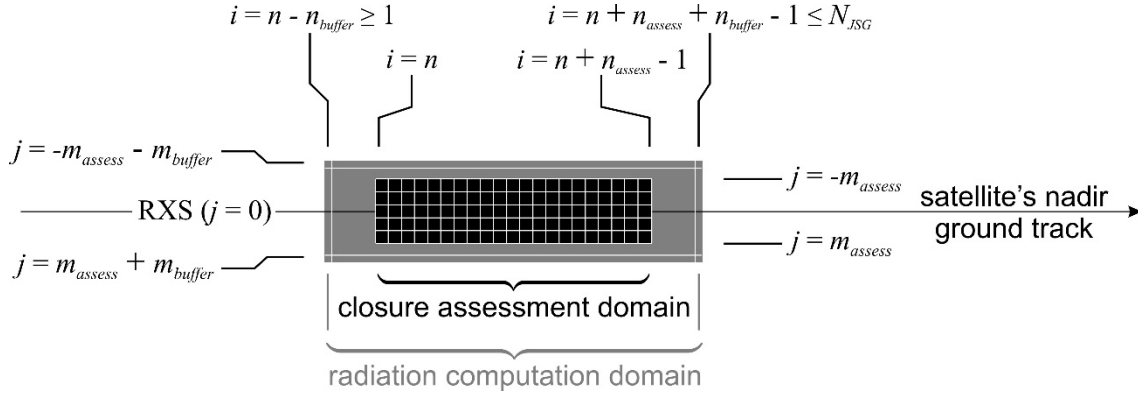

170

171 **Figure 2:** Top panel shows a swath of passive imagery and the location of an off-nadir pixel at
 172 (i, j) whose radiances match best with those along nadir at $(m^*, 0)$. Lower panel is a schematic
 173 illustrating attribution of the (recipient) column associated with the pixel at (i, j)
 174 column of information inferred from EarthCARE's active-passive measurements at $(m^*, 0)$.

175

176 2.2. Assessment domains and their buffer-zones

177 The 3D RT models used for EarthCARE employ cyclic horizontal boundary conditions. Real
 178 cloudy domains and those produced by the SCA are, however, non-cyclical and so when 3D RT
 179 models operate on them, adverse effects near the perimeter of D are affected by photon paths
 180 crossing discontinuous optical properties. One way to deal with this is to add atmosphere and sur-
 181 face to all edges of D so as to, not eliminate but rather, displace away from D any adverse effects
 182 set-up by the assumed cyclic boundary conditions. Hereinafter, the domain resulting from the com-
 183 bination of D and its buffer-zones is denoted as D^+ .

184

185 **Figure 3:** Schematic showing the radiative closure assessment domain $D(i)$ (black)
 186 radiation computation domain $D^+(i)$; the union of $D(i)$ and the buffer-zone (shaded). See the text
 187 for definitions of indices.
 188

189 Buffer-zones also accommodate the fact that the BBR's oblique radiances associated with D
 190 consist partly of photons that were scattered by the atmosphere and surface outside of D . Barker
 191 et al. (2015) described an adjustment to 3D RT Monte Carlo models that approximates fractional
 192 contributions to a BBR radiance from photons whose last scattering event, by any particular scat-
 193 tering species, took place in D . Their algorithm, however, is too time-consuming for EarthCARE's
 194 official data processing system. Nevertheless, the buffer-zone should adequately capture contribu-
 195 tions to BBR radiances that come from beyond D .

196 Setting the along- and across-track dimensions of buffer-zones is described in detail in Appendix
 197 B. *Figure 3* shows D , its associated D^+ , and the indices that locate them on the JSG. The number
 198 of pixels in the along-track that are out in front n_{buffer}^{\searrow} and trailing n_{buffer}^{\swarrow} D can vary and depend on
 199 the minimum along-track buffer length d_{\parallel}^{\min} , assumed to be ~ 5 km, BBR viewing zenith angle θ_v
 200 , and nearby cloudtop altitudes $h(m^*(i, j), 0)$ as defined by the radiance-matching algorithm. *Fig-*
 201 *ure 4* is a schematic of this process which is detailed in Appendix B.

202

203 **Figure 4:** Schematic showing the procedure for finding along-track buffer-zone size; in this case
 204 $n_{buffer}^{\check{}}$. (a) h_D^{\max} is maximum cloudtop altitude in assessment domain D , and d_{\parallel}^{\min} is the smallest
 205 size buffer-zone allowed. (b) As the algorithm searches out in front of D , a cloud is encountered;
 206 part of which lies between D and the satellite, and so the buffer-zone increases. (c) Continuing
 207 the search, still a higher cloud is encountered between D and the satellite, thus increasing the
 208 buffer-zone further. (d) There is still more cloud between D and the satellite so the buffer-zone
 209 increases again, this time to its final value of $n_{buffer}^{\check{}}$, despite the possibility of cloudtops further
 210 out being higher yet still. See text and Appendix B for details.

211

212 Note that $n_{buffer}^{\check{}}$ and n_{buffer}^{\searrow} are independent of θ_0 . This is because for EarthCARE's orbit, over
 213 80% of observations with $\theta_0 < 90^\circ$ have $30^\circ < \varphi_r < 150^\circ$ implying that, for most cases, projection
 214 of direct-beam (and hence cloud shadows) into the along-track walls of D will be small. Excep-
 215 tions are for very large θ_0 with $\varphi_r < 30^\circ$ or $\varphi_r > 150^\circ$, but these cases are usually avoided because
 216 the RT models rely on the plane-parallel approximation.

217

218 **Figure 5:** Schematic showing the procedure for finding the size of the cross-track buffer-zone
 219 size m_{buffer} . See text and Appendix B for details.

220

221 Determination of the size of cross-track buffer-zones m_{buffer} depends on $h(m^*(i, j), 0)$ adjacent
 222 to the sunlit side of D and minimum size for the across-track buffer-zone d_{\perp}^{\min} . If a cloud to the
 223 side of D casts a shadow that falls onto the region formed by D and its along-track buffer-zones,
 224 then the cross-track buffer-zone extends to include the cloud doing the shadowing. Unlike the
 225 along-track, m_{buffer} gets applied to both sides of D . Figure 5 summarizes definition of m_{buffer} .

226 2.3. Screening radiative closure assessment domains

227 Due to computational limitations and time constraints on product production, it is anticipated that
 228 only a small number of D per frame will participate in the 3D RT radiative closure exercise (i.e.,
 229 processor ACMB-DF). Hence, D that emerge from the SCA must be “screened and ranked” to
 230 ensure that an adequate range of cases, from “simple” to “complex”, be assessed in order to: i)

231 provide well-rounded pictures of algorithmic performances; ii) gauge whether mission objectives
232 are being met; and iii) provide guidance to data users who wish to focus on select conditions. At
233 the same time, screening and ranking should be flexible enough to be changed during the mission.
234 For instance, “simple” scenarios are likely to be of particular interest during the commissioning
235 phase (e.g., mono-phase, single-layer, overcast clouds).

236 The screening process eliminates D that are likely to yield uninformative assessments. It has
237 three stages as described in the following subsections. Each frame has two sets of surviving assess-
238 ment domains: D_{1D} contains domains that 1D RT results are averaged over; D_{3D} contains domains
239 that 3D RT models get applied to. Domains in D_{1D} and D_{3D} consist, respectively, of *radiative*
240 *assessment domains* D and *radiative computation domains* D^+ (see Figure 3).

241 2.3.1. Screening Stage 1: Failed retrievals and corrupt data

242 If there are corrupt data or failed retrievals for any column in either D or D^+ , the domain will not
243 be forwarded to subsequent processes. This is because they simply cannot be used by 3D RT mod-
244 els. Examples of failed retrievals include algorithms that did not converge to a solution or con-
245 verged to values that are out of bounds. Corrupt data, on the other hand, includes failure at the L1
246 level and data corrupted during transmission.

247 2.3.2. Screening Stage 2: Geophysical conditions

248 a) Solar zenith angle

249 Generally speaking, solar RT becomes increasingly complicated as solar zenith angle θ_0 increases.
250 This is because: i) radiances and fluxes for EarthCARE-sized domains will depend increasingly on

251 conditions outside D and D^+ ; and ii) Earth's sphericity becomes increasingly important; Earth-
 252 CARE's RT codes are plane-parallel models. Not only do large θ_0 impact the SCA directly, they
 253 stress retrieval algorithms that use MSI data. Hence, when the Sun is up, D or D^+ must have

$$254 \quad \max\{\theta_0(i,j)\} < \theta_0^* \quad \forall (i,j) \in D \text{ or } D^+, \quad (1)$$

255 where θ_0^* is the maximum allowed value of θ_0 , in order for solar radiances to be considered by the
 256 SCA. Initially, $\theta_0^* = 75^\circ$. When the Sun is down, however, data from solar channels are simply not
 257 used; as shown by Barker et al. (2011), this diminishes the SCA's performance.

258 *b) Single surface type*

259 To focus closure assessments on retrieved cloud and aerosol properties, and reduce potential com-
 260 plications due to boundary conditions that are outside the purview of EarthCARE's retrievals, D
 261 and D^+ must have at least 90% of its area occupied by a single broad class of surface type. These
 262 types are: water (oceans and lakes), land, and ice.

263 *c) Homogeneous land surfaces*

264 Each JSG pixel has a land-type designation obtained from the International Geosphere–Biosphere
 265 Programme (USGS 2018). Let f_ℓ be the fraction of JSG pixels in either D or D^+ that corresponds
 266 to the ℓ^{th} surface-type. For reasons listed above, if D and D^+ is a “land” domain, then for them to
 267 be included in \mathbf{D}_{1D} and \mathbf{D}_{3D} , they must have

$$268 \quad \max\{f_\ell\} > f^*, \quad (2)$$

269 where f^* is set initially to 0.9.

270 *d) Surface elevation*

271 Uncertainties in spectral bidirectional reflectance and emittance functions as well as albedos and
 272 emissivities are complicated by variations in surface elevation. In an attempt to limit uncertainties
 273 associated with the setting of these lower boundary conditions in the RT models, only very flat
 274 assessment domains are allowed. Hence, if σ_{srf} is standard deviation of surface elevation for D or
 275 D^+ , then for them to be included in D_{1D} and D_{3D} , they must have

$$276 \quad \sigma_{srf} < \sigma_{sfc}^*, \quad (3)$$

277 where σ_{sfc}^* is set initially to 0.1 km.

278 *2.3.3. Screening Stage 3: Quality of radiance matching*

279 Where SCA reconstructed MSI radiances are poor, it is reasonable to assume that corresponding
 280 constructed 3D domains are, too. Thus, the final screening stage addresses the quality of recon-
 281 structed MSI imagery, but it also provides bias-correction estimates for modelled TOA quantities.

282 For an assessment domain D of n_{assess} JSG pixels along-track and $j \in [-m_{assess}, m_{assess}]$ across-
 283 track, the n^{th} moment of r_k over D , excluding the L2-line along $j = 0$, is

$$284 \quad \langle r_k^n \rangle = \frac{1}{2m_{assess}n_{assess}} \sum_{i=i_1}^{i_1+n_{assess}-1} \sum_{j \in [-m_{assess}, -1] \cup [1, m_{assess}]} r_k^n(i, j). \quad (4)$$

285 where i_1 is along-track JSG index at the edge of D . Corresponding reconstructed values are

$$286 \quad \langle \hat{r}_k^n \rangle = \frac{1}{2m_{assess}n_{assess}} \sum_{i=i_1}^{i_1+n_{assess}-1} \sum_{j \in [-m_{assess}, -1] \cup [1, m_{assess}]} r_k^n(m^*(i, j), 0). \quad (5)$$

287 Therefore, errors stemming from the radiance-matching algorithm, for the k^{th} MSI channel, are

$$288 \quad \Delta \langle \hat{r}_k^n \rangle = \langle \hat{r}_k^n \rangle - \langle r_k^n \rangle. \quad (6)$$

289 Let $\langle F_{\text{SW}} \rangle$ and $\langle F_{\text{LW}} \rangle$ be TOA shortwave (SW) and longwave (LW) fluxes, averaged over D ,
 290 as estimated by angular direction models in the BMA-FLX processor (Velázquez-Blázquez et al.
 291 2023). Since MSI radiances r_1 ($0.67 \mu\text{m}$) and r_6 ($10.80 \mu\text{m}$) often correlate well with $\langle F_{\text{SW}} \rangle$
 292 and $\langle F_{\text{LW}} \rangle$ (Barker et al. 2014), TOA flux bias errors due to the radiance-matching algorithm can
 293 be approximated as

$$294 \quad \Delta \langle \hat{F}_{\text{SW}} \rangle \approx \langle F_{\text{SW}} \rangle \frac{\langle r_1 \rangle - \langle \hat{r}_1 \rangle}{\langle \hat{r}_1 \rangle} \quad \text{and} \quad \Delta \langle \hat{F}_{\text{LW}} \rangle \approx \langle F_{\text{LW}} \rangle \frac{\langle r_6 \rangle - \langle \hat{r}_6 \rangle}{\langle \hat{r}_6 \rangle}. \quad (7)$$

295 If these values satisfy

$$296 \quad \left| \Delta \langle \hat{F}_{\text{SW}} \rangle \right| > \Delta F_{\text{SW}}^* \mu_0 \quad \text{and} \quad \left| \Delta \langle \hat{F}_{\text{LW}} \rangle \right| > \Delta F_{\text{LW}}^*, \quad (8)$$

297 where ΔF_{SW}^* and ΔF_{LW}^* are tolerable broadband TOA flux errors arising from the radiance-match-
 298 ing algorithm, D is *not* included in neither $\mathbf{D}_{1\text{D}}$ nor $\mathbf{D}_{3\text{D}}$. Both $\Delta \langle \hat{F}_{\text{SW}} \rangle$ and $\Delta \langle \hat{F}_{\text{LW}} \rangle$ get passed to
 299 ACMB-DF and used to bias-correct estimated TOA fluxes made by both 1D and 3D RT models.
 300 This completes the screening processes leaving $\mathbf{D}_{1\text{D}}$ and $\mathbf{D}_{3\text{D}}$ with $m_{1\text{D}}$ and $m_{3\text{D}}$ assessment do-
 301 mains, respectively.

302 *Table 1* provides a glimpse into success rates of D and D^+ , in all three frames, for the screenings
 303 just described using conditions as summarized in the table. Of course, overall success rate for
 304 $\theta_0 < 75^\circ$ will be much smaller than most reported here owing to these being “descending” frames.

305 Note also the tendency for success rates for D^+ to be less than those for D . This is because the areal
 306 extents of D^+ are always larger than that for D .

307 **Table 1.** Success rates of D and D^+ for the three frames that meet the conditions as listed.

screening variable	condition	Halifax		Baja		Hawaii	
		D	D^+	D	D^+	D	D^+
cloud retrieval quality	more than 10% of columns have valid retrievals	97	98	96	97	97	99
flux reconstruction	both $\Delta F_{\text{SW}}^* \mu_0$ and $\Delta F_{\text{LW}}^* = 5 \text{ W m}^{-2}$ (see (8))	100	94	100	93	100	82

308

309 2.4. Ranking radiative assessment domains

310 As noted above, the EarthCARE mission will provide near-real time products with limited compu-
 311 tational resources. The portion of the processing chain constrained most by this involves 3D SW
 312 RT models. For them to achieve adequate signal-to-noise ratios, just a small fraction of the thou-
 313 sands of potential D^+ per frame can be assessed. Thus, to enhance efficacy of the radiative assess-
 314 ment process, an algorithm was developed that ranks D^+ in D_{3D} . At any time, ranking can be
 315 overruled manually, such as when testing during commissioning phase. The ranking algorithm that
 316 was decided upon samples cloud scenarios in proportion to relative frequencies of occurrence.

317 For the initial version of the algorithm, 1 km resolution MODIS-retrieved values (MYD06_L2)
 318 of cloud optical depth τ_{cld} and cloudtop pressure P_{cld} , inferred from measurements made during
 319 2020, were grouped into 5 x 21 km arrays, to match EarthCARE's planned 5 x 21 km domains D ,
 320 and for each array, mean values $\langle \tau_{cld} \rangle$ and $\langle P_{cld} \rangle$ were computed along with total cloud fraction
 321 A_c (Platnick et al. 2015). They were then assigned to bins defined by 10° ranges of latitude and
 322 longitude, and ranges for $\langle \tau_{cld} \rangle$, $\langle P_{cld} \rangle$, A_c , and time of observation of

$$\begin{aligned}
 \langle \tau_{cld} \rangle & : (0,4];(4,23];(23,150] \\
 \langle P_{cld} \rangle & : (0,440];(440,680];(680,\infty) \\
 A_c & : (0,0.25];(0.25,0.75];(0.75,0.99];(0.99,1] \\
 time & : DJF;MAM;JJA;SON
 \end{aligned} \tag{9}$$

324 Since only cloud-bearing domains need be ranked, the number of applicable bins is 23,328, of
 325 which the n^{th} has N_n domains. When $\theta_0 \geq 90^\circ$, $\langle \tau_{cld} \rangle$ is not retrieved, so the same ranking proce-
 326 dure uses the remaining three variables only. Radiative closure assessments for SW fluxes are not
 327 done when $75^\circ < \theta_0 < 90^\circ$ on account of too many overwhelming uncertainties with retrievals and
 328 plane-parallel RT modelling. Thus, domains in this range are not ranked.

329 For EarthCARE frames with 6,400 1-km L2 columns in the L2-plane there is the potential for
 330 $6,400 - 21 + 1 = 6,380$ (over-sampled) assessment domains, each of which falls into one of the
 331 MODIS bins. Now, using only domains with $A_c > 0.01$, form the frame-specific cumulative fre-
 332 quency such that the i^{th} domain has a value

$$N(i) = \frac{1}{N(6,380)} \sum_{j=1}^i N_n(j) \quad ; \quad i = 1, \dots, N_{cld} \leq 6,380. \tag{10}$$

334 Then, generate a uniform pseudo-random number $R \in (0,1]$ and find the closest $N(i)$; this iden-
335 tifies the top-ranked D^+ . This is repeated, without replacement, until (possibly all) the domains are
336 ranked. The resulting lists are passed on to ACM-RT.

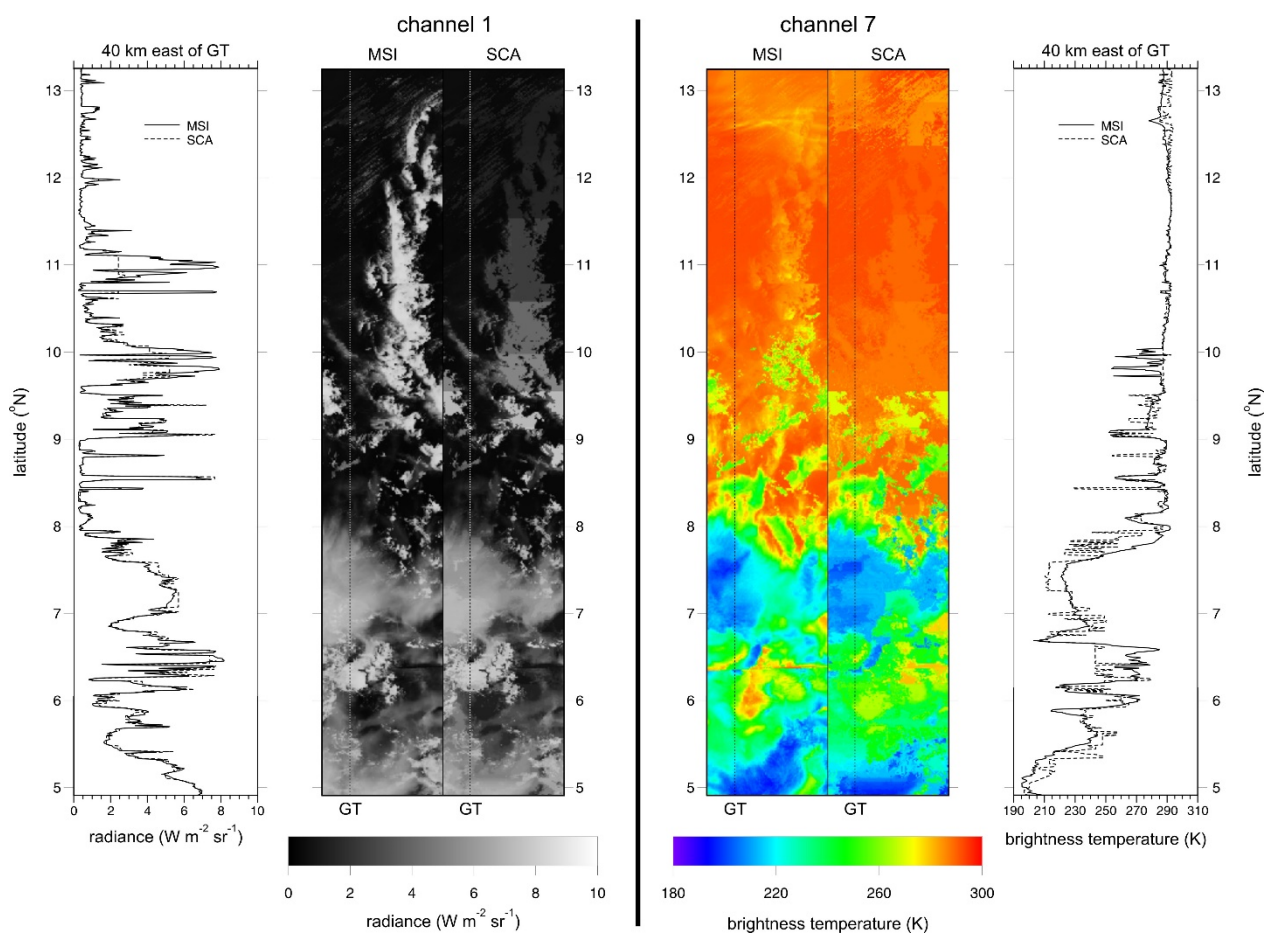

337 **3. Results**

338 The SCA's sub-algorithms are discussed in series in this section. The only part not evaluated here
339 is the ranking algorithm (see section 2.4). Its performance is demonstrated in Cole et al. (2023; in
340 this issue) where radiative transfer models act on the highest ranked assessment domains.

341 **3.1. Reconstruction of passive radiances**

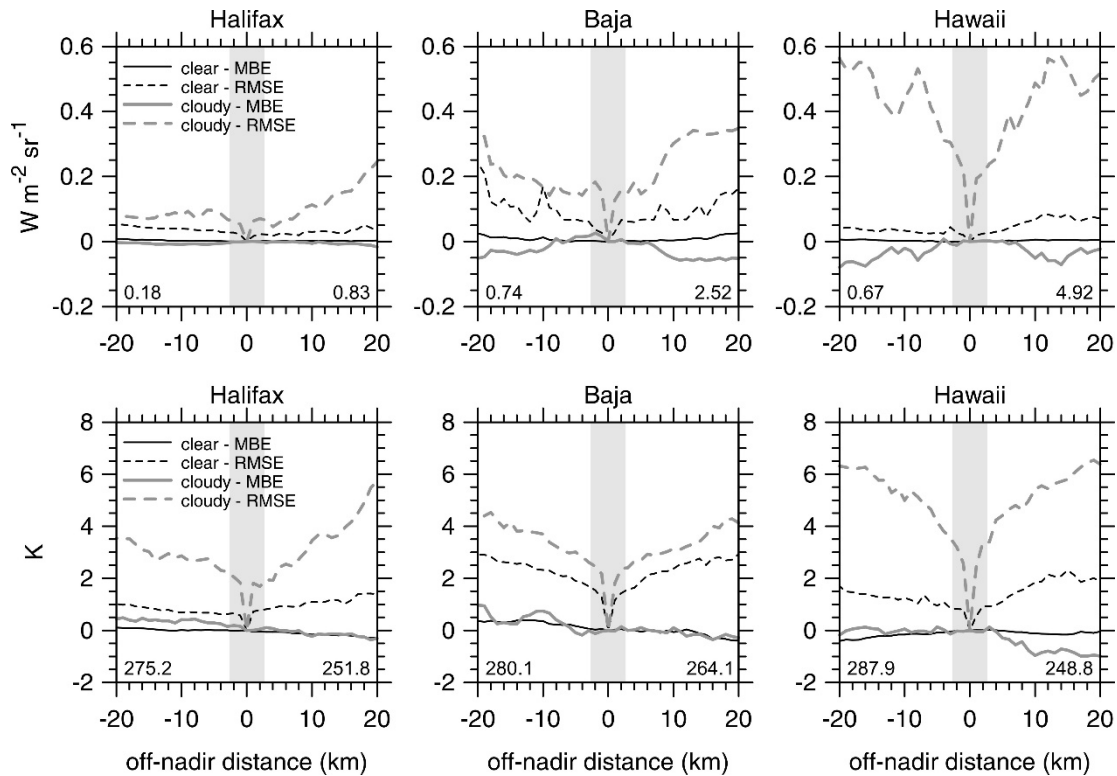

342 Radiance matching is the essence of the SCA, and a sampling of results is provided here. More
343 details are in Barker et al. (2011; 2012; 2014) and Sun et al. (2016). All results presented here, and
344 when $\theta_0 < 90^\circ$, come from using MSI channels: 1 ($0.67 \mu\text{m}$), 4 ($2.21 \mu\text{m}$), 5 ($8.80 \mu\text{m}$), and 7
345 ($12.00 \mu\text{m}$); i.e., $K_s = 4$ in (11). Obviously, when $\theta_0 \geq 75^\circ$ the SW channels are not used. The
346 largest impediment facing this algorithm is when conditions off the ground-track (GT) differ much
347 from the relatively few samples along the GT (Barker et al. 2011). Figure 6 shows a full-width
348 segment of the *Hawaii* frame that contains both catastrophic failure due to inadequate conditions
349 along the GT and excellent performance for the opposite reason. Approximately 50 - 100 km east
350 of the GT, between 9.5°N and 13°N , radiances, especially channel 1's, that are associated with
351 much cloud are severely short-changed on account of a long stretch of near-cloudless conditions at
352 nadir. To partially remedy this, the algorithm would have to be permitted to search the GT much
353 further than 200 km, as in this example, but in so doing it would run the risk of identifying donor

354 columns associated with increasingly different meteorological conditions. On the other hand, be-
 355 tween 5°N and 8°N performance is extremely good across the entire 150 km wide frame.

356
 357 **Figure 6:** Left panel shows MSI and corresponding SCA channel 1 radiances for a segment of
 358 the *Hawaii* frame measuring 150 km wide and 900 km long. Right panel is corresponding bright-
 359 ness temperatures from channel 7 radiances. Dashed lines marked GT indicate the ground-track
 360 at nadir, which coincides with the L2-plane. Line graphs show MSI and SCA values along the
 361 centres of the domains, which are 40 km east of GT.

362

363

364 **Figure 7:** Full-frame mean bias errors (MBE) and root mean square errors (RMSE) for SCA re-
 365 constructed radiances as functions of distance (-ve values are W) from the ground-track (GT in
 366 Figure 6). Upper and lower rows are for MSI channel 1 radiances and 7 brightness temperatures.
 367 Full-frame mean values are listed on the base of each plot: clear-sky on the left, cloudy-sky on
 368 the right. Grey bands indicate EarthCARE's default assessment domains.

369

370 Figure 7 shows mean bias errors (MBE) and root mean square errors (RMSE) for reconstructed
 371 MSI channels 1 and 7 as functions of distance, east and west, of GT for the full lengths of the three
 372 test frames (see Qu et al. 2023). By definition, MBE and RMSE along GT are zero. For channel
 373 1's reconstructions, MBEs out to ± 20 km are generally smaller than $0.05 \text{ W m}^{-2} \text{ sr}^{-1}$, with smaller
 374 errors for cloudless pixels. The negative biases for *Baja* and *Hawaii* frames out past ~ 5 km from
 375 GT stem from clouds along the GT being slightly darker than those elsewhere over the frames (see
 376 Figure 6). Likewise, MBEs for channel 7 are generally smaller than 0.5 K. Over the 5 km wide
 377 assessment domains centred on GT, MBEs for both channels are almost negligible relative to the
 378 frame-wide average values that are listed along the base of each plot.

379

380 **Figure 8:** Along-track and across-track length of assessment domain plus buffer-zones as func-
 381 tions of latitude for the *Hawaii* frame. All assessment domains are 5 km across-track by 21 km
 382 along-track. Minimum size for all buffer-zones is 5 km. Also shown are corresponding values of
 383 mean cloudtop altitude and cloud fraction for 5 x 21 km assessment domains.

384

385 Unlike MBEs, however, RMSE values jump immediately off the GT. In general, they continue
 386 to increase with distance from GT, but it is difficult to say at what distance they become unusable.
 387 It is important to note that RMSE values plotted here get reduced by at least a factor of 10 for
 388 averages over assessment domains.

389 3.2. Definition of assessment domain buffer-zones

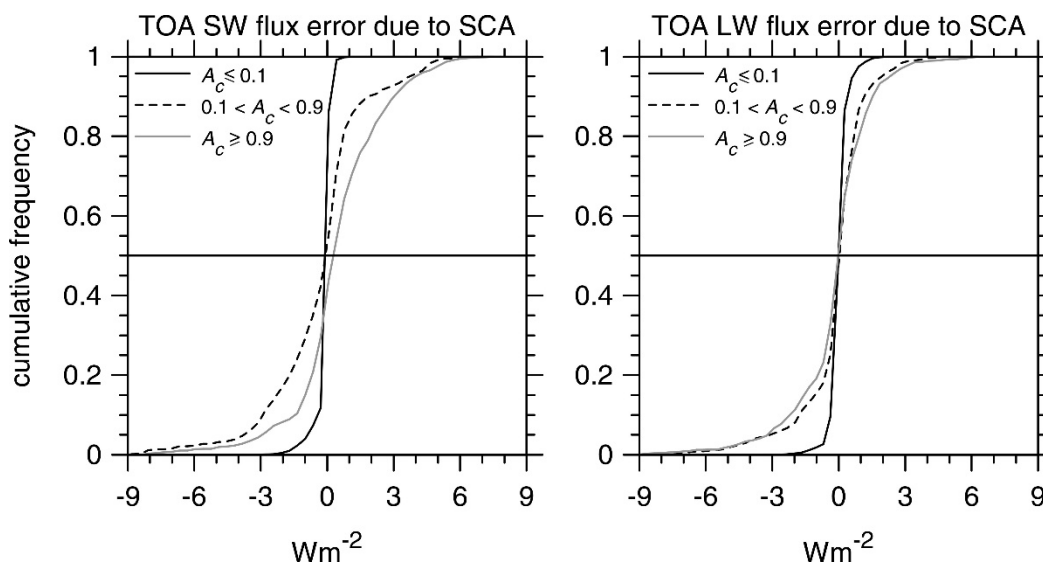

390 The planned initial default values for both d_{\parallel}^{\min} and d_{\perp}^{\min} is 5 km. Thus, for D measuring 5 x 21
 391 km, 3D RT will be applied to D^+ that measure at least ~ 15 km across-track by ~ 31 km along-track.
 392 Figure 8 shows sizes of D^+ along the *Hawaii* frame. The most notable feature is that along-track
 393 lengths vary much more than across-track lengths. This is driven by the fixed along-track off-nadir
 394 views of the BBR; whenever cloud occurs, especially high cloud, values of n_{buffer}^{\searrow} and n_{buffer}^{\swarrow} exceed

395 0. Lengths of D^+ maximize between about 3°N and 6°N where mean cloudtop altitudes h reach
 396 ~ 17 km; this despite cloud fractions for D^+ being substantially less than 1.

397 While across-track buffer sizes m_{buffer} depend on h , too, they also depend on φ_r and θ_0 . Near
 398 latitude 10°N , while $\varphi_r \approx 107^\circ$ (Sun is shining in almost perpendicular to GT), $\theta_0 \approx 30^\circ$ and so
 399 lengths of cloud shadows cast perpendicular to GT are small. As such, there is little need to expand
 400 the domain across-track, and so $m_{buffer} = 0$ and cross-track size of D^+ equal the default 15 km.
 401 Near latitude 21°S , however, where mean h are the same as near 10°N , clouds are more overcast,
 402 but equally important, $\varphi_r \approx 130^\circ$, which is still not far off shining in perpendicular to GT, and
 403 $\theta_0 \approx 50^\circ$. Together these conspire to cast cloud shadows well beyond D resulting in D^+ that are
 404 slightly larger than the default.

405 3.3. Estimation of SCA-related bias errors for TOA broadband fluxes

406 In a manner similar to cloud radiative effects, estimation of errors for TOA broadband radiative
 407 fluxes that arise from the SCA process provide a simple, integrated indication of SCA performance.
 408 Figure 9 shows cumulative frequency distributions of $\Delta\langle\hat{F}_{\text{SW}}\rangle$ and $\Delta\langle\hat{F}_{\text{LW}}\rangle$ (see (7)), for the *Ha-*
 409 *waii* frame. Errors for this frame are the largest of the three. As is often the case, errors tend to be
 410 largest for SW fluxes, and increase slightly as assessment domain A_c increases. The latter point
 411 basically indicates that the SCA does extremely well in clear-sky conditions; even for the *Baja*
 412 frame that was mostly over variable land.

413
 414 **Figure 9:** Cumulative frequency distributions of estimated errors in broadband TOA upwelling
 415 SW and LW fluxes stemming from the SCA for all 5 x 21 km assessment domains in the *Hawaii*
 416 frame. Distributions are partitioned for three ranges of assessment domain total cloud fraction A_c .
 417

418 It is encouraging to see that median errors for both bands are negligible for all conditions. More-
 419 over, as Figure 9 shows, with $\sim 90\%$ of errors being within $\pm 3 \text{ W m}^{-2}$, and slightly better for the
 420 other frames, errors imparted on TOA flux estimates by the SCA will not hinder assessment of
 421 EarthCARE's objective of retrieving cloud-aerosol properties well enough as to be able to model,
 422 on average, TOA fluxes to within $\pm 10 \text{ W m}^{-2}$.

423 4. Summary and discussion

424 The EarthCARE satellite mission has set itself a very high bar with its plan to infer cloud and
 425 aerosol properties, from its observations, well enough that when used to initialize radiative transfer
 426 (RT) models, their estimates of TOA fluxes will differ from observed values by, typically, less than
 427 $\pm 10 \text{ W m}^{-2}$. To realize, and gauge the success of, this *radiative closure assessment* it will be nec-
 428 essary to employ, operationally, 3D atmospheric RT models. This by itself will set EarthCARE

429 apart from its predecessors, which have relied entirely on 1D RT models. The immediate issue
430 facing this plan is that L2-retrievals at nadir are just ~ 1 km wide, and at this scale net fluxes of
431 lateral flowing radiation, not accounted for by 1D RT models, can be substantial (e.g., Marshak et
432 al. 1998). To justifiably use 3D RT models, however, the atmosphere-surface system has to be
433 defined on both sides of the narrow L2-plane. The point of this paper was to demonstrate Earth-
434 CARE's method of expanding its L2-retrievals perpendicular to the L2-plane. At the core of this
435 *3D scene construction algorithm* (SCA) is a radiance-matching (RM) scheme that uses Earth-
436 CARE's MSI passive imagery (cf. Barker et al. 2011; 2012; 2014). There are, however, other as-
437 pects of this process that have been documented here for the first time.

438 Synthetic radiances measured virtually by EarthCARE's MSI for three test frames, which were
439 produced for *end-to-end simulation* of EarthCARE's measurement-processing chain (see Qu et al.
440 2023), were used here to demonstrate the performance of the SCA. "Reconstruction" of measured
441 MSI radiances forms the foundation of the SCA. Basically, off-nadir pixels are paired with a nadir
442 pixel whose spectral radiances best match theirs. The 3D domains to be used by the 3D RT models
443 are "constructed" by taking columns of geophysical information associated with matching nadir
444 pixels and inserting them at the off-nadir pixels.

445 Comparing reconstructed radiances to their observed counterparts provides a straightforward
446 indication of the success of the SCA. If observed radiances are reconstructed poorly, one has to
447 also assume that correspondingly constructed 3D surface-atmosphere domains are unfit for both
448 3D RT models and radiative closure assessment. SCA errors flare-up when conditions needed at
449 off-nadir locations are lacking from the nearby the L2-plane. Typical performances of the SCA
450 were shown in Section 3.1, and as expected, generally erode the further recipient pixels are from
451 their donors. This is not much of an issue for radiative assessment domains themselves, for they

452 extend just 2 km from the L2-plane. Their buffer-zones, however, which were described in section
453 2.2, can be as much as 10 km from the L2-plane (see Figure 3). The reason why assessment do-
454 mains are so small is because EarthCARE's radiative closure assessment seeks to verify the narrow
455 L2 retrievals, not the SCA; the SCA should help achieve this as invisibly as possible.

456 Once defined, assessment domains and their buffer-zones get screened (see section 2.3) in an
457 attempt to identify those most likely to realize useful closure assessments. Furthermore, the inter-
458 section of EarthCARE's data processing limitations with the computational demand of the 3D solar
459 RT model (Cole et al. 2023) forces the need to rank assessment domains to ensure that the few that
460 get assessed per frame lead to good samplings, over the mission's life, of conditions that occur over
461 the globe and the year. This process was described in section 2.4.

462 The simple method of estimating TOA flux bias errors that are likely to arise from the SCA
463 (Barker et al. 2014) was assessed using test frame synthetic observations. Reassuringly, it was
464 shown in Section 3.3 that most TOA flux errors due to the SCA's imperfect atmospheres, for as-
465 sessment domains measuring 5 x 21 km, can be expected to be much smaller, and rarely larger,
466 than EarthCARE's stated goal of $\pm 10 \text{ W m}^{-2}$.

467 To conclude, it is tempting to view the SCA as a very cost-effective (i.e., almost free) *scanning*
468 *active sensor system* (cf. Illingworth et al. 2018). But one almost always gets what one pays for,
469 and the SCA is, when pushed, no exception. Its performance, especially well-removed from the
470 L2-plane, cannot be expected to rival that of an authentic scanning active sensor system (Barker et
471 al. 2021); to use it as a full-up replacement would be cavalier. In its current role, however, as
472 purveyor of approximate, ancillary information that both facilitates use of 3D RT models and
473 strengthens verification of L2 retrievals, it appears as though its shortcomings will be tolerable and
474 outweighed by its benefits.

475 **Acknowledgements**

476 Work reported on in this paper was funded by the European Space Agency and in-kind support
477 from ECCO. This paper, and studies leading to it, benefited much from numerous discussions with
478 Dr. Tobias Wehr who passed away on 1-Feb-2023.

479

480 **Data availability**

481 Data used in this report, and in other EarthCARE reports in this issue, can be obtained at van Za-
482 delhoff et al. (2022).

483

484

APPENDIX A

485

Radiance-matching algorithm

486 Let $r_k(i, j)$ be MSI radiance, for the k^{th} MSI channel, at (i, j) on the joint standard grid (JSG) in which
 487 $j = 0$ is along the L2-plane. Following Barker et al. (2011), when seeking to populate a column at
 488 $(i, j \neq 0)$ with a suitable proxy from $(i, j = 0)$, begin by computing, for K_s channels,

$$489 \quad F(i, j; m) = \Lambda(i, j; m) \sum_{k=1}^{K_s} a_k \left[\frac{r_k(i, j) - r_k(m, 0)}{\max[r_k(i, j), r_k(m, 0)]} \right]^2 ; \quad m \in [i - M, i + M]; j \neq 0, \quad (11)$$

490 where $(m, 0)$ holds potential *donor* profiles for the *recipient* at $(i, j \neq 0)$, a_k are weights that could
 491 depend on channel but were assumed to equal 1, and M is number of pixels, forward and backward,
 492 along the L2-plane to be searched for a donor. The function $\Lambda(i, j; m)$ is defined as

$$493 \quad \Lambda(i, j; m) = \begin{cases} -1 & ; \quad \chi = .false. \\ 1 & ; \quad \chi = .true. \end{cases} \quad (12)$$

494 By requiring

$$495 \quad \chi = \left\{ \begin{array}{l} \text{surface at } (i, j) = \text{surface at } (m, 0) \\ \quad .\text{and.} \\ |\mu_0(i, j) - \mu_0(m, 0)| < \Delta\mu_0 \\ \quad .\text{and.} \\ \mu_0(i, j) \cdot \mu_0(m, 0) > 0 \\ \quad .\text{and.} \\ |\varphi_r(i, j) - \varphi_r(m, 0)| < \Delta\varphi_r \\ \quad .\text{and.} \\ m \in [1, N_{JSG}], \end{array} \right. \quad (13)$$

496 it controls whether or not a pixel at $(m,0)$ is to be considered as a potential donor (see section 2.3).
 497 The upper condition means that surface types (land, sea, and snow/ice) must be the same at (i,j)
 498 and $(m,0)$. The next two conditions mean that at (i,j) and $(m,0)$ cosine of solar zenith angles μ_0
 499 must differ by less than $\Delta\mu_0 = 0.005$, and the Sun must be up or down at both locations. Next, the
 500 difference between solar azimuth angles relative to the satellite's tracking direction φ_r must be less
 501 than $\Delta\varphi_r = 5^\circ$. The final condition simply means that the search cannot go past the ends of a frame.
 502 It almost goes without saying, but when the Sun is down at $(m,0)$, SW radiances are simply not
 503 used in (11).

504 For the $1 \leq M' \leq 2M + 1$ values of $F(i,j;m) \geq 0$ that get computed, define Euclidean distances
 505 between the centres of (i,j) and $(m,0)$ as

$$506 \quad L(i,j;m) = \Delta L \left[(i-m)^2 + j^2 \right]^{1/2}, \quad (14)$$

507 where ΔL is horizontal resolution, which for EarthCARE is ~ 1 km, and sort $F(i,j;m)$ from small-
 508 est to largest (i.e., best to worst radiance match), with $L(i,j;m)$ going along passively. Denote the
 509 reordered sequences as $\{\hat{F}(i,j;m)\}_{m=1}^{M'}$ and $\{\hat{L}(i,j;m)\}_{m=1}^{M'}$. Finally, the donor for location $(i,j \neq 0)$
 510 is deemed to reside at

$$511 \quad m^*(i,j) = \arg \min_{m \in [1, M'.f]} \{\hat{L}(i,j;m)\} \quad (15)$$

512 which reads: find m that corresponds to the smallest distance between the recipient at (i, j) and those
 513 pixels that constitute the smallest $100f\%$ of $\hat{F}(i, j; m)$. The tuneable parameter f will be set initially to
 514 0.05, but this could change (see Barker et al 2011). The procedure outlined here is performed for all
 515 $(i, j \neq 0)$ across the MSI's swath, with pixels at $(i, 0)$ donating to themselves.

516

APPENDIX B

517

518

Calculation of buffer-zone sizes519 *a. Along-track length*520 Let $h(i^*(i, j), 0)$ be cloudtop altitude at JSG cell (i, j) using the SCA's field. Using these values,521 define for each i in a frame the highest cloudtop in across-track swaths of JSG pixels spanning the

522 assessment domains as

523
$$h_{\perp}^{\max}(i) = \max\{h(i^*(i, j), 0)\} : j \in [-m_{\text{assess}}, m_{\text{assess}}]. \quad (16)$$

524 The symbols \perp and \parallel indicate across- and along-tracks, respectively. Thus, maximum cloudtop525 altitude in an assessment domain $D(n)$ is

526
$$h_D^{\max}(n) = \max\{h_{\perp}^{\max}(i)\} : i \in [n, n + n_{\text{assess}} - 1]. \quad (17)$$

527 Consider first the buffer-zone out in front of $D(n)$; applicable most to the BBR's backward

528 view. The minimum number of JSG pixels that one need be concerned about searching to see if

529 clouds outside of $D(n)$ obscure part of $D(n)$ is

530
$$n_{\text{buffer}} = \text{rint} \left(\frac{\max\{d_{\parallel}^{\min}, h_D^{\max}(n) \tan \theta_v\}}{\langle \Delta x \rangle} \right), \quad (18)$$

531 where d_{\parallel}^{\min} is the absolute minimum along-track buffer length, assumed for EarthCARE to be ~ 5 532 km, θ_v is BBR viewing zenith angle, and $\langle \Delta x \rangle$ is mean length of JSG pixels in the along-track

533 direction. For EarthCARE, $\langle \Delta x \rangle \approx 1$ km. If maximum cloudtop altitude across the entire useable
 534 part of the 6,000 km frame is

$$535 \quad h_F^{\max} = \max \{h(i, j)\} : i \in [m_1 + 1, N_{JSG} - m_2 + 1], j \in [-m_{\text{assess}}, m_{\text{assess}}], \quad (19)$$

536 then the absolute maximum number of JSG pixels one need search for outside of $D(n)$ that might
 537 obscure part of $D(n)$ is

$$538 \quad n_{\text{buffer}}^{\max} \approx \text{nint} \left(\frac{h_F^{\max} \tan \theta_v}{\langle \Delta x \rangle} \right). \quad (20)$$

539 This can be reduced by knowing the location of the along-track JSG pixel that houses the highest
 540 cloud between the last pixel of $D(n)$ and n_{buffer}^{\max} pixels out in front of it. This is expressed as

$$541 \quad n_{\text{buffer}}^{\max}(n) = \arg \max_{i \in [n + n_{\text{assess}} + n_{\text{buffer}}(n), n + n_{\text{assess}} + n_{\text{buffer}}(n) + n_{\text{buffer}}^{\max}]} h_{\perp}^{\max}(i). \quad (21)$$

542 Proceed then to search

$$543 \quad h_{\perp}^{\max}(i) \geq \frac{[i - (n + n_{\text{assess}})] \langle \Delta x \rangle}{\tan \theta_v} : i = n + n_{\text{assess}} + n_{\text{buffer}}, \dots, n + n_{\text{assess}} + n_{\text{buffer}}^{\max}(n), \quad (22)$$

544 where n_{buffer} comes from (18). Let values of i for which the condition in (22) is met form the set
 545 $\{i'\}$. Therefore, the size of the buffer-zone for the back-looking view associated with $D(n)$ is

$$546 \quad n_{\text{buffer}}^{\leftarrow}(n) = \begin{cases} n_{\text{buffer}} & ; \text{ if (22) is never met} \\ \max \{i'\} & ; \text{ if (22) is met.} \end{cases} \quad (23)$$

547 To set the size of the buffer-zone for the fore-looking view $n_{buffer}^{\searrow}(n)$, (21) through (23) are reap-
 548 plied reversing indices. Figure 4 is a schematic of this process.

549 Note that determination of $n_{buffer}^{\swarrow}(n)$ and $n_{buffer}^{\searrow}(n)$ are independent of θ_0 . This is because for
 550 EarthCARE's orbit over 80% of observations with $\theta_0 < 90^\circ$ have $30^\circ < \varphi_r < 150^\circ$ implying that,
 551 for most cases, projection of direct-beam (and hence cloud shadows) into the along-track ends of
 552 $D(n)$ will be small. The exceptions are for very large θ_0 with $150^\circ < \varphi_r < 30^\circ$; but most of these
 553 cases will be avoided via the screening process as discussed in section 2.3.2.

554 *b. Across-track length*

555 Next, determine the size of across-track buffer-zones m_{buffer} . They are set using cloud information
 556 on the sunlit side of $D(n)$. Here the idea is that if a cloud anywhere to the side of D casts a shadow
 557 that falls onto the region formed by D and its along-track buffer-zones, then the across-track buffer-
 558 zone extends to include the cloud doing the shadowing. Once m_{buffer} is established, it is applied to
 559 the opposing side of $D(n)$, too.

560 Begin by setting a minimum size for the buffer-zone of d_{\perp}^{\min} , so that searching starts at cross-
 561 track JSG pixel $\pm m_{assess} \pm m_{buffer}$, where $m_{buffer} = nint(d_{\perp}^{\min} / \langle \Delta y \rangle)$ is the minimum buffer size in
 562 JSG pixels; choice of using + or - depends on which side of D the Sun is on. For EarthCARE,
 563 $d_{\perp}^{\min} = 5$ km. One then determines the highest cloud in the row of JSG pixels at distance j pixels
 564 from L2-plane as

565
$$h_{\parallel}(n, j) = \max \{h(i, j)\} : i \in \left[n - n_{buffer}^{\leftarrow}(n), n + n_{assess} + n_{buffer}^{\rightarrow}(n) \right]. \quad (24)$$

566 If it happens that

567
$$h_{\parallel}(n, j) \geq \frac{abs(j - m_{assess}) \langle \Delta y \rangle}{\tan \theta_0 \sin \varphi_r}, \quad (25)$$

568 is satisfied at j , the across-track buffer gets reset to $m_{buffer} \leftarrow abs(j - m_{assess})$. This process is con-
 569 tinued out to the edge of the MSI's swath. *Figure 5* is a schematic of this procedure. The aggrega-
 570 tion of an assessment domain D and its buffer-zones is denoted as D^+ .
