Abstract. Instrumentation packages of eddy covariance (EC) have been developed for a small unmanned aerial vehicle (UAV) to measure the turbulent fluxes of latent heat (LE), sensible heat (H), and CO_2 (~~F_e~~)(F_c) in the atmospheric boundary layer. This study evaluates the measurement performance of this UAV-based EC system. First, the precision (1σ) of georeferenced wind measurement was estimated at 0.07 m s^{-1} . Then, the effect of calibration parameter and aerodynamic characteristics of the UAV on the quality of the measured wind was examined by conducting a set of calibration flights. The results shown that the calibration improved the quality of measured wind field, and the influence of upwash and leverage effect can be ignored in the wind measurement. Third, for the measurement of turbulent fluxes, the measurement error caused by instrumental noise was estimated at $0.03 \mu\text{mol m}^{-2} \text{ s}^{-1}$ for F_c , 0.02 W m^{-2} for H , and 0.08 W m^{-2} for LE. Fourth, the precision (1σ) of the measurements was estimated at 0.04 m s^{-1} for wind velocity, $0.08 \mu\text{mol m}^{-2} \text{ s}$ for F_e , 1.61 W m^{-2} for H , 0.15 W m^{-2} for LE, and 0.02 m s^{-1} for friction velocity (u^*). Second, the effect of calibration parameter and aerodynamic characteristics of the UAV on the quality of the measured wind was examined by conducting a set of calibration flights. The results shown that the calibration improved the quality of measured wind field, and the influence of upwash and leverage effect can be ignored in the wind measurement. Third, data from the standard operational flights are used to assess the influence of resonance on the measurements and to test the sensitivity of the measurement under the variation ($\pm 30\%$) of the calibration parameters around their optimum values. of the system by adding an error of $\pm 30\%$ to their calibrated value. Results shown that the effect of resonance mainly affect the measurement of CO_2 ($\sim 5\%$). The pitch offset angle (ε_θ) significantly affected the measurement of vertical wind ($\sim 30\%$) and turbulent fluxes ($\sim 1525\%$). The heading offset

35 angle (ε_ψ) ~~only-mainly~~ affected the measurement of horizontal wind ($\sim 15\%$), and other calibration parameters had no
36 significant effect on the measurements. The results lend confidence to use the UAV-based EC system, and suggest future
37 directions for optimization and development of the next generation system.

38 **1 Introduction**

39 In environmental, hydrological and climate change sciences, the measurement of surface fluxes at the regional scale (level of
40 several to tens of kilometerskilometers-level) has attracted great interest despite often being considered a gordian knot
41 (Mayer et al., 2022; Chandra et al., 2022). Process-based or remote sensing (RS)-based models are often used to estimate
42 land surface fluxes of matter and energy at continental to global scales with typical spatial resolution from 1-10 km (Hu and
43 Jia, 2015; Mohan et al., 2020; Liu et al., 1999). However, observational data, especially at similar scales to models'
44 estimates, are-is often lacking, which presents a significant challenge for the validation and evaluation of the surface flux
45 products from these models' estimates (Li et al., 2018; Li et al., 2017). On the ground, in the past decades, extensive ground-
46 eddy-covariance (EC) flux sites with their composed networks and optical-microwave scintillometer (OMS) sites have been
47 built to provide temporally continuous monitoring of surface fluxes at local (hundreds of meters around the measurement site
48 of ground EC) and path (a distance of a few hundred meters to near 10 kilometers between transmitter and receiver terminal
49 of OMS) scales (Yang et al., 2017; Liu et al., 2018; Zhang et al., 2021; Zheng et al., 2023). Generally speaking, F fluxes from
50 ground measurements need to be scaled up to kilometers-scale to provide comparable spatial surface "relative-truth" flux
51 data for the process- or RS-based models at larger spatial scales (Liu et al., 2016). However, the spatial density of these flux
52 measurements sites is still low compared to the complex-variabilityheterogeneity of surface fluxes, which means that major
53 scaling bias may exist in the upscaled flux data (Wang et al., 2016; Li et al., 2021). Therefore, regional-scaled flux
54 measurement techniques need to-are-needed-to be developed to complement the ground- and models-based approaches
55 (Vellinga et al., 2010).

56 The-a aircraft-based EC flux measurement method, which has been developed for turbulence measurements for more than
57 40 years (Lenschow et al., 1980; Desjardins et al., 1982), is considered as the optimum method to measure turbulent flux at
58 regional scale (several hundred square kilometers), thus bridging the scale gap between ground and model-derived methods
59 (Gioli et al., 2004; Garman et al., 2006). To date, several types of aircrafts, including manned or unmanned fixed-wing
60 aircrafts, delta-wing aircrafts, and helicopters, have been used for measurements of turbulent flux by equipping them with
61 the EC sensors to measure three-dimensional (3D) wind, air temperature, and gas concentrations at high-a frequency of 50
62 Hz (Gioli et al., 2006; Metzger et al., 2012; Thomas et al., 2012; Bange and Roth, 1999). Among them, fixed-wing aircrafts
63 and delta-wing aircrafts are better airborne platforms for EC measurements compared to helicopters due to their tightly
64 coupled structure with the wind sensor and because their flow distortion around the fuselage can be more easily avoided or
65 modeled (Prudden et al., 2018; Garman et al., 2008). A wide range of manned aircrafts has been developed to measure
66 turbulent flux, including single-engine light aircrafts (e.g., Sky Arrow 650, Long-EC, WSMA) (Gioli et al., 2006; Crawford

67 and Dobosy, 1992; Metzger et al., 2012), twin-engine aircrafts (e.g., Twin Otter, NASA CARAFE) (Desjardins et al., 2016;
68 Wolfe et al., 2018) and larger quad-engine utility aircrafts (e.g., NOAA WP-3D) (Khelif et al., 1999). These airborne flux
69 measurements, in combination with ground measurements, provide an excellent opportunity to produce regional-scaled,
70 spatio-temporal continuous surface flux datasets that can improve our understanding of the interactive processes between the
71 land surface and the atmosphere of land-atmosphere interactions in regional and global change (Chen et al., 1999; Liu et al.,
72 1999; Prueger et al., 2005). However, manned aircrafts are expensive to operate and maintain. Aviation safety and
73 operational regulations require that manned aircrafts must fly above a minimum altitude (400 m above the highest elevation
74 within 25 km on each side of the center line of the air route) and must avoid hazardous conditions such as icing or severe
75 turbulence (Elston et al., 2015). The flow distortion induced by the aircraft itself (from the wings, fuselage, and the
76 propellers) complicates the wind vector measurement from aircraft platform, which means that sophisticated correction
77 procedures should be applied to compensate for the flow distortion effects (Elston et al., 2015; Williams and Marcotte, 2000;
78 Drüe and Heinemann, 2013).

79 In recent years, interesting in unmanned aerial vehicle (UAV) fixed-wing platforms for atmospheric studies has have been
80 fast growing, especially because of their lower construction, operation, and maintenance costs compared with manned
81 platforms. High-performance fixed-wing UAVs offer a high payload capacity (5-10 kg) and similar endurance (2-3 h) and
82 operating altitude (up to 3500 m above the sea level) to manned aircrafts, but with much less turbulence disturbance due to
83 their small fuselage size (Reineman et al., 2013). More importantly, the advancements in small, fast, and powerful sensors
84 and microprocessors make it possible to use of UAVs for comprehensive atmospheric measurements (Sun et al., 2021a).
85 Several types of UAVs with different turbulence measurement objectives have been developed and deployed, ranging from
86 small payload capacity (e.g., 140 g SUMO) to medium (e.g., 1.5 kg M²AV, 1.0 kg MASC) and large (e.g., 6.8 kg Manta, 5.6
87 kg ScanEagle) (Reuder et al., 2016; Båserud et al., 2016; Van Den Kroonenberg et al., 2012; Reineman et al., 2013). A
88 comprehensive overview of the use of these UAVs for turbulence sampling can be found in Elston et al. (2015) and Sun et al.
89 (2021a). For turbulence measurements, the UAVs were equipped with a commercial or custom multi-hole (5- or 9-hole)
90 probe paired with an integrated navigation system (INS) to obtain the wind vector. Small and medium UAVs typically could
91 only measure fast 3D wind vector and air temperature fluctuations for measurements of momentum and sensible heat flux,
92 whereas, large UAVs were equipped with more types (e.g., radiation, imageoptics, or gas concentration) and more accurate
93 sensors for measurement of a larger range of meteorological properties including sensible and latent heat fluxes, CO₂ flux,
94 radiation fluxes as well as surface properties (Reineman et al., 2013; Sun et al., 2021a). UAVs equipped with scientific
95 instruments can be deployed in a variety of application environments and conditions. UAVs offer distinct advantages over
96 manned aircraft in their ability to safely perform measurements and greatly reduce operational costs especially in low-
97 altitude conditions (below 100 m above the ground level), which are optimal for measuring turbulent flux (Witte et al., 2017).
98 Anderson and Gaston (2013) predict that UAVs will revolutionize the spatial data collection in ecology and meteorology.

99 The-EC method is a well-developed technology for directly measuring vertical turbulent flux (flux of sensible heat, matter-
100 latent heat and momentumCO₂) within the atmospheric boundary layers (ABL) (Peltola et al., 2021). It requires accurate time

101 (for ground tower) or spatial (for mobile platform) series of both the transported scalar quantity and the transporting
102 turbulent wind. Each should be measured at sufficient frequency to resolve the flux contribution from small eddies (Vellinga
103 et al., 2013). The measurement of the geo-referenced 3D wind vector, which is the prerequisite for EC measurements, is
104 challenging [for airborne platform](#). Airborne measurement of geo-referenced 3D wind is the vector sum between the aircraft
105 velocity relative to the earth (inertial velocity) and the velocity relative to the air (relative wind vector, or true airspeed).
106 Therefore, accurate measurements of the relative wind as well as the motion and attitude of the platform are essential to
107 accurately measure the geo-referenced wind vector and turbulent flux (Metzger et al., 2011). Garman et al. (2006) estimated
108 the [measurement \$1\sigma\$ -precision \(\$1\sigma\$ \)](#) of the vertical wind measurements of a commercial 9-hole turbulence probe (known as
109 “Best Air Turbulence Probe”, often abbreviated as the “BAT Probe”) to be 0.03 m s^{-1} by combining the precision of the BAT
110 Probe and the integrated navigation device. The BAT Probe is widely used on manned fixed-wing aircrafts, such as Sky
111 Arrow 650 ERA (Environmental research aircraft), Beechcraft Duchess, and Diamond DA42, for turbulent flux
112 measurement (Gioli et al., 2006; Garman et al., 2008; Sayres et al., 2017). A light delta-wing EC flux measurement aircraft
113 developed by Metzger et al. (2011) reported a 1σ precision of wind [measurement](#) of 0.09 m s^{-1} for horizontal wind and 0.04
114 m s^{-1} for vertical wind [using a specially customized five-hole probe \(5HP\). On this basis, in combination with a commercial](#)
115 [infrared gas analyzer](#), ~~the~~ 1σ precision of flux measurement was 0.003 m s^{-1} for friction velocity, 0.9 W m^{-2} for sensible
116 heat flux, and 0.5 W m^{-2} for latent heat flux. ~~The smallest resolvable magnitudes for the wind velocity and turbulent flux~~
117 ~~were estimated from these values by assuming a signal-to-noise ratio of 5:1~~ (Metzger et al., 2012). The EC flux measurement
118 from a UAV platform can now be achieved with a similar reliability to a manned platform. The Manta and ScanEagle UAV-
119 based EC measurements developed by Reineman et al. (2013) achieved precise wind measurements (0.05 m s^{-1} for horizontal
120 and 0.02 m s^{-1} for vertical wind) using a custom nine-hole probe and a commercial high precision ~~integrated navigation~~
121 ~~system (INS) integrated navigation system (INS)~~, at a lower price and lighter weight than the commercial BAT probe.
122 However, the onboard instrument packages for Manta and ScanEagle UAV are independent of each other in their
123 measurements of turbulent and radiation flux, and the CO_2 flux measurement is lacking.

124 Inspired by these studies, Sun et al. (2021a) used a high-performance fuel-powered vertical take-off and landing (VTOL),
125 fixed-wing platform to integrate the scientific payloads for EC and radiation measurements to obtain a comprehensive
126 measurement of turbulent and radiation flux using an UAV. This UAV-based EC system measured turbulent fluxes
127 ~~including of~~ sensible heat, latent heat, and CO_2 , as well as radiation including net radiation and upward- and downward-
128 looking photosynthetically active radiation (PAR). This system was successfully tested in the Inner Mongolia of China and
129 applied to measure the regional sensible and latent heat fluxes in the Yancheng coastal wetland in Jiangsu, China (Sun et al.,
130 2021a; 2021b). During these field studies, the UAV-based EC measurements achieved a near consistent observational result
131 compared with ground EC measurements (Sun et al., 2021b). However, some shortcomings in the developed UAV-based EC
132 system were also identified. In particular, the noise effects from the engine and propeller were not fully isolated, resulting in
133 high frequency noise in the measured scalars (air temperature, H_2O , and CO_2 concentration). This UAV-based EC system is
134 being continuously improved (in Section 2.1) based on ~~previous~~ field measurements. However, there is no quantitative

135 evaluation of the measurement ~~capability~~precision of the wind field and turbulent flux ~~or as well as~~ of the influence of the
136 resonance noise from the ~~UAV-based EC measurement system operation yet~~. Previous work using ground EC ~~measurements~~
137 as a benchmark to assess the measurement performance of the UAV-based EC system has been disputed, due to difference in
138 EC sensors, platforms, measurement height, and source areas (i.e., footprint), as well as the influence of surface
139 heterogeneity, flux divergence, inversion layer and the stochastic nature of turbulence (Sun et al., 2021b; Wolfe et al., 2018;
140 Hannun et al., 2020).

141 This study attempts to ~~quantitatively~~ evaluate the performance of ~~a the~~ UAV-based EC system developed by Sun et al.
142 (2021a) in the measurement of wind field and turbulent fluxes. For these purposes, data from two field measurement
143 campaigns, including a set of calibration flights and some standard operation flights, were used in this study. First, the
144 current study investigated s the quality of the measurement of geo-referenced wind vector including measurement error (1σ)
145 and the improvements for wind measurement after system calibration. Second, using the measured data from standard
146 operation flights, flux measurement error related to instrumental noise was estimated with a method proposed by Billesbach
147 (2011). Errors propagated through the correction terms [i.e., Webb-Pearman-Leuning (WPL) correction for latent heat and
148 CO₂ flux] were also included in our analysis (Webb et al., 1980; Kowalski et al., 2021). Then, the impacts of resonance noise
149 on the measured scalar variance and the flux covariance were also estimated by comparing the real (co)spectra curve with the
150 theoretical reference curve from Massman and Clement (2005). Lastly, the sensitivity of the measured geo-referenced wind
151 vector and turbulent flux to the errors in the calibration parameters (determined by the calibration flight) were assessed by
152 adding an error of $\pm 30\%$ to their optimum calibration value.

153 ~~the 1σ measurement error of the geo-referenced wind vector and turbulent flux by propagating the error of each EC sensor~~
154 ~~along the data process procedure. Then, a set of calibration flights were conducted to assess how the calibration parameters~~
155 ~~and aerodynamic characteristics of the UAV affect the quality of the wind measurement. The effects of resonance noise on~~
156 ~~the measured scalar variance and the fluxes were also estimated by comparing the real (co)spectra curve with the theoretical~~
157 ~~reference curve from Massman and Clement (2005). Lastly, the sensitivity of the measured geo-referenced wind vector and~~
158 ~~turbulent flux to the calibration parameters (determined by the calibration flight) were assessed by adding an error of $\pm 30\%$~~
159 ~~to their optimum calibration values.~~

160 **2 Materials and Methods**

161 **2.1 The UAV-based EC system**

162 The UAV platform used for EC measurement is a high-performance, fuel-powered VTOL, fixed-wing UAV, which has
163 minimal requirements for the takeoff location and offers a high payload capacity of up to 10 kg. The UAV has a wing-span
164 of 3.7 m, a fuselage length of 2.85 m, and a maximum take-off weight of 60 kg. The UAV engine is mounted in a pusher
165 configuration, allowing for the turbulence probe to be installed directly on the nose of the UAV, minimizing or eliminating

166 airflow contamination due to upwash and sidewash generated by the wings (Crawford et al., 1996). Control of the UAV is
 167 totally autonomous, and the pilots have the option to enable manual and semi-manual control in emergency conditions. The
 168 UAV has a cruise flight speed of 28 to 31 m s⁻¹ with an endurance of almost 3 h, and it has a flight ceiling of up to 3800 m
 169 above the sea level. Detailed information on this UAV could be found in Sun et al. (2021a).

170 The ~~fluxflux~~ payloads of the UAV-based EC system include a precision-engineered 5-hole pressure probe (5HP) for
 171 measurement of the true airspeed and the attack (α) and sideslip (β) angles of incoming flow relative to the UAV, a dual-
 172 antenna integrated navigation system (INS) for high accuracy measurement of UAV ground speed and attitude, an open path
 173 infrared gas analyzer (IRGA) for recording the atmospheric densities of CO₂ and water vapor, a fast temperature sensor for
 174 measurement of the fast temperature fluctuations, and a slow-response temperature probe for providing a mean air
 175 temperature reference. ~~The auxiliary payloads include a net radiometer and two photosynthetically active radiation (PAR)-~~
 176 ~~radiometers that look upward and downward.~~The sample rate ~~of the flux payloads~~ is 50 Hz except for the slow-response
 177 temperature probe (1 Hz), yielding a turbulence horizontal resolution of approximately 1.2 m at a cruising speed of 30 m s⁻¹.
 178 The system was improved according to deficiencies identified after several field measurements with the following
 179 adjustments: 1) a laser distance measurement unit was mounted for measuring the distance between the UAV and the ground
 180 level, 2) the platinum resistance thermometer was replaced by a thermocouple (Omega T-type COCO-003; \varnothing 0.075 mm) for
 181 improving the resistance of the high-frequency temperature measurements to vibration noise from the engine, 3) the
 182 vibration isolator structure of the IRGA was improved, and 4) the original datalogger (CR1000X, Campbell, USA) was
 183 replaced with a lighter one (CR6, Campbell, USA). All the digital and analog signals from the measurement sensors modules
 184 are stored and synchronized by the on-board datalogger, and the on-board scientific payloads are designed to be isolated
 185 from the electronic components of the UAV to ensure that any problems occurring would not jeopardize the safety of the
 186 UAV (Sun et al., 2021a).

187 In the present study, to estimate the measurement ~~1 σ~~ precision ~~for of the measured~~ geo-referenced wind and turbulent flux,
 188 the sensor modules and their 1 σ precision of the measurement ~~variables~~ related to EC measurement were used, as presented
 189 in Table 1. For the 5HP, the 1 σ measurement precision was acquired from the wind tunnel test after ~~the~~ wind tunnel
 190 calibration (Sun et al., 2021a).

191 **Table 1:** Summary of tThe sensor modules, measured variables, and their measurement p ~~1 σ~~ precision used to determine the
 192 geo-referenced wind velocity and turbulent flux.

Sensor (Module, <u>company, country</u>)	Variables	Precision (1σ)
GNSS/INS (Trimble BD992-INS, <u>Trimble, USA</u>)	Roll, Pitch, Heading	0.1°
	Horizontal velocity	0.007 m s ⁻¹
	Vertical velocity	0.02 m s ⁻¹
5HP (Simtec AG ADP-55, <u>Simtec AG, Switzerland</u>)	Attack angle	0.02° [#]
	Sideslip angle	0.04° [#]
	True airspeed	0.05 m s ⁻¹ [#]

IRGA	Static pressure	1.1 hPa
(Campbell -EC150, <u>Campbell, USA</u>)	Dynamic pressure	0.003 hPa
Thermistor	CO ₂ density	0.2 mg m ⁻³
(BetaTherm -100K6A11A, <u>Campbell, USA</u>)	H ₂ O density	0.004 g m ⁻³
Thermocouple	Temperature (slow)	0.2 °C
(Omega -T-type COCO-003, <u>Omega, USA</u>)	Temperature (fast)	0.5 °C

193 # Results from the wind tunnel test.

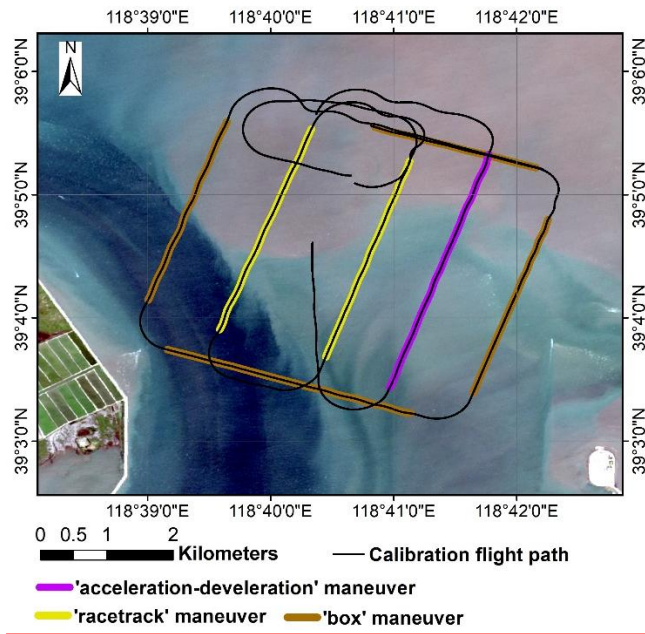

194 2.2 Field campaign

195 2.2.1 In-flight calibration campaign

196 In order to calibrate the wind measurement component of the UAV-based EC system, Aan in-flight calibration campaign
 197 was carried out on 4 September 2022 at the Caofeidian Shoal Harbor (39°2'55" N, 118°38'48" E) in the Bohai Sea of
 198 northern China. The average water depth of this area is approximately 0-5 m, with a maximum water depth of 22 m. At low
 199 tide, a large area of the tidal flat is exposed; while at high tide, only the barrier islands are visible (Xu et al., 2021). The
 200 assumptions for calibration flight include 1) low turbulent transport condition (i.e., no disturbance), 2) a constant mean
 201 horizontal wind, and 3) mean vertical wind near zero (Drüe and Heinemann, 2013; Vellinga et al., 2013; Van Den
 202 Kroonenberg et al., 2008). This allows identical wind components for several consecutive straights in opposite or vertical
 203 flight directions. These assumptions are usually well satisfied above the ABL or under stable atmospheric conditions (Drüe
 204 and Heinemann, 2013). Over the sea surface, due to its uniform and cool surface property, the turbulence fluctuations are
 205 weaker than that over the land surface (Mathez and Smerdon, 2018), making where a more ideal environment to conduct
 206 calibration flight.

207 ~~The optimum atmospheric conditions for the in-flight calibration include 1) no large turbulent transport, 2) a constant mean~~
 208 ~~horizontal wind, and 3) mean vertical wind near zero (Van Den Kroonenberg et al., 2008). These conditions are easier to~~
 209 ~~meet over the sea surface than land, due to the uniform nature of the sea surface. Additionally, the sea-atmosphere~~
 210 ~~interaction is relatively weaker than the land-atmosphere interaction (Mathez and Smerdon, 2018).~~

211 The in-flight calibration campaign included three flight maneuvers, including a ‘box’ maneuver, ‘racetrack’ maneuver,
 212 and ‘acceleration-deceleration’ maneuver. The trajectory of the calibration flight is shown in Figure 1, with different color
 213 corresponding to different flight maneuvers. The calibration flight was executed between 7:28-7:48 a.m. (China Standard
 214 Time, CST) to coincide with the ebb tide stage. During this time, the average water depth was approximately 1.1 m, and the
 215 average flight altitude was 400 m ($\sigma = \pm 0.78$ m) above the sea level. Considering the ~~conditions of the regional uniform and~~
 216 ~~cool~~ underlying surface ~~and~~ ~~and~~ the stable atmospheric conditions ~~in~~ the early morning, we assume no disturbance from
 217 underlying surface was present during the calibration flight.

218

219

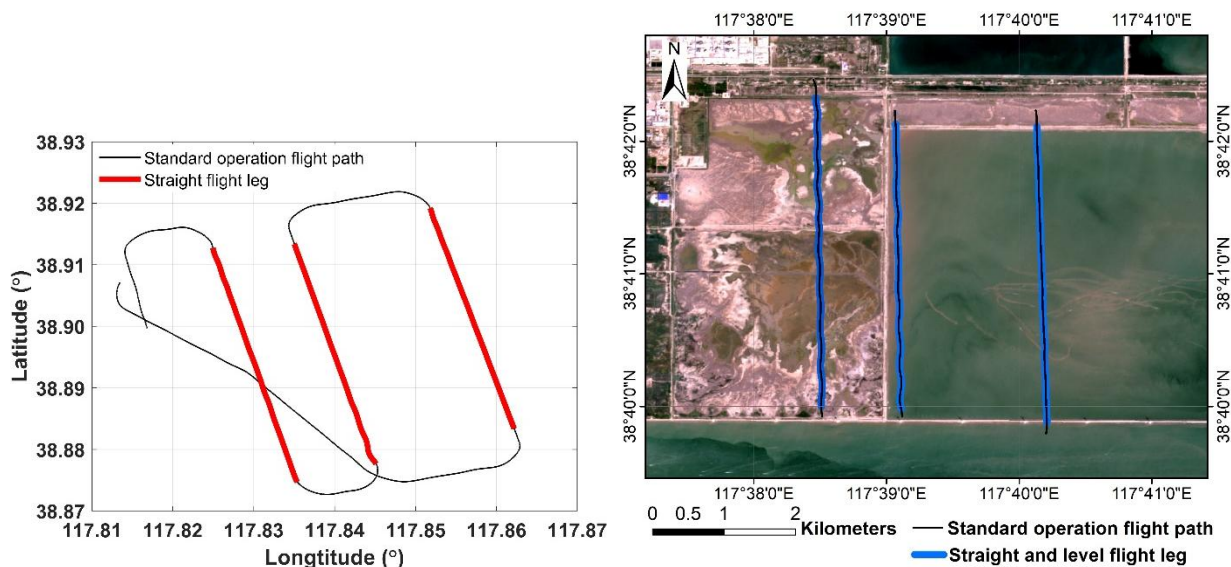

220 **Figure 1. Flight trajectory of the calibration campaign on 4 September 2022 at the Caofeidian Shoal Harbor in the Bohai Sea of**
 221 **northern China. The land surface image is from Sentinel-2A satellite image with true color combination acquired on 1 September**
 222 **2022.**

223 In this study, the ‘box’ maneuver is used to determine the mounting misalignment angle in the heading (ϵ_ψ) and pitch (ϵ_θ)
 224 between the 5HP and the center of gravity (CG) of the UAV. The flight path is a box in which the four straight legs are
 225 flown at constant cruising speed, flight altitude, and heading for 2 minutes. The ‘racetrack’ maneuver is used to evaluate the
 226 quality of the calibration parameters acquired from the previous ‘box’ maneuver. The flight path consists of two parallel
 227 straight flight tracks connected by two 180° turns. Each straight flight section lasts 2 minutes at constant speed and flight
 228 altitude. Lastly, the ‘acceleration-deceleration’ maneuver is used to check the influence of lift-induced upwash from the wing
 229 to the measured attack angle by the 5HP. During this maneuver, the aircraft is kept straight and level at constant pressure

230 altitude. When beginning this maneuver, the aircraft accelerates to its maximum airspeed (35 m s^{-1}). Then, the airspeed
231 reduces gradually to near its minimum airspeed (25 m s^{-1}) and back up to its maximum airspeed. The pressure-altitude of the
232 aircraft is maintained throughout this maneuver, and the entire maneuver lasts one minute. This maneuver creates a series
233 continuous changed pitch (θ) and attack (α) angle. A relationship between the measured incident flow attack angles (α) by
234 the 5HP and the measured pitch angle by the INS of close to 1:1, indicates that the effect from the fuselage-induced flow
235 distortion on the wind measurements is negligible (Garman et al., 2006).

236 2.2.2 Standard operation flight campaign

237 The reliability of the EC measurement from UAV is susceptible to several factors, mainly including instrumental noise,
238 resonance noise, and the quality of the calibration parameter. In order to evaluate the flux measurement error related to
239 instrumental noise, the effects of resonance on the measured scalar and to investigate the sensitivity of the measured geo-
240 referenced wind and turbulent flux to uncertainty in the calibration parameter, Previous studies have shown that the
241 measured scalars were affected by the vibration noise from the engine and propeller of the UAV (2021b; Sun et al., 2021a)-
242 In order to evaluate the effects of resonance on the measured scalar and to investigate the sensitivity of the measured geo-
243 referenced wind and turbulent flux to uncertainty in the calibration parameters, we used data from 7 flights in the Dagang
244 district ($38^{\circ}54'27'' \text{ N}$, $117^{\circ}48'16'' \text{ E}$) in Tianjin, China between 8 and 16 August 2022. This area is located on the west coast
245 of the Bohai Sea and is a coastal alluvial plain with altitudes between 1-3 m (Chen et al., 2017). The flight path, shown in
246 Figure 2, includes three parallel transect lines of approximately 4 km in length each and at 1-2 km intervals. All flights
247 occurred during the daytime, and were performed in the same trajectory at low altitude about 90 m above sea level. The
248 flight area covered three different underlying surfaces: land, coastal zone, and water surfaces, that can represent typical flux
249 intensity characteristics for different surface conditions. -

250

251 **Figure 2. Flight trajectory of the standard operation flight campaign, 8-16 August 2022, at Dagang district, Tianjin, China. The**
252 **land surface image is from Sentinel-2A satellite image with true color combination acquired on 27 August 2022.**

253 During the operation flight campaign, the atmospheric stability conditions changed from stable (Monin-Obukhov stability
254 parameter, $z/L = 1.93$) to very unstable ($z/L = -10.28$) as measured by the UAV, where z is the flight height above the
255 ground level, L is the Obukhov length. The stable condition mostly occurred on flight path located over the sea surface,
256 while the unstable condition mostly occurred on flight path located over the land surface. The average net radiation of each
257 transect flight line changed from -40 W m^{-2} over the sea surface to 626 W m^{-2} over the land surface. These flight data
258 provide various measurement conditions for us to evaluate the performance of the UAV-based EC system.

259 **2.3 Data processing**

260

261 The raw data collected with the on-board datalogger (CR6, Campbell, USA) is subsequently saved in Network Common
262 Data Form (netCDF) format. It includes dynamic and static pressure, attack, and sideslip angle of incoming flow; slow (1 Hz)
263 and fast (50 Hz) air temperature; mass concentration of H_2O and CO_2 ; as well as the full navigation data (including 3D
264 location, ground speed, angular velocity, and attitude, etc.) of the UAV. The subsequent data processing includes three basic
265 processing stages in order to calculate flux data from raw measured data.

266 In the first stage, Before processing the raw data into geo-referenced wind vector and turbulent flux, a moving average
267 filter was used to detect outliers in each variable. Detected outliers were removed and replaced by values obtained by linear
268 interpolation. Outliers tend to be rare. However, if outliers constitute more than 20 % of the data points, the corresponding
269 flight data should be discarded. The cleaned raw data was then used to calculate the geo-referenced wind vector, (co)spectra,
270 and turbulent fluxes.

271 **In the second stage, geo-referenced 3D wind vector is calculated. 2.3.1 Wind measurements**

272 The full form of the equations of motion for calculating the geo-referenced wind vector by ~~the our~~ UAV-based EC system
273 is described in detailed in Supplement Part A. From the aircraft platform, geo-referenced turbulent wind vector is measured
274 in two independent reference coordinate systems: the relative true airspeed (\hat{U}_a) measurement in the aircraft coordinate
275 system and the ground speed of the aircraft (U_p) in the geo-referenced coordinate system. The geo-referenced wind (U) is the
276 vector sum of the relative true airspeed (\hat{U}_a), the UAV's motion (U_p) and the tangential velocity due to the rotational motion
277 of the aircraft ("lever arm" effect), which is described in Eq. (S2). In this stage, the acquired calibration parameters (ϵ_{ψ} and
278 ϵ_{θ}) from the calibration flight are substituted into the Eq. (S8) to correct the mounting angle offset errors between the 5HP
279 and the CG of the UAV. The final equations for geo-referenced wind vector calculation (Eqs. S15 to S17) revealed that the
280 lever arm effects due to the spatial separation between the tip of the wind probe and the CG of UAV can influence the wind
281 measurements.

282 The relative wind vector (\hat{U}_a) measured by the aircraft is susceptible to flow distortion because the airplane must distort
283 the flow to generate lift and thrust, and the aircraft's propellers, fuselage, and wings are the main sources of flow distortion
284 as flow barriers (Metzger et al., 2011). For fixed-wing aircrafts, the wind probe mounted on the nose of the UAV and
285 extended as far forward of the fuselage as possible could avoid significant influence from flow distortion from the fuselage
286 and propellers. Nevertheless, the wind measurement is still subject to lift induced upwash due to the wings distorting the
287 flow to generate lift and thrust. The influence of upwash decreases with linear distance from the wing and appears as an
288 additional vertical component of airflow ahead of the wind probe (Crawford et al., 1996; Garman et al., 2008). The
289 magnitude of upwash influence generally increases with airplane size and airspeed, typically ranging from 0.5 to 2.5 m s⁻¹ as
290 reported by the manned fixed-wing aircraft (Garman et al., 2008). Therefore, for EC measurements by manned fixed-wing
291 aircrafts, the upwash effects must be corrected for wind measurements (Garman et al., 2008; Kalogiros and Wang, 2002).
292 However, wind measurements using a multi-hole probe on the UAV seldom need this correction due to the fuselage size and
293 because the airspeed is very low compared to a manned aircraft. This is considered in the equations for relative wind
294 calculation (in Supplement) used in this study as well. The 'acceleration-deceleration' flight maneuver (Section 2.2.1) was
295 used to assess whether the lift induced upwash could be safely ignored by the UAV-based EC system.

296 The lever arm effects due to the spatial separation between the tip of the wind probe and the CG of UAV can influence the
297 wind measurements (Eqs. S15 to S17). Typically, the separation distance (L) is small, and the influence of the lever arm
298 effects can be ignored when the L is less than about 10 m (Lenschow, 1986). In the current UAV-based EC system, the
299 displacements of the 5HP tip with respect to the CG of the UAV along the three axes of UAB body coordinate are: $x^b =$
300 1.459 m, $y^b = 0$ m, and $x^b = 0.173$ m (in Supplement Part A). Therefore, in practice, the influence of leverage effects in
301 geo-referenced wind calculation was also ignored in this study. ; thus, ~~the influence of leverage effects in geo-referenced~~
302 ~~wind calculation was also ignored.~~ This was confirmed by assessing the difference in the geo-referenced wind vectors with
303 and without the leverage effect correction term (in Section 3.1).

304 305 In the final stage, 2.3.2 Spectra and turbulent flux calculation

306 Unlike traditional ground-based EC measurements, those recorded on aircraft platforms are subject to several simultaneous
307 motions, including flow distortion around the fuselage and resonance from the rotation of the engine and propeller. Spectral
308 analysis is an effective way to assess if and to what extent the UAV's motion influences the EC measurements. For this
309 reason, the fast Fourier transform (FFT) method was used to calculate the spectra and co-spectra of the measured turbulent
310 variables. Before calculating the turbulence (co)spectra, condition of the raw turbulence data was performed, including a
311 linear detrend and tapering using the Hamming window to reduce the spectral leakage (sharp edge) according to Kaimal et al.
312 (1989).

313 Based on the EC technology and spatial averaging, the turbulent flux is calculated using the covariances of vertical wind
314 (w) with horizontal wind components (u, v) for vertical flux of momentum (τ), with virtual potential air temperature ($T_a \theta_v$)
315 for sensible heat flux (H), with water vapor density (q) for latent heat flux (LE), and with CO₂ density (c) for CO₂ flux (F_c),

316 ~~and with the necessary correction (Webb et al., 1980).~~ The time lag due to the separation between the 5HP tip, the adjacent
317 temperature probe, and the open-path gas analysis did not need to be corrected because the time delay was less than 1 second
318 at the cruise airspeed of 30 m s⁻¹ and sensor separation less than 20 cm. Only the measurement data from the straight-line
319 portion of the flight path can be used in flux calculation. Detailed calculation procedure and formulas of H , LE , and F_c used
320 by the present UAV-based EC system are provided in Supplement Part B, including spatially averaging, coordinate rotation,
321 and necessary correction (i.e., WPL correction for LE and F_c).

322 ~~Detailed information about the EC method and airborne EC calculation can be found in other studies (Aubinet et al., 2012;~~
323 ~~Vellinga et al., 2013; Gioli et al., 2006).~~

324 One important aspect for airborne EC measurement is the definition of a proper spatial averaging length to calculate
325 turbulent flux (Sun et al., 2018). Such spatial averaging length depends on the flying altitude, surface characteristics, and
326 atmospheric stability, and could be determined using Ogive analysis (Gioli et al., 2004; Kirby et al., 2008). In this study, ~~the~~
327 ~~objective is not to quantify the actual flux exchange between the surface and the atmosphere, but rather to assess the~~
328 ~~sensitivity of the calculated turbulent flux to external parameters. Therefore,~~ the entire measurement-measured data of each
329 straight and level flight leg (each with length about 4 km) from the standard operational flight campaign was used to
330 calculate turbulent flux, regardless of the uncertainty ~~of the flux results~~ in fluxes associated with spatial averaging.

331 **2.4 Evaluation strategiescheme**

332 **2.4.1 Propagation of sensor errors Wind measurement evaluation**

333 ~~The EC technique relies upon the precise measurement of the geo-referenced wind vector and atmospheric scalars~~ The key to
334 successful aircraft EC measurements lies in the translation of accurately measured, aircraft-orientated, wind vector to geo-
335 referenced orthogonal wind vector (Thomas et al., 2012). ~~Measured from an aircraft,~~ d ~~Determining the geo-referenced wind~~
336 ~~vector requires a sequence of thermodynamic and trigonometric equations, and the calculation of turbulent flux also needs a~~
337 ~~series of data operations and corrections to the turbulent variables (Metzger et al., 2012).~~ The EC data processing procedure
338 and_ these equations propagate various sources of error to the measured geo-referenced wind vector and turbulent flux. To
339 estimate the measurement errors in the geo-referenced wind vector, we used the linearized Taylor series expansions of Eqs.
340 (S15) to (S17) derived by Enriquez and Friehe (1995) (in Supplement Part A) to determine the sensitivities of each of the
341 geo-referenced wind vector components with respect to the relevant variables. Then, these sensitivity terms can be combined
342 to compute the overall measurement error (1σ) in the geo-referenced 3D wind vector (Eqs. S21 to S23 in Supplement Part
343 A).

344 ~~To estimate the errors in the geo-referenced wind vector and turbulent flux, we performed a Monte Carlo simulation of the~~
345 ~~data processing procedure.~~

346 ~~The Monte Carlo simulation method consists of repeated calculation of the target quantity, each time varying the input~~
347 ~~data randomly within their stated limits of precision. The distribution of the calculated quantity then shows the effects of the~~

348 imprecision of the input data (Anderson, 1976). In this study, all input variables (Table 1) used to calculate the geo-
 349 referenced wind vector and turbulent flux were randomly sampled from the Gaussian distributions with means corresponding
 350 to the constant altitude straight line flight and one standard deviation (1σ) widths given by individual component typical
 351 precision specifications from the manufacturer. Errors in the input variables are considered uncorrelated. The Monte Carlo
 352 process was repeated $N = 10^5$ times, and the measurement precision of the geo-referenced wind vector and turbulent flux
 353 was estimated as the standard deviation of the distribution of the simulated results.

354 The ~~above wind measurement error analysis Monte Carlo error simulation~~ gives the nominal measurement precision of the
 355 geo-referenced wind ~~and turbulent flux~~, but does not consider the influence of environmental changes. Following the
 356 methods of Lenschow and Sun (2007), we assess whether the accuracy of wind measurements from the UAV in satisfying
 357 the minimum signal level needed for resolving the mesoscale variations of the three wind components in the encountered
 358 atmospheric conditions. Firstly, the minimum required signal level for measurement of vertical air speed (ω) under the
 359 encountered atmospheric conditions could be estimated as (Lenschow and Sun, 2007):

$$360 \frac{\partial w}{\partial t} < 0.2\sqrt{2}\sigma_w 2\pi k U_a \quad (1)$$

361 with the true airspeed (U_a) set to mean cruise speed 30 m s^{-1} , the peak signal magnitude (σ_w) of the power spectra, and the
 362 corresponding wavenumber (k) (Thomas et al., 2012). The measurement error of the system in the vertical wind component
 363 can be calculated as (Lenschow and Sun, 2007):

$$364 \frac{\partial w}{\partial t} \cong \theta \frac{\partial U_a}{\partial t} + U_a \frac{\partial \theta}{\partial t} + \frac{\partial w_{UAV}}{\partial t} \quad (2)$$

365 with $\theta = \alpha - \theta$, where α is the attack angle, θ is the pitch angle, w_{UAV} is the UAV's vertical velocity. According to
 366 Lenschow and Sun (2007), the signal level and mesoscale fluctuation of horizontal wind components (u and v) are
 367 considerably larger than that of vertical wind, so the accuracy criteria are not nearly as stringent. The measurement error of
 368 the horizontal wind component could be calculated as (Lenschow and Sun, 2007):

$$369 \frac{\partial u}{\partial t} \cong -\frac{\partial U_a}{\partial t} + \frac{\partial u_{UAV}}{\partial t} \quad (3)$$

$$370 \frac{\partial v}{\partial t} \cong \Psi \frac{\partial U_a}{\partial t} + v_{tas} \frac{\partial \Psi}{\partial t} + \frac{\partial v_{UAV}}{\partial t} \quad (4)$$

371 and,

$$372 \Psi \equiv \psi' + \beta \quad (5)$$

373 where u_{UAV} , v_{UAV} are the UAV's horizontal velocity measured from INS, ψ' is the departure of the measured true heading
 374 from the average true heading, and β is the sideslip angle of airflow. If the measurement error of the 3D wind vector from
 375 Eqs. (2) to (4) is smaller than the required minimum signal level of the vertical and horizontal wind components, it can be

376 confirmed that the measurement accuracy of the geo-referenced 3D wind vector from UAV is sufficient to resolve the
377 mesoscale variations of the three wind components in the encountered atmospheric conditions.

378 **In addition, 2.4.2 Wind measurement evaluation**

379 ~~The key to successful aircraft EC measurements lies in the translation of accurately measured, aircraft orientated, wind~~
380 ~~vectors to geo-referenced orthogonal wind vectors (Thomas et al., 2012).~~ Accurate measurements of geo-referenced wind
381 vectors typically not only depend on the measurement precision of the sensors (i.e., 5HP and INS), but also related to the
382 quality of the calibration parameters, as well as and the geometry structure of the UAV-based EC system (i.e., flow
383 distortion and leverage effect). For evaluation of the effect of the latter two aspects, a calibration flight campaign (Section
384 2.2.1) was performed to determine the calibration parameter ($\epsilon_\psi, \epsilon_\theta$), check its quality, as well as to ascertain the effects of
385 the lever arm and up-wash by the wings. The methods for acquiring the calibration parameter were given by Vellinga et al.
386 (2013) and Sun et al. (2021a), and the results are reported in Supplement Part C (Figs. S2 and S3). ~~In~~ During the in-flight
387 calibration campaign, a ‘racetrack’ maneuver was performed to check the quality of the calibration parameters determined
388 from the ‘box’ flight maneuver. The initial ($\epsilon_\psi = 0^\circ, \epsilon_\theta = 0^\circ$) and calibrated ($\epsilon_\theta = -0.183^\circ, \epsilon_\psi = 2^\circ$, in Supplement Part C)
389 set of parameters were used to calculate the geo-referenced wind vector. By comparing the mean and standard deviation of
390 the horizontal and vertical wind vector between the initial and calibrated set, the quality of the geo-referenced wind vector
391 measurement in real environment conditions can be verified.

392 ~~The relative wind vector (\hat{U}_q) measured by the aircraft is susceptible to flow distortion because the airplane must distort~~
393 ~~the flow to generate lift and thrust, and the aircraft’s propellers, fuselage, and wings are the main sources of flow distortion~~
394 ~~as flow barriers (Metzger et al., 2011). For fixed-wing aircrafts, the wind probe mounted on the nose of the UAV and~~
395 ~~extended as far forward of the fuselage as possible could avoid significant influence from flow distortion from the fuselage~~
396 ~~and propellers. Nevertheless, E~~ effects from the flow distortion around the body of the aircraft, especially the induced upwash
397 by the wings can, can also significantly influence significantly influence the correspondence between measured and free-
398 stream flow variables (Garman et al., 2008). The induced upwash by the wings modifies the local angle of attack, causing the
399 measured attack angle (α) to be larger than the free-stream attack angle (α_∞). The magnitude of upwash influence generally
400 increases with airplane size and airspeed, typically ranging from 0.5 to 2.5 m s⁻¹ as reported by the manned fixed-wing
401 aircraft (Garman et al., 2008). Therefore, for wind measurements by manned fixed-wing aircrafts, the upwash effects must
402 be corrected (Garman et al., 2008; Kalogiros and Wang, 2002). However, wind measurements using a multi-hole probe on
403 the UAV seldom need this correction due to the fuselage size and because the airspeed is very low compared to a manned
404 aircraft.

405 In order to access whether the lift-induced upwash could be safety ignored by the current UAV-based EC system, the
406 ‘acceleration-deceleration’ flight maneuver was performed. According to Crawford et al. (1996), the pitch angle (θ) by the
407 INS instrument can be utilized as an estimate of the free-stream attack angle (α_∞) if the aircraft’s vertical velocity is zero,

408 since it is unaffected by lift-induced upwash and varies directly with α_∞ when the ambient vertical wind is zero. Under ideal
409 conditions (zero aircraft vertical velocity and zero ambient vertical wind), the approximation relationship of $\theta \cong \alpha_\infty$ is valid
410 when $\theta < 6^\circ$ (Crawford et al., 1996; Vellinga et al., 2013). Departures from the 1:1 relationship can be caused by airflow
411 distortion around the airplane behind the 5HP. The ‘acceleration-deceleration’ maneuver produced various pitch and attack
412 angles measured under various airspeeds, which allowed a direct comparison between the pitch angle (θ) and the attack
413 angle (α). If the slope between α and θ is close to unity, it indicates that the influence of lift-induced upwash can be ignored;
414 otherwise, its influence should be corrected using upwash models (Garman et al., 2006). At last Meanwhile, the influence of
415 leverage effects was also evaluated based on the measurement data from the ‘acceleration-deceleration’ maneuver by
416 considering or ignoring the leverage effect correction term in Eqs. (S15) to (S17).

417 2.4.2 Flux measurement error caused by instrumental noise

418 Errors or uncertainties in EC measurements can be systematic or random. Measurement from UAV, they can be attributed to
419 several sources, mainly including instrumental noise, data handing, atmospheric conditions, insufficient flux calculation
420 length, and bumpy flight environment (Mahrt, 1998; Finkelstein and Sims, 2001; Mauder et al., 2013). Knowledge of the
421 measurement precision is of great importance for interpretation of EC measurements especially when detecting small fluxes
422 in terms of turbulent exchange or signal-to-noise (SNR) of the instrumentation. Determination of the flux measurement error
423 from instrument noise is very useful, as it is related not only to the system performance, but also to the minimum resolvable
424 capability for the flux to be measured. In the current study, uncertainty related to instrumental noise (listed in Table 1) was
425 estimated with a directly method proposed by Billesbach (2011). This method can be called as “random shuffle” (denoted as
426 the RS) method and was “designed to only be sensitive to random instrument noise”. According to Billesbach (2011), the
427 uncertainty of the flux covariance can be expressed as:

$$428 \sigma_{\overline{w'x'}} \equiv \frac{1}{N} \sum_{i,j=1}^N w'(t_i)x'(t_j) \quad (6)$$

429 where x is the target entity of the covariance, N is the number of measurements contained in the block averaging period, $j \in$
430 [1... N] but the values are in the random order. The idea behind the RS method was that the randomly shuffled will remove
431 the covariance between biophysical (source/sink) and transport mechanisms, leaving only the random “accidental”
432 correlations attributed mostly to instrument noise (Billesbach, 2011). It means that the shuffled component x makes it
433 uncorrelated in time/space and decorrelates x from w , resulting in two independent variables (i.e., $\overline{w'x'} \sim 0$), and any residual
434 value of the covariance is attributed to random instrument noise. In addition to the basic assumptions made in EC flux
435 calculation, one additional assumption in RS method is that the block averaging period should be sufficiently long to
436 accurately represent the lowest significant frequencies contributing to the covariance which could be verified by forming
437 Ogive plots of the covariance (Billesbach, 2011).

438 In this study, in order to obtain robust estimates of the instrumental noise, $\sigma_{\overline{w'x'}}$ was repeatedly calculated 20 times for
439 every straight and level flight leg in operation flight (Fig. 2), and the mean of the absolute values of these 20 replicated

440 estimates for $\sigma_{\overline{w'x'}}$ were used to estimate the random uncertainty related to instrumental noise. According to Rannik et al.
 441 (2016), RS method tends to overestimate the covariance uncertainty due to instrumental noise only. Then, the uncertainty in
 442 the flux covariance of sensible heat ($\sigma_{\overline{w'T'}}$), latent heat ($\sigma_{\overline{w'\rho'_v}}$), and CO₂ ($\sigma_{\overline{w'\rho'_c}}$) were estimated using RS method,
 443 respectively.

444 It should be noted that the measurement error of EC flux measurement is influenced not only by the uncertainty in the raw
 445 covariance but also by the propagated errors from correction terms (i.e., WPL correction) or any lens contamination
 446 (Serrano-Ortiz et al., 2008). For EC measurement from our UAV, the signal quality of the IRGA is checked before each
 447 flight measurement to ensure that the measurement of gas concentration is not affected by lens contamination. The final
 448 uncertainty of flux measurement was evaluated using the partial derivatives of the full flux calculation equation with respect
 449 to their flux value derived by Liu et al. (2006) (Eqs. S29 to S31 in Supplement Part B). These equations (Eqs. S29 to S31)
 450 ignored the perturbations terms from the errors in the individual scalar (i.e., ρ_v, ρ_c, T) which were proved negligible small
 451 (Serrano-Ortiz et al., 2008). At last, after several repetitive calculation of the Eq. (6), their averaged value then be combined
 452 to Eqs. (S29) to (S31) for estimating the final flux measurement error due to instrumental noise.

453

454 2.4.3.3 Resonance effects

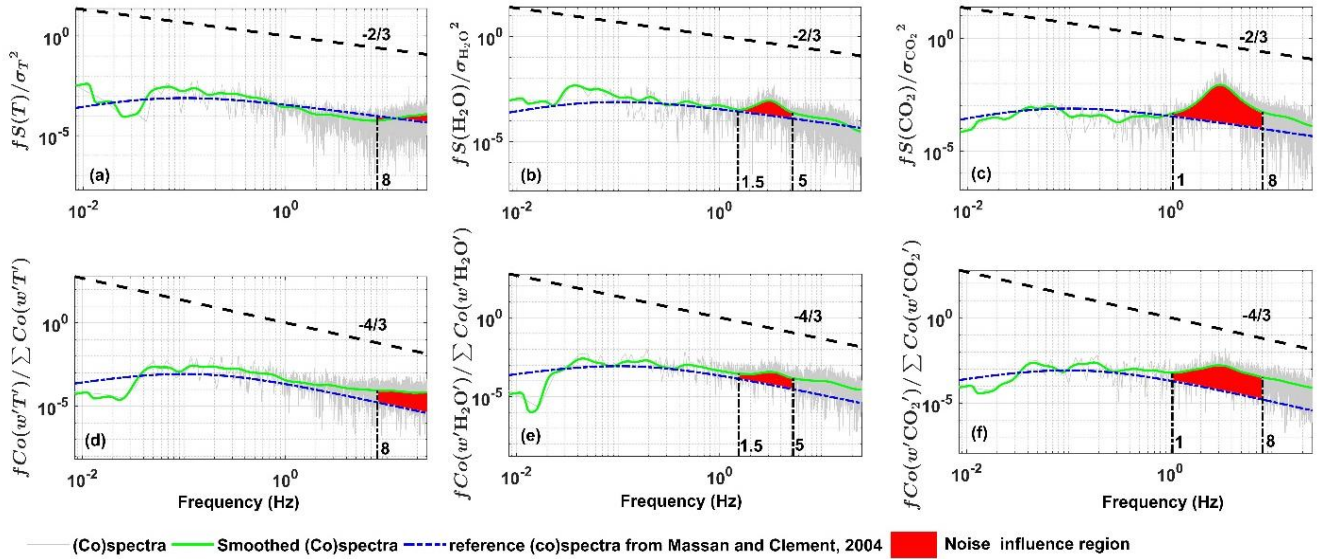

455 Previous work found that the measurement of the atmospheric scalars (e.g., air temperature, H₂O, and CO₂ concentration) is
 456 susceptible to resonance effects caused by the operation of the engine and propeller (Sun et al., 2021b). In order to further
 457 reduce the resonance effects, the vibration damping structure of the developed UAV-based EC system was further optimized.
 458 The reference (co)spectra curve of Massman and Clement (2005) was used to quantify the influence of the resonance effects
 459 remaining after vibration isolation optimization. Massman and Clement (2005) gave the generalization mathematical
 460 expression of the models of spectra and co-spectra:

$$461 \text{Co}(f) = A_0 \frac{1/f_x}{[1+m(f/f_x)^{2\mu}]^{2\mu} \left(\frac{m+1}{m}\right)} \quad (6)$$

462 where f is frequency (Hz), f_x is the frequency at which $f\text{Co}(f)$ reaches its maximum value, A_0 is a normalization parameter,
 463 m is the (inertial subrange) slope parameter, and μ is the broadness parameter. To describe co-spectra, m should be 3/4; to
 464 describe spectra, m should be 3/2. According to Massman and Clement (2005), $\mu = 7/6$ under stable atmospheric condition
 465 and $\mu = 1/2$ under unstable atmospheric condition. Fast Fourier transform (FFT) method was used to calculate the spectra
 466 and co-spectra of the measured turbulent variables. Before calculating the turbulence (co)spectra, condition of the raw
 467 turbulence data was performed, including a linear detrend and tapering using the Hamming window to reduce the spectral
 468 leakage (sharp edge) according to Kaimal et al. (1989).

469 According to Sun et al. (2021b), the noise influence from resonance mainly appears in the high frequency domain,
 470 According to the feature of spectral curve, the frequency range of the noise region was artificially designated to $f > 8$ Hz for

471 air temperature, $f = 1\sim 5$ Hz for water vapor, and $f = 1\sim 8$ Hz for CO₂. The normalized spectra and co-spectra curve were
 472 adopted and the area difference of the designated frequency range beneath the (co)spectra curve between the measured and
 473 reference (co)spectra curve was calculated to quantify the influence of resonance noise in the variance and flux covariance of
 474 the measurement atmosphere scalars. An example is shown in Figure 3, and also shown is the reference (co)spectra curve of
 475 Massman and Clement (2005), with the (co)spectral maximum at $f_x = 0.1$. The red region in Fig. 3 represents the impact
 476 extent of the resonance noise in the variance (Figs. 3a to 3c) and flux covariantees (Figs. 3d to 3f) of the measured scalars.
 477 The systematic noise deviation in the fluxes of sensible, latent heat and CO₂ could be derived relative to the entire frequency
 478 range.

480 **Figure 3.** The influence of resonance noise on the spectra (top row) and co-spectra (bottom row) curve of the measured scalars
 481 based on the measurement from the standard operation flight campaign on 8 August 2022 at Dagang district, Tianjin, China. The
 482 red region is the area difference of the designated frequency range (vertical black dashed-dotted line) beneath the (co)spectral
 483 curve between the measured and reference (co)spectral curve.

484 2.4.4 Sensitivity analysis

485 To understand the relevance relative influence of external-the calibration parameters -onfor the measurements of geo-
 486 referenced wind vector and turbulent flux, two sensitivity tests were conducted. The magnitude of the change-perturbation
 487 in the wind vector and turbulent flux was investigated as a function of the uncertainties of-in the four calibration parameters,
 488 including: -three mounting misalignment angles ($\epsilon_\psi, \epsilon_\theta, \epsilon_\phi$) between the 5HP and the CG of the UAV and one temperature
 489 recover factor ($\epsilon_r = 0.82$) used to calculate the ambient temperature (Eq. 3 in Sun et al. 2021a).

490 First, the sensitivity of the geo-referenced 3D wind vector and turbulent flux to the uncertainties of the individual
 491 parameter was investigated. The geo-referenced 3D wind vector and turbulent flux was calculated based on the straight leg
 492 (about 4 km) of the standard operational flight with-an-by addeing and error of $\pm 30\%$ to the optimum value of each

493 calibration parameter alternately; except for ϵ_ϕ , for which the typical range of $\pm 0.9^\circ$ was taken for sensitivity analysis
494 (Vellinga et al., 2013).

495 Then, ~~in order to test the overall interaction between the parameters, a second sensitivity test was performed to calculate~~
496 ~~the geo-referenced 3D wind vector and turbulent fluxes by adding $\pm 30\%$ error to all calibration parameters~~
497 ~~simultaneously.~~ ~~to test the overall interactions between the parameters, a second sensitivity test was run to calculate the geo-~~
498 ~~referenced 3D wind vector and turbulent flux using an error of $\pm 30\%$ added to all the calibration parameters simultaneously.~~
499 Lastly, ~~their relative errors (RE) with respect to the original value were the relative errors of the calibrated set and the added~~
500 ~~error set of geo-referenced 3D wind vector and turbulent flux values was~~ calculated to evaluate the perturbation of the wind
501 vector and turbulent flux under the variation of each calibration parameter as well as under simultaneous variation of all
502 calibration parameters. During the sensitivity analysis, the calculated geo-referenced wind and turbulent flux results whose
503 absolute value was less than their least resolvable magnitude (~~in Table 2~~) were filtered out to avoid the influence of the
504 errors contained in the measurements themselves on the results.
505 ~~ing the error contained in the measurement itself from impacting results.~~

506 2.4.5 Relative error

507 In this study, relative error (*RE*) was used to evaluate the influence of different factors on the measurements of geo-
508 referenced wind vector and turbulent flux by the UAV-based EC system. It is defined as:

$$509 \quad RE = \frac{|x_0 - |x||}{|x|} \times 100 \% \quad (7)$$

510 where ‘| |’ means the absolute value, x is the ‘true’ value, x_0 is the influenced value. $RE > 0$ means the exerted influence will
511 cause the measurement value to be larger than ‘true’ value and vice versa.

512 3 Results

513 3.1 ~~Wind measurement evaluation~~ Error analysis

514 ~~Evaluation of the wind measurement performance from the UAV-based EC system includes three contents: (1) measurement~~
515 ~~precision and its ability to resolve the mesoscale variations of the wind, (2) checking the quality of the acquired calibration~~
516 ~~parameters, and (3) checking whether the measured wind vector is affected by upwash flow and leverage effects.~~

517 ~~First, according to the equations described in Supplement Part A (Eqs. S18 to S23), the measurement precision for~~
518 ~~horizontal wind components is a function of true airspeed and true heading, while, the measurement precision for vertical~~
519 ~~wind component is largely decided by the true airspeed. The typical values of true airspeed ranging from 25 m s^{-1} to 35 m s^{-1}~~
520 ~~(interval of 1 m s^{-1}) and the true heading values ranging from 0° to 180° (interval of 30°) were used in the evaluation of~~
521 ~~wind measurement error. Then, the measurement precision (1σ) of the geo-reference 3D wind vector from aircraft was~~

522 estimated using the measurement precision of the related parameters from Table 1. The results are shown in Figure 4 for the
 523 measurement precision of horizontal wind (σ_u and σ_v in Figs. 4a and 4b) and vertical wind (σ_w in Fig 4c), respectively. The
 524 typical values of the measurement precision are ranging from 0.05 m s⁻¹ to 0.07 m s⁻¹ for horizontal wind component u ,
 525 ranging from 0.02 m s⁻¹ to 0.08 m s⁻¹ for horizontal wind component v , and ranging from 0.05 m s⁻¹ to 0.07 m s⁻¹ for vertical
 526 wind component w . When the flight direction is towards due east or due west, the horizontal wind (u and v) has the smallest
 527 measurement error.

528
 529 **Figure 4. Estimated measurement precision (1σ) of the horizontal wind (a, b) and vertical wind (c) according to the equations**
 530 **described in Supplement Part A (Eqs. S18 to S23).**

531 Generally speaking, an autopiloted UAV can maintain a near-constant true airspeed during the cruise flight phase. For a
 532 true airspeed of 30 m s⁻¹ for the current UAV-based EC system during the cruising, the maximum measurement error in the
 533 northward, eastward, and vertical velocities of the geo-referenced wind components were calculated as approximately 0.06,
 534 0.07, and 0.06 m s⁻¹, respectively. Then, we assume that a minimum signal-to-noise ratio of 10:1 is required to measure the
 535 wind components with sufficient precision for EC measurements (Metzger et al., 2012). Accordingly, in the real
 536 environments, horizontal and vertical wind speed greater than 0.7 m s⁻¹ and 0.6 m s⁻¹ can be reliably measured, respectively
 537 (Table 2).

538 After running $N = 10^5$ samples through the data processing procedure, the results of Monte Carlo error simulation for
 539 geo-referenced wind vector and turbulent flux are summarized in Table 2. The least resolvable magnitude of the
 540 measurements of wind and turbulent flux was calculated by assuming the minimum required signal-to-noise ratio of 5:1
 541 (Metzger et al., 2012). The 1σ precision of the geo-referenced wind vector measurement was $\pm 0.04 \text{ m s}^{-1}$ for the horizontal
 542 and vertical wind components, and the magnitude of the wind velocity greater than 0.2 m s⁻¹ could be reliably measured. The
 543 calculated measurement 1σ precision of the geo-referenced vertical wind component agreed well with the 1σ uncertainty in
 544 the vertical wind measurement (0.057 m s^{-1}) calculated by propagating instrument errors through linear combination, as
 545 described by Sun et al. (2021a).

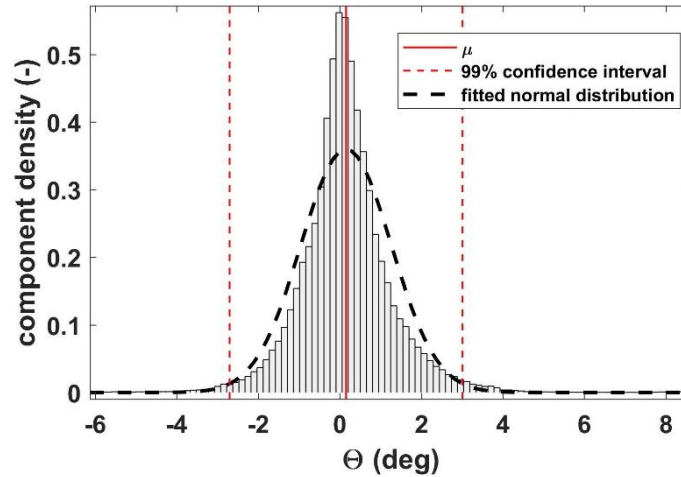

546 **Table 2: The maximum measurement error in the northward (u), eastward (v), and vertical (w) velocities of the geo-**
 547 **referenced wind components at the true airspeed of 30 m s⁻¹. Results of the simulated measurement precision (1σ) of the geo-**

548 ~~referenced wind vector and turbulent flux from the Monte Carlo error simulation with $N=10^5$ runs~~ and the least resolvable
 549 magnitude assuming the minimum required signal-to-noise ratio of ~~105~~:1.

Measurements	Measurement precision (1σ)	Least resolvable magnitude
u-windspeed (m s^{-1})	0.064	0.62
v-windspeed (m s^{-1})	0.073	0.7
w-windspeed (m s^{-1})	0.064	0.62
CO_2 flux ($\mu\text{mol m}^{-2}\text{s}^{-1}$)	0.08	0.4
Sensible heat flux (W m^{-2})	1.61	8.05
Latent heat flux (W m^{-2})	0.15	0.75
Friction velocity (m s^{-1})	0.02	0.1

550 ~~The simulated 1σ measurement precision of the turbulent flux was $0.08 \mu\text{mol m}^{-2}\text{s}$ for the CO_2 flux, 1.61 W m^{-2} for the~~
 551 ~~sensible heat flux, 0.15 W m^{-2} for the latent heat flux, and 0.02 m s^{-1} for the friction velocity, respectively. Using a signal to-~~
 552 ~~noise ratio of 5:1, the minimum magnitudes for reliably resolving the CO_2 flux, friction velocity, sensible and latent heat~~
 553 ~~fluxes were $0.4 \mu\text{mol m}^{-2}\text{s}$, 0.1 m s^{-1} , 8.05 W m^{-2} , and 0.75 W m^{-2} , respectively.~~

554 The ~~Monte Carlo error simulation~~ above results gave the nominal precision for wind measurements that does not consider
 555 the influence of environmental conditions. Changes in the environment will lead to sensor drift, increasingly deteriorating
 556 the measurement with flight duration (Metzger et al., 2012; Lenschow and Sun, 2007). Following the methods of Lenschow
 557 and Sun (2007), the ability of the limitations of the accuracy of wind field measurements from UAV to resolve the mesoscale
 558 variations of the 3D wind components in the encountered atmospheric conditions was assessed. For the vertical wind, the
 559 mesoscale variability was defined as the peak signal magnitude of the power spectra curve. The corresponding average
 560 wavenumber was determined as 0.09 m^{-1} based on the straight flight leg (about 4 km, lasting about 120 s) of the standard
 561 operational flight. Then, the minimum required signal level for the vertical wind measurement was estimated as $\partial w/\partial t \approx$
 562 0.14 m s^{-2} . The accuracy of the vertical wind measurement using Eq. (2) is estimated as follows. The first term on the right-
 563 hand side of Eq. (2) is dominated by the drift in the differential pressure transducer, the value of $\partial U_a = 0.05 \text{ m s}^{-1}$ acquired
 564 from the wind tunnel test was applied (Table 1). The histogram of Θ derived from the standard operational flights is shown
 565 in Figure 45. The 99 % confidence interval indicates that the value of Θ seldom exceeds $\pm 3^\circ$, i.e., ± 0.053 radians. Thus, the
 566 value of the first term was estimated as $2.2 \times 10^{-5} \text{ m s}^{-2}$.

567

568 | **Figure 54. Histogram of Θ derived from the standard operational flight. Component density is scaled so that the histogram has a**
 569 **total area of one. Red vertical lines indicate distribution average (solid) and 99% confidence interval (dashed). The black dashed**
 570 **bell curve displays a reference fitted normal distribution.**

571 The second term in Eq. (2) is a combination of INS pitch accuracy and drift in the measured attack angles. The combined
 572 accuracies of these two sensors were applied to derive $\partial\Theta = 0.0024$ radians. Thus, the second term in Eq. (2) was estimated
 573 as $6 \times 10^{-4} \text{ m s}^{-2}$. Finally, the third term in Eq. (2) was estimated as $1.7 \times 10^{-4} \text{ m s}^{-2}$, according to the stated accuracy of
 574 the vertical velocity from the INS. The overall performance of the vertical wind measurement ($7.9 \times 10^{-4} \text{ m s}^{-2}$) was
 575 accurate enough to resolve the mesoscale variations in vertical air velocity.

576 The required accuracy of horizontal wind for mesoscale measurement was estimated as 10 times larger than that of
 577 vertical wind, i.e., $\partial u/\partial t \simeq \partial v/\partial t \simeq 1.4 \text{ m s}^{-2}$. The measurement accuracy of the horizontal wind component u was
 578 estimated as $4.8 \times 10^{-4} \text{ m s}^{-2}$ according to Eq. (3). Like the first term in Eq. (2), with the value of Ψ rarely exceeding
 579 ± 0.18 radians, the measurement accuracy of the horizontal wind component v was estimated as $2.7 \times 10^{-2} \text{ m s}^{-2}$ according
 580 to Eq. (4). Thus, the measurement accuracy of the horizontal wind components was accurate enough to resolve the
 581 mesoscale variations in the horizontal air velocity as well.

582 **3.2 Wind measurement**

583 **Second, before checking the quality of the acquired calibration parameters,** the calibration results of the offset in pitch
 584 (ϵ_θ) and heading (ϵ_ψ) angles based on the ‘box’ maneuver are provided in Supplement **Part C** (Figs. S2 and S3). The final
 585 calibration values are $\epsilon_\theta = -0.183^\circ$ and $\epsilon_\psi = 2^\circ$. In order to verify the quality of these calibration parameters, a ‘racetrack’
 586 maneuver was performed. Figure **5–6** shows the verification results by plotting wind vectors and calculating summary
 587 statistics for the ‘racetrack’ maneuver (including turns), using the initial ($\epsilon_\theta = \epsilon_\psi = 0^\circ$, Fig. **5a6a**) and calibrated (Fig. **5b6b**)
 588 set of parameters. The introduction of the calibration parameter effectively improved the quality of geo-referenced wind
 589 vector measurement. The standard deviation for wind direction, $\sigma_{U_{dir}}$, is 4.9° for the calibrated set compared to 8.7° for the

590 initial set, and the standard deviation of wind speed, σ_U , is 0.52 m s^{-1} for the calibrated set compared to 1.12 m s^{-1} for the
 591 initial set. The average vertical wind speed is much closer to zero ($\bar{w} = -0.006 \text{ m s}^{-1}$) for the calibrated set than for the
 592 initial set ($\bar{w} = 0.1 \text{ m s}^{-1}$). For the horizontal wind, it is evident from Fig. 5-6 that the wind direction and velocity are little
 593 affected by sharp turns. On the contrary, the measurement of the vertical wind component is obviously affected by turns in
 594 flight, as shown by the large ripple in the vertical wind speed around the scan value of 150 (Fig. 56). It should be noted that
 595 the influence of upwash flow and the leverage effect are not considered in the calculated of geo-referenced wind vector.

596
 597 **Figure 56.** Quality check of the calibration parameter by plotting wind vectors and calculating summary statistics for the
 598 'racetrack' maneuver, using the initial (a) and calibrated (b) set of parameters. The calibration flight was carried out on 4
 599 September 2022 at the Caofeidian Shoal Harbor.

600 **Third.** In order to check the influence of the lift-induced upwash on the attack angle measurement from the 5HP, an
 601 'acceleration-deceleration' flight maneuver was performed. During the 'acceleration-deceleration' maneuver, INS data
 602 shown a vertical velocity of the UAV at $0.05 \pm 0.2 \text{ m s}^{-1}$, the altitude of UAV at $392 \pm 0.6 \text{ m}$, the heading of UAV at $199 \pm 2.4^\circ$.
 603 The flight conditions met the requirements of the 'acceleration-deceleration' maneuver (Vellinga et al., 2013). The
 604 relationship between the pitch angle (θ) measured by INS and the attack angle (α) measured by 5HP is plotted in Figure 67,
 605 where the attack angle was not corrected for lift-induced upwash. The slope (0.94) between θ and α is close to its theoretical
 606 value of 1, and the intercept (0.16) is close to zero. This result indicates that the lift-induced upwash has only a very small
 607 effect on the attack angle, and the influence of upwash could be ignored.

608

609 | **Figure 67.** Relationship between the pitch angle (θ) measured by INS and the attack angle (α) measured by 5HP. The fitted linear
 610 | equation is also shown.

611 | Finally, the geo-referenced wind vector was calculated with and without the correction for the leverage effect based on the
 612 | measurement data from the ‘acceleration-deceleration’ flight maneuver. The average relative differences between the
 613 | corrected and uncorrected horizontal and vertical wind speeds are 0.1 % and 0.2 %, respectively. The standard deviation for
 614 | horizontal wind speed is 0.307 m s^{-1} without the level arm term compared to 0.306 m s^{-1} when the level arm term is
 615 | introduced. The standard deviation of vertical wind speed is 0.254 m s^{-1} without the level arm term compared to 0.253 m s^{-1}
 616 | with the level arm term. The correction of leverage effect had minimal effect on improving the geo-referenced wind vector
 617 | measurement; therefore, this correction term can be ignored.

618 | 3.2 Flux measurement error caused by instrumental noise

619 | Flux measurement error caused by the instrumental noise gives the lowest limit of the flux that the UAV-based EC system is
 620 | able to measure. Such measurement error was assessed by combining the covariance uncertainty estimated by RS method
 621 | and the propagation of errors in flux correction terms. Before estimating the flux covariance uncertainty using RS method,
 622 | using the measured data from each straight and level flight leg of the standard operational flight (Fig. 2), the normalized
 623 | integrated cospectra (ogives) curves of sensible heat (Fig. 8a), latent heat (Fig. 8b), and CO_2 (Fig. 8c) flux are formed as a
 624 | function of wavenumber (k), where $k \equiv 2\pi f/U_a$. As shown in Figure 8, although the heterogeneous turbulence (or
 625 | mesoscale turbulence) interfered the shape of ogive curves, most curves converged at the high and low frequency ends,
 626 | which indicated that these segmented data were sufficiently long to represent the lowest significant frequencies contributing
 627 | to the covariance.

628

629 **Figure 8. Normalized ogive curves as a function of wavenumber for the flux covariance of sensible heat (a), latent heat (b), and**
 630 **CO₂ (c) from each straight and level flight leg of the standard operational flight in Section 2.2.2.**

631 Then, the results of instrumental noise related relative flux measurement error compared to the magnitude of the flux are
 632 shown in Figure 9. It can be seen that the flux measurement error caused by instrumental noise significantly decreases when
 633 the flux magnitude increases. It is not surprising since, in theory, instrumental noise is usually close to a constant and the
 634 relative flux measurement error caused by instrumental noise will decrease with increasing measurement magnitude.
 635 Overall, instrumental noise has the least effect on latent heat flux (ranging from 0.02% to 2.42% in this study) measurements,
 636 followed by sensible heat flux (ranging from 0.05% to 8.6% in this study), and has the greatest effect on the measurement of
 637 CO₂ flux (ranging from 0.22% to 75.6% in this study). Then, a simple rational function relationship between the relative
 638 measurement error and the flux magnitude is fitted according to the measured data, where the constant term in the
 639 denominator is set to 0. The fitted coefficient in the numerator can be considered as the flux measurement error caused by
 640 instrumental noises, which are $0.03 \mu\text{mol m}^{-2} \text{s}^{-1}$, 0.02 W m^{-2} , and 0.08 W m^{-2} for the measurement of CO₂ flux, sensible and
 641 latent heat flux, respectively. At last, using the signal-to-noise ratio of 10:1, the minimum magnitudes for reliably resolving
 642 the CO₂ flux, sensible and latent heat fluxes were estimated as $0.3 \mu\text{mol m}^{-2} \text{s}^{-1}$, 0.2 W m^{-2} , and 0.8 W m^{-2} , respectively.

643

644 **Figure 9. Relative flux measurement error caused by instrumental noise plotted against the magnitude of the flux. Also shown the**
 645 **fitted error curves. Measured data was from the standard operation flights in Section 2.2.2.**

646

647 3.3 Resonance noise

648 The resonance noise from the engine and propeller can lead to systematic overestimation of the variance and covariance of
649 the observed atmospheric scalars. Since the noise mainly appears in the high frequency domain of the (co)spectra, the
650 reference (co)spectral curve of Massman and Clement (2005) was used to quantify the systematic bias caused by the
651 resonance noise.

652 All spectra curves of the variance of measured scalars (including air temperature, H₂O, and CO₂ concentration)
653 approximately followed the reference spectra curve and the reference -2/3 slope in the inertial subrange (Figs. 3a to 3c). The
654 largest scatter occurred in the spectra of CO₂ (Fig. 3c). When comparing the spectra curve with the reference spectra, the
655 resonance noise led to a systematic deviation in the variance of air temperature, H₂O, and CO₂ concentration of 0.1±0.1 %,
656 1.0±0.79 %, and 4.4±0.66 %, respectively, relative to the entire frequency range. For the flux covariances of sensible, latent
657 heat and CO₂, all the co-spectra curves approximately follow the reference co-spectra curve and the reference -4/3 slope in
658 the inertial subrange (Figs. 3d to 3f). Compared with the reference co-spectra, the resonance noise led to a systematic
659 deviation in the flux of sensible, latent heat, and CO₂ of 0.07±0.004 %, 0.3±0.25 %, and 2.9±1.62 %, respectively, relative to
660 the entire frequency range.

661 The results show that the resonance noise has a very little impact on the measured variance and flux covariances. Among
662 them, the measurements of CO₂ concentration and flux are most susceptible to the resonance noise, but the impact of this
663 noise is limited to around 5 % of the observed value.

664 3.4 Sensitivity analysis

665 In this study, in order to investigate the relevance of the calibration parameters for the measurement of the sensitivity of the
666 geo-referenced wind vector and turbulent flux measurements to the uncertainties of the external calibration parameter, two a
667 sensitivity tests were conducted by adding an error of ±30 % to the used optimum parameters (ϵ_ψ , ϵ_θ , ϵ_ϕ , ϵ_r). calibrated
668 value of each calibration parameter. We it is assumed that the maximum uncertainties contained in the calibration parameter
669 is not more than 30 % of its own value.

670 First, the sensitivity of the geo-referenced 3D wind and turbulent flux to the uncertainty ies in of the individual parameters
671 was tested. The RE value is was used to quantify the sensitivity. Tables 3 and 4 show the and the RE results are summarized
672 in Tables 3 and 4. For the measurement of the geo-referenced wind vector, Table 3 shows that the uncertainty ies in the
673 temperature recovery factor (ϵ_r) and 5HP mounting misalignment error in the roll (ϵ_ϕ) angle do not contribute significantly
674 to errors in the wind measurements, which were typically smaller than 4% of the observed value in this study. The
675 parameter ϵ_θ had the largest effect on the vertical wind component (up to 30 %), whereas ϵ_ψ had the largest effect on the
676 horizontal wind component. For the measurement of turbulent fluxes, Table 4 shows that the errors in ϵ_r and ϵ_ϕ does not
677 significantly influence significantly the flux measurements (typically small than 5% of the observed value in this study).
678 The uncertainties in C calibration parameters ϵ_θ and ϵ_ψ had significant effects on the measurement of turbulent flux. Adding

679 an error of $\pm 30\%$ to ~~the calibration parameter ε_θ may result in significant perturbation (large RE variance) uncertainty~~ in the
 680 measured turbulent fluxes ~~including sensible heat, latent heat and CO_2 (large RE variance)~~. ~~While, errors in ε_ψ to some~~
 681 ~~extent mainly affect the measurement of~~ Similarly, adding an error of $\pm 30\%$ to the calibration parameter ε_ψ resulted in the
 682 ~~largest effect on~~ latent heat fluxes (RE may up to 15 %).

683 **Table 3:** RE of the sensitivity test for the geo-referenced 3D wind vector (u, v, w). An error factor of $\pm 30\%$ was added to
 684 each calibrated parameter. The geo-referenced 3D wind vector was calculated based on the straight leg of the standard
 685 operational flight.

Parameter	Error (%)	RE of geo-referenced 3D wind vector		
		mean \pm std		
		u (%)	v (%)	w (%)
ε_r	-30	0.04 ± 0.41	-0.004 ± 2	0 ± 0
	30	0.06 ± 0.43	0.27 ± 1.1	-0.07 ± 0.23

	30	-0.99 ± 3.96	-0.57 ± 3.26	2.66 ± 11.76	-0.59 ± 4.42

689 * See Table 3.

690 The second sensitivity test was performed to evaluate the overall interaction between calibration parameters and the
 691 calculation of geo-referenced wind vector and turbulent flux by adding an error of $\pm 30\%$ to all the calibration members
 692 simultaneously. overall sensitivity of the geo-referenced 3D wind vector and turbulent flux to the external calibration
 693 parameters was tested by adding an error of $\pm 30\%$ to all the calibration members simultaneously. Tables 5 and 6 provided a
 694 summary of the RE results from the second sensitivity test. For the measurement of geo-referenced wind vector (Table 5),

695 adding an error of $\pm 30\%$ to all the calibration parameters at the same time resulted in great perturbations to both the
 696 horizontal (low RE with high variance) and vertical wind components (high RE with low variance). For the measurement of
 697 turbulent fluxes, 30% error in the calibration parameters can result in errors in measured fluxes more than 10%. In addition,
 698 Table 6 reveals that the a high RE (near 30%) for vertical wind and a low RE (about 4%) for horizontal wind, which also
 699 had high RE variance (up to 28%). For the measurement of turbulent fluxes, the measurement of the latent heat flux (mean
 700 RE > 6%) is more sensitivity to the errors in the calibration parameter than other flux measurements (higher mean and
 701 variance of the RE compared to other measurements) (mean RE < 3%) and had a larger RE variance (>10%). In general,
 702 CO₂ and sensible heat fluxes as well as friction velocity are not sensitive to errors in the external calibration parameters, but
 703 there were also some exceptions where the response to errors was large (e.g., the RE variance of CO₂ flux up to 10%).

704 **Table 5:** RE of the sensitivity test for the geo-referenced 3D wind vector (u, v, w) calculated by adding an error of $\pm 30\%$ to
 705 all the calibrated parameter simultaneously. The geo-referenced 3D wind vector was calculated based on the straight leg of
 706 the standard operational flight.

Parameter	Error (%)	RE of geo-referenced 3D wind vector		
		mean \pm std		
		u (%)	v (%)	w (%)
All	-30	4.24 \pm 27.89	-3.2 \pm 21.1	-29.35 \pm 4.63
	30	-4.15 \pm 27.46	3.55 \pm 21.91	29.16 \pm 4.86

707 **Table 6:** RE of the sensitivity test for the turbulent flux calculated by adding an error of $\pm 30\%$ to all the calibrated
 708 parameter simultaneously. The turbulent flux was calculated based on the straight flight leg of the standard operational flight.

Parameter	Error (%)	RE of turbulent flux			
		mean \pm std			
		f_{CO_2-Fc} (%)	H (%)	LE (%)	u^* (%)
All	-30	-1.19 \pm 10.51	-0.9 \pm 8.06	2.71 \pm 13.91	-2.92 \pm 8.19
	30	-0.49 \pm 10.01	-1.66 \pm 5.4	-6.07 \pm 13.24	1.74 \pm 6.55

709 4 Discussions

710 As one in a new generation of airborne flux measurement platforms, the UAV-based EC system can significantly reduce the
 711 cost of implementing airborne flux measurement campaigns and greatly promote their wide application at regional scales.
 712 ~~The trend of sensor miniaturization further promotes the rapid development of technology in this field. Sun et al. (2021a)~~
 713 ~~developed an UAV-based EC system for measuring the turbulent flux of sensible heat, latent heat, CO₂, as well as radiation~~
 714 ~~fluxes of net radiation and photosynthetically active radiation (PAR).~~ The current study aimed to quantitatively evaluate
 715 the basic performance of this system UAV-based EC system developed by Sun et al. (2021a) in the measurement of wind
 716 vector and turbulent flux.

717 First, the wind measurement precision (nominal precision) of the UAV-based EC system was evaluated ~~estimated~~ by
 718 propagating the sensor errors to the geo-referenced wind vector ~~and turbulent flux~~ using the linearized Taylor series

719 ~~expansions from~~ Enriquez and Friche (1995) ~~Monte Carlo error simulation~~. The 1σ precision ~~for of~~ geo-referenced wind
720 measurement was estimated to be $\pm 0.04\text{--}07\text{ m s}^{-1}$, and the ~~least resolvable magnitude for wind measurement was estimated~~
721 ~~at 0.7 m s^{-1} by assuming the minimum signal-to-noise ratio of 10:1. 1σ precision for turbulent flux was $0.08\text{ }\mu\text{mol m}^{-2}\text{ s}$ for~~
722 ~~the CO_2 flux, 1.61 W m^{-2} for the sensible heat flux, 0.15 W m^{-2} for the latent heat flux, and 0.02 m s^{-1} for the friction velocity.~~
723 ~~As proposed by Lenschow and Sun (2007), a minimum signal-to-noise ratio of 5:1 was assumed to be required to measure~~
724 ~~the wind field and turbulent flux. Using that ration, the least resolvable magnitude for wind and turbulent flux measurement~~
725 ~~was estimated at 0.2 m s^{-1} for wind velocity, $0.4\text{ }\mu\text{mol m}^{-2}\text{ s}$ for the CO_2 flux, 8.05 W m^{-2} for the sensible heat flux, 0.75 W
726 ~~m^{-2} for the latent heat flux, and 0.1 m s^{-1} for the friction velocity.~~ These derived wind measurement minimum resolvable
727 magnitudes ~~for measurements of wind vector and turbulent flux~~ can be used as a basic reference for thewind measurement
728 capability of the UAV-based EC system, and the measured values of wind vector ~~and scalar fluxes~~ smaller than the
729 minimum resolvable values should be considered unreliable. The accuracy of the sensors was also assessed by examining the
730 collected data in the real environment (Lenschow and Sun, 2007; Thomas et al., 2012). Our results revealed that ~~T~~the overall
731 performance of geo-referenced wind measurement is sufficient accuracy for resolving the mesoscale variations of the 3D
732 wind components under the encountered atmospheric conditions. Therefore, it is possible to capture the mesoscale variability
733 of the atmospheric boundary layer (ABL) over a wide range of spatial scales by performing longer flight paths.~~

734 ~~Second~~Second, based on the measurement data from the in-flight calibration campaign, several key factors affecting the
735 accuracy of geo-referenced wind measurement were analysed. First, the UAV-based EC system was calibrated (in
736 Supplement Part C) using measured data from the ‘box’ flight maneuver to correct the mounting misalignment between the
737 5HP and the CG of the UAV in the heading ($\epsilon_\theta = -0.183^\circ$) and pitch ($\epsilon_\psi = 2^\circ$) angles. The quality of the acquired
738 calibration parameters was verified using the ‘racetrack’ flight maneuver, and the acquired calibration value effectively
739 improved the observed wind field with smaller variance compared with the wind calculated using their initial value. ~~The~~
740 ~~measured geo-referenced 3D wind vector was consistent with the assumptions made about the atmospheric condition for~~
741 ~~calibration campaign (constant horizontal wind and near zero mean vertical wind) especially in the standard operation flight.~~
742 At the same time, ~~T~~the measurement of the vertical wind component was significantly affected by the in-flight turn
743 (maintaining about 20° roll). Therefore, it is necessary to avoid using the measured data from the turn section for turbulent
744 flux calculation. Compared to ~~the~~ other studies (Vellinga et al., 2013; Reineman et al., 2013), the relatively large variance in
745 the ~~calibrated~~ horizontal wind and wind direction after calibrated in this study may be caused by the nonstationary condition
746 of the turbulence. This was caused by the reason that the flight altitude of 400 m was not high enough to totally avoid
747 interaction from the underlying surface.

748 The current calibration procedure did not include methods to determine the offset angle in roll (ϵ_ϕ) and the temperature
749 recovery factor (ϵ_r) because of the small vertical separation (27.3 cm) between the 5HP and the roll axis of the UAV and the
750 small Mach number (<0.1) during operational flight. The default ($\epsilon_\phi = 0^\circ$) and empirical ($\epsilon_r = 0.82$) value were adopted for

751 | these two calibration parameters. The sensitivity analysis shown these two parameters have no large effect on the wind
752 | vector and turbulent flux.

753 | It should be noted that ~~W~~wind measurements from the airborne platform may be susceptible to flow distortion and rigid-
754 | body rotation (leverage effects). ~~However~~Generally, the influence of these two aspects-factors were ignored by UAV
755 | platform when calculating the geo-referenced wind vector. To confirm that these effects could be safely ignored, data from
756 | ‘acceleration-deceleration’ flight maneuver was used to analyse the effects of lift-induced upwash and the leverage effect on
757 | the wind measurements. ~~Our~~The results demonstrate that the upwash has almost no effect on the wind measurement, which
758 | was indicated by the near 1:1 relationship (0.94 in Fig. 7) between the measured attack angles and pitch angle. The slight
759 | departures from the ideal 1:1 relationship may have been caused by the nonstationary condition during the flight. For the
760 | influence from the leverage effects, the differences in 3D wind vector between corrected and uncorrected for the leverage
761 | effect is very small. were very minor between the 3D wind vector corrected and uncorrected for the leverage effect. Thus,
762 | ignoring the influence of the leverage effect has almost no effect on the measurement of wind. Therefore, we concluded that
763 | the geo-referenced 3D wind vector can be measured reliably by the current UAV-based EC system without considering the
764 | possible disturbance/interference from the lift-induced upwash and leverage effect ~~as indicated by the results~~.

765 | Third, instrumental noise related relative flux measurement error was estimated by combining the covariance uncertainty
766 | estimated by RS method and the propagation of errors in flux correction terms. By assuming that the instrumental noise is
767 | close to a constant, we fitted a simple rational function relationship between the relative measurement error and the flux
768 | magnitude according to measured data (Fig. 9), and the fitted coefficient in the numerator can be considered as the flux
769 | measurement error caused by instrumental noises. The estimated flux measurement error of CO₂, sensible and latent heat
770 | flux are 0.03 $\mu\text{mol m}^{-2} \text{s}^{-1}$, 0.02 W m^{-2} , and 0.08 W m^{-2} , respectively. Since the RS method directly uses the shuffled raw
771 | measurement data to calculate the instrumental noise induced flux measurement error, its estimated results inevitably
772 | included the effects of resonance noise from the UAV. Using the signal-to-noise ratio of 10:1, the least resolvable magnitude
773 | for turbulent flux measurement was estimated to be 0.3 $\mu\text{mol m}^{-2} \text{s}^{-1}$ for the CO₂ flux, 0.2 W m^{-2} for the sensible heat flux,
774 | 0.8 W m^{-2} for the latent heat flux, respectively.

775 |
776 | ThirdFourth, because the UAV-based EC system has not completely insulated the noise from the operation of the engine
777 | and propeller and its effect on the measured scalars, the reference (co)spectra of Massman and Clement (2005) was used to
778 | quantify the effect of the resonance noise on the variance and flux of the measured scalars. Previous studies found that the
779 | influence of resonance noise mainly appears in the high frequency domain of the power spectra of the measured atmospheric
780 | scalars (e.g., air temperature, H₂O, and CO₂ concentration). The frequency range of the noise region was artificially
781 | designated for air temperature, water vapor and CO₂. By calculating the area difference of the designated frequency range
782 | beneath the (co)spectral curve between the measured and reference (co)spectral curves, the resonance effect could be
783 | quantified. The results shown that, overall, resonance noise has little impact on the variance and flux covariances of the
784 | measured scalars. The measurements of CO₂ concentration and its flux covariance were the most susceptible to resonance

785 noise, but the maximum effect was less than 5 %. It should be noted that this method may overestimate the deviation caused
786 by resonance noise as indicated by the reference (co)spectra curve and the measured (co)spectra not fully overlapping in the
787 inertial subrange (shown in Fig. 3).

788 In general, Gas detection based on optical absorption methods can achieve fast and high precision gas concentration
789 measurements, but they are extremely sensitive to vibration noise. However, due to the limited space inside the UAV, it is
790 difficult to install all the hardware needed for a complex vibration isolation structure to effectively isolate the impact of
791 vibration on the gas analyser. The weight and the aerodynamic shape of the UAV also present challenges. In the future, a
792 new UAV-based EC system based on a pure electric UAV ~~could~~will be developed. The electro-powered UAV has similar
793 performance to the current fuel-powered UAV but can minimize the impact of vibration noise from the engine and propeller
794 rotation, which makes it possible to completely isolate the resonance effect using a simple vibration isolation structure.
795 Electro-powered UAVs also have other advantages including larger wingspan (lower cruising speed), a constant CG position,
796 and lower operational complexity compared to the current system.

797 ForthFifth, two sensitivity tests ~~were~~was conducted to assess the perturbation of the geo-referenced wind ~~vector-velocity~~
798 and turbulent flux under variation (+30 %) of each calibration~~ed~~ parameter around its ~~calibrated-optimum~~ value ($\epsilon_\psi \equiv$
799 2° , $\epsilon_\theta \equiv -0.183^\circ$, $\epsilon_\phi \equiv 0^\circ$, $\epsilon_r \equiv 0.82$) as well as under simultaneous variation (+30 %) of all calibration~~ed~~ parameters.
800 ~~Their RE was used to evaluate the sensitivity, and values of wind and flux less than their least resolvable magnitude were~~
801 ~~removed from the calculation. The sensitivity analysis was carried out based on the straight flight leg (about 4 km) by adding~~
802 ~~an error of $\pm 30\%$ to the calibrated parameter value and then calculating the RE of the geo-referenced wind vector and~~
803 ~~turbulent flux between the calibrated and added error sets of results. Values less than the least resolvable magnitude were~~
804 ~~removed from the dataset.~~ The results revealed that uncertainties in the temperature recovery factor (ϵ_r) and mounting offset
805 in roll angle (ϵ_ϕ) do not significantly contribute to an error in the measurement of wind vector and turbulent fluxes. The
806 typical RE for the geo-referenced wind measurements is less than 1.2 % with variance less than 3 %, and the typical RE for
807 turbulent flux is less than 1.1 % with variance less than 5 %. ~~The sign of the added errors of ϵ_ϕ and ϵ_r also has no significant~~
808 ~~effect on the sign of the RE.~~ Calibration parameters that had the largest effect on the measurement of geo-referenced wind
809 vector and turbulent flux are the mounting offset angle in pitch (ϵ_θ) and heading (ϵ_ψ). Uncertainties in ϵ_θ had a direct effect
810 on the measurement of vertical wind component, and ~~these~~ then these errors propagate to the measured fluxes, resulting in a
811 large ~~fluctuation-error contains~~ in the RE (~12%)measured fluxes (~15 %). A negative error ~~of in the ϵ_θ will resulted~~
812 ~~inlead to smaller-an underestimation of the~~ vertical wind and vice versa. ~~Uncertainties-Errors~~ in ϵ_ψ directly affect the
813 measurement of the horizontal wind, and to some extent, the measurement of turbulent flux. The ~~most-obvious~~
814 ~~phenomenondifference~~ is that the added error in ϵ_ψ lead to a great variability (up to 25 %) in the RE of horizontal wind. By
815 checking the relationship between the magnitude of the horizontal wind (u, v) and RE, a near exponential relationships was
816 seen, ~~as shown in Figure 10.-As shown in Figure 7, †~~The influence of the error in the ϵ_ψ decreased significantly with the
817 increase in the magnitude of the horizontal wind velocity. Additionally, the measurement of latent heat flux may be greatly

818 affected by the error in ε_ψ , which is reflected by the relatively large deviancy ($\sim 14\%$) of the RE . Therefore, calibration
819 parameter ε_θ and ε_ψ need to be carefully calibrated.

820
821 **Figure 107. Relationship between the magnitude of the horizontal wind velocity (u, v) and RE from the sensitivity test. Wind-
822 velocity of less than 0.2 m s^{-1} was excluded.**

823 The second sensitivity test varied all the external calibration parameters simultaneously, which resulted in a slightly larger
824 but similarly varied REs compared with the first test. The results confirm that the quality of calibration parameter ε_θ and ε_ψ
825 had the largest effect on the reliability of measurement for geo-referenced wind vector and turbulent flux. The parameter ε_θ
826 directly affected the measurement of vertical wind and propagated its errors to the measured turbulent flux. The parameter ε_ψ
827 significantly affected the measurement of horizontal wind, and in the measurement of turbulent flux, its effect on latent heat
828 flux was somewhat more pronounced than for other fluxes. Therefore, these two parameters need to be carefully calibrated.

829 Lastly, it should be noted that the accuracy of the measured geo-referenced wind vector and turbulent flux from the UAV-
830 based EC system is subject to the combination of many factors, mainly including sensor accuracy, UAV powerplant, UAV
831 fluctuation (e.g., variation of the UAV attitude and flight height), and the atmospheric conditions during the measurements,
832 etc. This study mainly focused on assessing the effects of sensor precision and UAV powerplant on the measurement errors
833 of geo-referenced wind vector and turbulent flux. Evaluation results gave the lowest limit of the wind vector and turbulent
834 flux that the UAV-based EC system can measure. this study could not evaluate the accuracy of the measured geo-referenced
835 wind vector and turbulent flux by the UAV-based EC system compared to their actual true value. AnAnother effective way
836 to evaluate the measurement accuracy of this new technique is by comparing measured values with those from the
837 traditionally recognized measurement. However, the direct comparison of flux measurements between aircraft and traditional
838 ground tower is still challenging due to the difference in the measurement height, mechanism (time series for ground EC and
839 space series for aircraft), and instruments (e.g., wind sensor). Previous studies have extensively compared the measurement
840 of fluxes and wind vector between airborne and ground-based EC methods and found consistent results (Gioli et al., 2004;
841 Metzger et al., 2012; Sun et al., 2021b). At the same time, substantial and consistent over- or underestimation of the
842 measured wind and fluxes by UAV compared to ground measurements were observed and reported. These differences may

843 be due to several factors such as vertical flux divergence (the measurement height of UAV is higher than ground-tower),
844 surface heterogeneity (induced by the larger footprint region of the UAV compared to the ground tower), measurement
845 errors (e.g., window length, resonance noise, etc.) as well as their difference in platform and sensors. Therefore, it is
846 necessary to conduct a comparison test on the same platform and under the same environment to exclude the influence of
847 these factors. Inspired by Reineman et al. (2013), future work can include developing a ground-vehicle-based UAV flux
848 validation platform. This platform could carry both the UAV-based and traditional ground EC system to assess the
849 measurement accuracy of the UAV-based EC system with the measurement of ground EC as the benchmark in a flight-like
850 scenario.

851 5 Conclusions and further works

852 The main objective of this study was to quantitatively evaluate the performance of the developed UAV-based EC system in
853 the measurement of geo-referenced wind vector and turbulent flux. In terms of measuring precision, turbulence
854 measurements from the UAV-based EC system were achieved with sufficient precision to enable reliable measurement of
855 geo-referenced wind and EC flux. Magnitudes larger than $0.2\text{--}7\text{ m s}^{-1}$ for wind velocity, $0.4\text{--}3\text{ }\mu\text{mol m}^{-2}\text{ s}^{-1}$ for CO_2 flux,
856 80.052 W m^{-2} for sensible heat flux, and 0.8 W m^{-2} for and-latent heat flux,and 0.1 m s^{-1} for friction velocity could be
857 reliably measured by the UAV-based EC system by assuming the minimum required signal-to-noise ratio of 105:1 for EC
858 application. Based on the data from the calibration flight, the carefully calibrated offset angle in pitch (ϵ_θ) and heading (ϵ_ψ)
859 were shown to effectively improve the quality of wind field measurements, and the influences of flow distortion and the
860 leverage effect on the wind measurement were minimal and could be ignored. The influence of resonance noise was small on
861 the measurement of air temperature and water vapor (typically $< 1\%$ for their variance and flux covariance), but relatively
862 large on the measurement of CO_2 (around 5% for variance and flux covariance).

863 The relevance of the calibration parameters (ϵ_r , ϵ_ϕ , ϵ_ψ , ϵ_θ) for the measurement of the geo-referenced wind vector and
864 turbulent flux was also assessed based on two sensitivity tests. uncertainties in the external calibration parameters
865 (ϵ_r , ϵ_ϕ , ϵ_ψ , ϵ_θ) to the computation of geo-referenced wind vector and turbulent flux was also assessed based on a sensitivity
866 test.The measurements of the geo-referenced wind vector and turbulent flux were insensitive to the errors in the ϵ_r and ϵ_ϕ .
867 The uUncertainties in the calibration parameter ϵ_θ and ϵ_ψ had the strongest effects on the measurements. Because of ϵ_θ
868 directly effects-determining the magnitude of the vertical wind, its error will create-lead to inaccuracies-uncertainties in
869 vertical wind measurement and then propagate the errors-uncertainties to the measurement of turbulent flux. The
870 uncertainties in ϵ_ψ have a direct effect on the measurement of horizontal wind, and to some extent, the measurement of
871 turbulent flux. Therefore, these two calibration parameters need to be carefully calibrated. Conducting the UAV-based EC
872 measurement when wind velocity is larger than $1\text{--}2\text{ m s}^{-1}$ can led to more stable and reliable (RE < 20%) results of the wind
873 speed measurement compared to a relatively windless environmental (< 1 m s⁻¹).

874 Finally, we concluded that the developed UAV-based EC system measured the geo-referenced wind vector and turbulent
875 flux with sufficient precision. The lift-induced upwash and leverage effect had almost no effect on the measurement of geo-
876 referenced wind vector. The resonance effect caused by the operation of engine and propeller mainly affected the
877 measurement of CO₂, and its effect on variance and flux covariance was around 5 %. The quality of calibration parameters
878 ε_ψ and ε_θ has a significant effect on the measurement of the geo-referenced wind vector and turbulent flux, underscoring the
879 importance of careful calibration. Although UAV-based EC measurements have many advantages over manned aircraft and
880 tower-based EC measurements, airborne EC measurements themselves have some shortcomings, such as flux results hard to
881 interpret (e.g., influence from surface heterogeneity, flux divergence, etc.), the measurements are restricted to short periods
882 of time, and the interaction between the UAV and turbulence. Future researches may include the development of a new
883 generation UAV-based EC system with the following improvements: 1) a new electro-powered UAV platform with the
884 advantages of being quieter (low noise), having a low cruising speed, and being easy to operate; 2) a ground-vehicle-based
885 validation platform to enable direct comparative evaluation of the UAV-based EC system with traditional ground EC
886 methods under near-identical environmental conditions; 3) a graphics based real-time monitoring system to make it possible
887 to change the flight pattern according to real-time data; and 4) a number of integrated field observation experiments that
888 combining ground-based EC networks, OMS, and multi-source satellite RS to further prompt the development of theory and
889 methodology for scaling transformation. Ultimately, the versatility of the UAV-based EC system as a low cost and widely
890 applicable environmental research aircraft facilitates further improving our understanding of the energy and matter cycling
891 processes at regional scales.

892
893 **Author contributions.** SY, GB and LX planned the field campaign; SY, LB, JJ, ZZ and JS carried out the field
894 measurements. SY ~~and~~, LS and XZ analysed the data and wrote the manuscript draft. ~~XZ~~, SB, and QZ reviewed and edited
895 the manuscript.

896 **Competing interests.** The authors declare that they have no conflict of interest.

897 **Acknowledgments.** This work was supported by the National Natural Science Foundation of China (Grant No. 42101477).
898 We would like to thank F-EYE UAV Technology Co. Ltd. for building, maintaining, and operating the UAV in this study.

899 **Data availability.** Data for this research are not publicly available due to its proprietary nature currently. The UAV
900 calibration flight data and the standard operation flight data in this study are available upon request to the corresponding
901 author.
