13 **Abstract.** When making measurements of air quality, having a reliable estimate of the measurement uncertainty  
14 is key to assessing the information content that an instrument is capable of providing, and thus its usefulness in a  
15 particular application. This is especially important given the widespread emergence of Low Cost Sensors (LCS)  
16 to measure air quality. To do this, end users need to clearly identify the data requirements a priori and design  
17 quantifiable success criteria by which to judge the data. All measurements suffer from errors, with the degree to  
18 which these impact the accuracy of the final data often determined by our ability to identify and correct for them.  
19 The advent of LCS has provided a challenge in that many error sources show high spatial and temporal variability,  
20 making laboratory derived corrections difficult. Characterising LCS performance thus currently depends primarily  
21 on colocation studies with reference instruments, which are very expensive and do not offer a definitive solution  
22 but rather a glimpse of LCS performance in specific conditions over a limited period of time. Despite the  
23 limitations, colocation studies do provide useful information on measurement device error structure, but the results  
24 are non-trivial to interpret and often difficult to extrapolate to future device performance. A problem that obscures  
25 much of the information content of these colocation performance assessments is the exacerbated use of global  
26 performance metrics ( $R^2$ , RMSE, MAE, etc.). Colocation studies are complex and time-consuming, and it is easy  
27 to fall into the temptation to only use these metrics when trying to define the most appropriate sensor technology  
28 to subsequently use. But the use of these metrics can be limited, and even misleading, restricting our understanding  
29 of the error structure and therefore the measurements' information content. In this work, the nature of common  
30 air pollution measurement errors is investigated, and the implications these have on traditional metrics and other  
31 empirical, potentially more insightful, approaches to assess measurement performance. With this insight we  
32 demonstrate the impact these errors can have on measurements, using a selection of LCS deployed alongside  
33 reference measurements as part of the QUANT project, and discuss the implications this has on device end-use.

34

## 35 1. Introduction

36 The measurement of air pollutants is central to our ability to both devise and assess the effectiveness of policies  
37 to improve air quality and reduce human exposure (Molina & Molina, 2004). The emergence of low-cost sensor  
38 (LCS) based technologies means a growing number of measurement devices are now available for this purpose  
39 (Morawska et al., 2018), ranging from small low-cost devices that can be carried on an individual's person all the  
40 way through to large, expensive reference and research-grade instrumentation. A key question that needs to be  
41 asked when choosing a particular measurement technology is whether the data provided is fit for purpose  
42 (Andrewes et al., 2021; Lewis & Edwards, 2016). In order to answer this, the user must first clearly define the  
43 question that is to be asked of the data, and thus the information required. For example, a measurement to  
44 characterize “rush hour” concentrations, or to determine if the concentration of a pollutant exceeded an 8 h average  
45 legal threshold value at a particular location would demand a very different set of data requirements than a  
46 measurement to determine if a change in policy had modified the average pollutant concentration trend in a  
47 neighbourhood. ~~Considerations such as measurement time resolution and ability to capture spatial variability~~  
48 ~~would be important for such examples (Feinberg et al., 2019).~~ Would the  $R^2$  or RMSE or any other global single-  
49 value metric be enough to decide between the different device’s options? Considerations such as the origin of the  
50 performance data, type of experiment (laboratory or colocation) (Jiao et al., 2016), the test location (Feenstra et  
51 al., 2019) and period (i.e. duration, season, etc.), the LCS and reference measurement method (Giordano et al.,  
52 2021), measurement time resolution and ability to capture spatial variability (Feinberg et al., 2019) would be  
53 important factors to consider for such examples. The measurement uncertainty is also of critical consideration, as  
54 this ultimately determines the information content of the data, and hence how it can be used (Tian et al., 2016).

55 All measurements have an associated uncertainty, and even in highly controlled laboratory assessments, the true  
56 value is not known, with any measurement error defined relative to our best estimate of the range of possible true  
57 values. However, quantifying and representing error and uncertainty is a challenge for a wide range of analytical  
58 fields, and often what these concepts represent is not the same to all practitioners. This results in a spectrum of  
59 definitions that take into account the way truth, error, and uncertainty are conceived (Grégis, 2019; Kirkham et  
60 al., 2018; Mari et al., 2021). For atmospheric measurements assessing uncertainty is complex and non-trivial.  
61 Firstly, given the “true” value can never be known, an agreed reference is needed. Secondly, the constantly  
62 changing atmospheric composition means that repeat measurements cannot be made and the traditional methods  
63 for determining the random uncertainty are not applicable. And finally, a major challenge arises from the multiple  
64 sources of error both internal and external to the sensor that can affect a measurement. Signal responses from a  
65 non-target chemical or physical parameter or electromagnetic interference are examples of an almost limitless  
66 number of potential sources of measurement error. In this work, we will follow the definitions given by the  
67 International Vocabulary of Metrology (JCGM, 2012) for measurement error (“measured quantity value minus a  
68 reference quantity value”) and for measurement uncertainty (“non-negative parameter characterising the  
69 dispersion of the quantity values being attributed to a measurand, based on the information used”). Also, when  
70 the term “uncertainty” is used here, it is referring to “diagnosis uncertainty”, in contrast with “prognosis  
71 uncertainty” (see Sayer et al., 2020 for more details).

72 The covariance of many of the physical and chemical parameters of the atmosphere, makes accurately identifying  
73 particular sources of measurement interference or error very difficult in the real world. Unfortunately, specific  
74 laboratory experiments for the characterization of errors is complex and very expensive, resulting in many sources  
75 of error being essentially unknown for many measurement devices. The use of imperfect error correction  
76 algorithms that are not available to the end-user (e.g. in many LCS devices) makes error identification and  
77 quantification even more complex. For this reason, colocation experiments in relevant environments are often the  
78 best option to assess the applicability of a given measurement method for its intended purpose.

79 The mentioned difficulties in defining and quantifying uncertainty across the full range of end-use applications of  
80 a measurement device, means that often the quoted measurement uncertainty is not applicable, or in some cases  
81 not provided or provided in an ambiguous manner. This makes assessing the applicability of a measurement device  
82 to a particular task difficult for users. In this work, we investigate the nature of common air pollution measurement  
83 errors, and the implications these have on traditional goodness-of-fit metrics and other, potentially more insightful  
84 approaches to assess measurement uncertainty. We then use this insight to demonstrate the impact these errors  
85 can have on measurements, using a selection of LCS deployed alongside reference measurements as part of the  
86 UK Clean Air program funded QUANT (Quantification of Utility of Atmospheric Network Technologies) project,  
87 a 2-year colocation study of 26 commercial LCS devices (56 gases measurements and 56 PM measurements) at  
88 multiple urban, background and roadside locations in the UK. After analysing some of the real-life uncertainty  
89 characteristics we discuss the implications this has on data use.

## 90 2. Error characterization

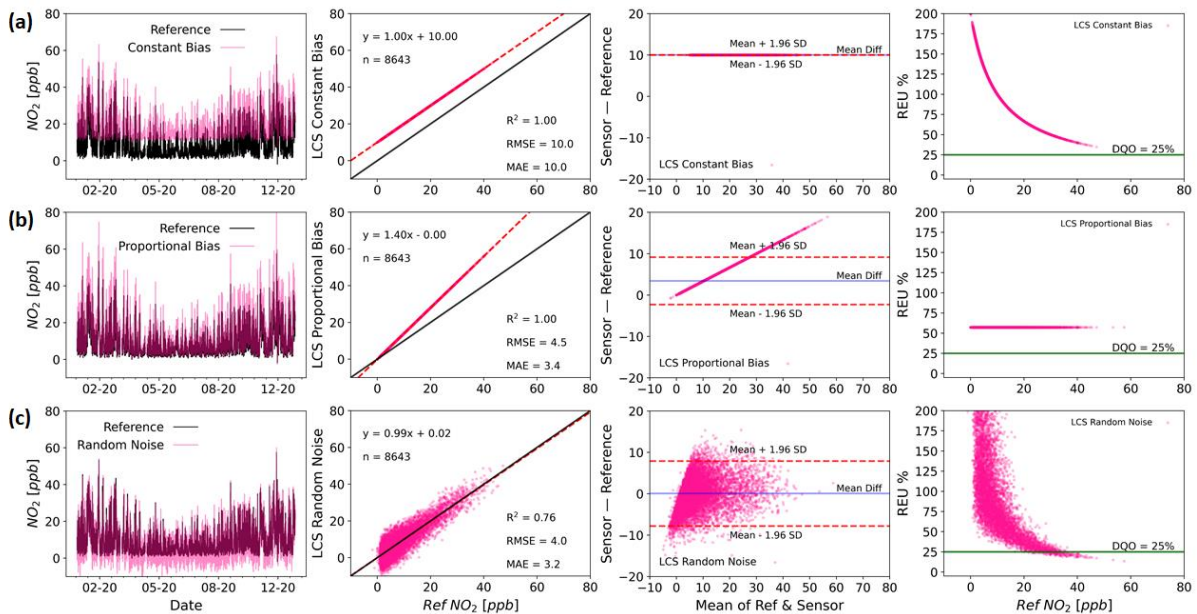

91 When characterising measurement error, in the absence of evidence to the contrary ~~it is often assumed~~ a linear  
92 additive model ~~is often assumed~~. Once the analytical form of the model is defined, its parameters aim to capture  
93 the error characteristics, and in the case of linear models (Eq. (1)), these are typically separated into three types  
94 (Tian et al., 2016): (i) proportional bias or scale error ( $b_1$ ), (ii) constant bias or displacement error ( $b_0$ ) and (iii)  
95 random error ( $\varepsilon$ ) (Tian et al., 2016). Any measurement ( $y_i$ , e.g from the LCS) can therefore be thought of as a  
96 combination of the reference value ( $x_i$ ) and the three error types, such that:

$$97 \quad y_i = b_1 x_i + b_0 + \varepsilon \quad (1)$$

98 As the simplest approximation, this linear relationship for the error characteristics is often used to correct for  
99 observed deviations between measurements and the agreed reference. It is worth to note, however, that this  
100 equation assumes time-independent error contributions and that the three error components are not correlated,  
101 which is often not the case on both counts (e.g. responses to non-target compounds). The parameter values  
102 determined for Eq. (1) are also generally only applicable for individual instruments, potentially in specific  
103 environments, unless the transferability of these parameters between devices has been explicitly demonstrated.

104 Figure 1 shows examples of how pure constant bias (a-panels), pure proportional bias (b-panels), and pure random  
105 noise (c-panels) would look like in time-series, regression, Bland-Altman (B-A) (Altman & Bland, 1983) and  
106 Relative Expanded Uncertainty (REU, as defined by the GDE (2010)) plots. In each of these ideal cases, the error  
107 plots enable the practitioner to view the error characteristics in slightly different ways, allowing the impacts of the  
108 observed measurement uncertainty to be placed into the context of the data requirements. In this work, we will

109 refer to them as “error types” (in contrast to “error sources”), which is the way they are distilled by the linear error  
 110 model.

111  
 112 **Figure 1. Time series (left panels), regression (middle-left panels), B-A Bland-Altman (middle-right panels) and REU**  
 113 **(right panels, DQO for  $NO_2 = 25\%$ ) plots for arbitrary examples of pure constant bias (Slope = 1, Intercept = 1,  $SD_\epsilon =$**   
 114 **0; a-panels), pure proportional bias (Slope = 1.4, Intercept = 0,  $SD_\epsilon = 0$ ; b-panels) and pure random noise (Slope = 1,**  
 115 **Intercept = 0,  $SD_\epsilon = 4$ ; c-panels) simulated errors.**

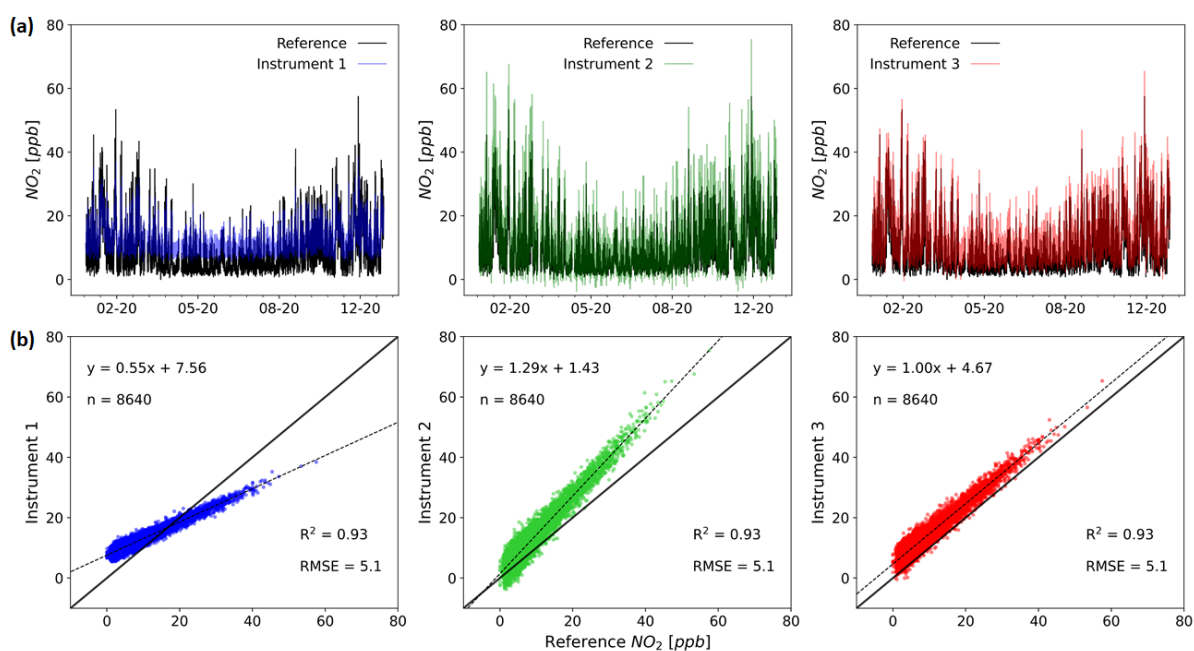

116

## 117 2.1 Performance indices, error structure and uncertainty

118 A major challenge faced by end-users of measurement devices characterised using collocation studies is the non-  
 119 trivial question of how the comparisons themselves are performed and how the data are is communicated. Often  
 120 single value performance metrics, such as the coefficient of determination ( $R^2$ ) or root mean squared error  
 121 (RMSE), are calculated between the assessed method (e.g. LCS) and an agreed reference, and the user is expected  
 122 to infer an expected device performance or uncertainty for a measurement in their application (Duvall et al., 2016;  
 123 Malings et al., 2019). ~~These metrics contain useful information about the measurement, but they are unable to~~  
 124 ~~fully describe the error characteristics, in part because they reduce the error down to a single value (Tian et al.,~~  
 125 ~~2016).~~ When evaluating multiple sensors during a collocation experiment, single metrics can be a useful way to  
 126 globally compare instruments/sensors. However, these metrics do little to communicate the nature of the  
 127 measurement errors and the impacts these will have in any end use application, in part because they reduce the  
 128 error down to a single value (Tian et al., 2016). Even more if a specific concentration range is of paramount  
 129 interest to the end-user, these metrics are not capable of characterising the weight of noise and/or the bias effect.  
 130 The  $R^2$  shows globally the data set linearity and gives an idea of the measurement noise. However, it is unable to  
 131 distinguish whether a specific range of concentrations is more or less linear (or more or less noisy) than another.  
 132 Similarly, the RMSE is also a very useful metric and perhaps more complete than  $R^2$ , as it considers both noise  
 133 and bias (although they need to be explicitly decomposed from RMSE). Nevertheless, the RMSE is an average

134 measure (of noise and bias) over the entire dataset under analysis. Using combinations of simple metrics increases  
 135 the information communicated, but does not necessarily make it easy to assess how the errors will likely impact  
 136 a particular measurement application. Visualising the absolute and relative measurement errors across the  
 137 concentration range (unreachable by global metrics) enables end users to view the errors, and any features (non-  
 138 linearities, step changes, etc.) that would impact the measurement but that global metrics (and in some cases time-  
 139 series and/or regression plots) are incapable of showing.

140 Unfortunately, the widespread use of a small number of metrics as the sole method to assess measurement  
 141 uncertainty, without a thorough consideration of the nature of the measurement errors, means measurement  
 142 devices are often chosen that are unable to provide data that is fit for purpose. In addition, unconscious about  
 143 potential flaws, users (e.g. researchers) could communicate findings or guide decision making based on results  
 144 that may not justify the conclusions drawn from the data. Figure 2 shows three simulated measurements compared  
 145 with the true values. Despite the measurements having identical  $R^2$  and RMSE values, the time series and  
 146 regression plots show that the error characteristics are significantly different, and would impact how the data from  
 147 such a device could viably be used.

148  
 149 **Figure 2. Time series (a-panels) and regression plots (b-panels) for three hypothetical instruments and a reference (1**  
 150 **year of data). The most used metrics for evaluating the performance of LCS ( $R^2$  and RMSE) are identical for the**  
 151 **systems shown, even when the errors have very different characteristics (time res 1 h).**

152 There are multiple performance metrics that can be used for the assessment of measurement errors and uncertainty.  
 153 Tian et al (2016) present an excellent summary of some of the major pitfalls of performance metrics and promote  
 154 an approach of error modelling as a more reliable method of uncertainty quantification. These modelling  
 155 approaches, however, rely on the assumption of statistical stationarity, whereby the statistical properties of the  
 156 error are constant in the temporal and spatial domains. The presence of unknown or poorly characterised sources  
 157 of error, for example, due to interferences from other atmospheric constituents or drifts in sensor behaviour, makes  
 158 this assumption difficult to satisfy, especially when the dependencies of these errors show high spatial and

159 temporal variability. Thus, if field collocation studies are the primary method for performance assessment, as is  
160 the case for LCS, only through a detailed assessment of the measurement errors across a wide range of conditions  
161 and timescales can the uncertainty of the measurement be realistically estimated.

## 162 **2.2 Dealing with errors: established techniques vs Low-Cost Sensors**

163 Different approaches are available to the user to minimise the impact of errors, generally by making corrections  
164 to the sensor data. For example, in the case of many atmospheric gas analysers, if the error is dominated by a  
165 proportional bias, a multi-point calibration can be performed using standard additions of the target gas.  
166 Displacement errors can be quantified, and then corrected for, by sampling a gas stream that contains zero target  
167 gas. **And** Random errors can be reduced by applying a smoothing filter (e.g moving average filter, time-averaging  
168 the data, etc.), at the cost of losing some information (Brown et al., 2008). These approaches work well for simple  
169 error sources that, ideally, do not change significantly over timescales from days to months. Unfortunately, more  
170 complex error sources can manifest in such a way that they contribute across all three error types, and also vary  
171 temporally and spatially. For example, an interference from another gas-phase compound could in part manifest  
172 itself as a displacement error, based on the instrument response to its background value, and in part as a  
173 proportional bias if its concentration correlates with the target compounds, with any short-term deviations from  
174 perfect correlation contributing to the random error component. In this case, time-averaging combined with  
175 periodic calibrations and zeros would not necessarily minimise the error, and the user would need to employ  
176 different tactics. One option would be to independently measure the interferent concentration, albeit with  
177 associated uncertainty, and then use this to derive a correction. This is feasible if a simple and cost-effective  
178 method exists for quantifying the interferent and its influence on the result is understood, but can make it very  
179 difficult to separate out error sources, and can become increasingly complex if this measurement also suffers from  
180 other interferences.

181 For many measurement devices, in particular for LCS based instruments, a major challenge is that the sources and  
182 nature of all the errors are unknown or difficult to quantify across all possible end-use applications, meaning  
183 estimates of measurement uncertainty are difficult. In the case of most established research and reference-grade  
184 measurement techniques, comprehensive laboratory and field experiments have been used to explore the nature  
185 of the measurement errors (Gerboles et al., 2003; Zucco et al., 2003). Calibrations have then been developed,  
186 where traceable standards are sampled and measurement bias, both constant and proportional, can be corrected  
187 for. Interferences from variables such as temperature, humidity, or other gases, have also been identified and then  
188 either a solution engineered to minimise their effect or robust data corrections derived. Unfortunately, these  
189 approaches have been shown not to perform well in the assessment of LCS measurement errors, due to the  
190 presence of multiple, potentially unknown, sensor interferences from other atmospheric constituents (Thompson  
191 & Ellison, 2005). These significant sensitivities to constituents such as water vapour and other gases mean  
192 laboratory-based calibrations of LCS become exceedingly complex, and expensive, as they attempt to simulate  
193 the true atmospheric complexity, often resulting in observed errors being very different to real-world sampling  
194 (Rai et al., 2017; Williams, 2020). This has resulted in collocation calibration becoming the accepted method for  
195 characterising LCS measurement uncertainties (De Vito et al., 2020; Masson et al., 2015; Mead et al., 2013;  
196 Popoola et al., 2016; Sun et al., 2017), where sensor devices are run alongside traditional reference measurement  
197 systems for a period of time, and statistical corrections derived to minimise the error between the two. As the true

198 value of a pollutant concentration cannot be known, this collocation approach assumes all the error is in the low-  
199 cost measurement. Although this assumption may often be approximately valid (i.e. reference error variance  $\ll$   
200 LCS error variance), no measurement is absent of uncertainty and this can be transferred from one measurement  
201 to another, obscuring attempts to identify its sources and characteristics. A further consideration when the fast  
202 time-response aspect of LCS data is important, is that reference measurement uncertainties are generally  
203 characterised at significantly lower reported measurement frequencies (typically 1 hr). This means that a high  
204 time-resolution (e.g. 1 min) reference uncertainty must be characterised in order to accurately estimate the LCS  
205 uncertainty (requiring specific experiments and additional costs). If a lower time-resolution reference data set is  
206 used as a proxy, then the natural variability timescales of the target compound should be known and any impact  
207 of this on the reported uncertainty caveated.

208 Another challenge with this approach is that, unlike targeted laboratory studies, real-world collocation studies at a  
209 single location, and for a limited time period, are not able to expose the measurement devices to the full range of  
210 potential sampling conditions. As many error sources are variable, both spatially and temporally, using data  
211 generated under a limited set of conditions to predict the uncertainty on future measurements is risky. Deploying  
212 a statistical model makes the tacit assumption that all factors affecting the target variable are captured by the  
213 model (and the data set used to build the model). This is very often an unrealistic demand, and in the complex  
214 multifaceted system that is atmospheric chemistry, this is extremely unlikely to be tenable, resulting in a clear  
215 potential for overfitting to the training dataset. Ultimately, however, these collocation comparisons with  
216 instruments with a well-quantified uncertainty need to be able to communicate a usable estimate of the information  
217 content of the data to end-users, so that devices can be chosen that are fit for a particular measurement purpose.

### 218 3. Methods

219 In this work, we explore measurement errors, and their impacts, using the most common single value metrics: the  
220 Coefficient of Determination or  $R^2$ , the Root Mean Squared Error or RMSE and the Mean Absolute Error or MAE  
221 (see the equation definitions in Cordero et al., 2018), ~~along with two additional widely used approaches to~~  
222 ~~visualise the error distribution across a dataset:~~. To visualise the error distribution across a dataset we have also  
223 employed two additional widely used approaches: the Bland-Altman plots (B-A) and Relative Expanded  
224 Uncertainty (REU).

225 The performance metrics provide a single value irrespective of the size of the dataset, and might appear convenient  
226 for users when comparing across devices or datasets, but can encourage over-reliance on the metric, often at the  
227 expense of looking at the data in more detail or bringing an awareness of the likely physical processes driving the  
228 error sources. On the other hand, the use of visualisations such as B-A and REU is complementary to the  
229 aforementioned metrics, with the added value that the user is now more aware of how the data looks like in an  
230 absolute and/or relative error space, allowing them to distinguish some characteristics of interest. These  
231 visualizations ~~The B-A and the REU plots~~ are indeed more laborious techniques and the interpretation can be  
232 challenging for non-experts, but they provide additional insights into the nature of the errors, not attainable by  
233 one or more combined performance metrics: while B-A plots shows the noise (dispersion of the data) and the bias  
234 effect (tendency of the data) in an absolute scale, the REU can be explicitly decomposed in the noise and bias  
235 components (see Yatkin et al., 2022).

236 In order to understand how the different tools used here show different characteristics of the error structure, some  
237 errors commonly found in LCS are examined through simulation studies. Subsequently, two real world case  
238 studies are presented: (i) LCS duplicates for NO<sub>2</sub> and PM<sub>2.5</sub> belonging to the QUANT project located in two sites  
239 -the Manchester Natural Environment Research Council (NERC) measurement Supersite, and the York Fishergate  
240 Automatic Urban and Rural Network (AURN) roadside site- and (ii) a set of duplicate reference instruments (only  
241 at Manchester Supersite). Table S1 shows the research grade instrumentation used for this study.

### 242 3.1 Visualisation tools

243 An ideal performance metric should be able to deliver not only a performance index but also an idea of the  
244 uncertainty distribution (Chai & Draxler, 2014). This is difficult to deliver through a simple numerical value, and  
245 easy to interpret visualisations of the data are often much more useful for conveying multiple aspects of data  
246 performance. Figure 2 shows the two most common data visualisation tools, the time-series plot and the regression  
247 plot. In the time series plot the instrument under analysis and the agreed reference are plotted together as a function  
248 of time. This allows a user to visually assess tendencies of over or under prediction, differences in the base line  
249 or other issues, but can be readily over interpreted and does not allow for easy quantification of the observed  
250 errors. In the regression plot the data from the instrument under analysis is plotted against the agreed reference  
251 data. This allows for the correlation between the two methods to be more readily interpreted, in particular any  
252 deviations from linearity, but gives little detail on the nature of the errors themselves.

253 In contrast to the regression plot -where the measured values from the two measurements (e.g. LCS vs Ref) are  
254 plotted against each other- the Bland-Altman plots essentially display the difference between measurements  
255 (abscissa) as a function of the average measurement (ordinate), enabling more information on the nature of the  
256 error to be communicated. This direct visualisation of the absolute error acknowledges that the true value is  
257 unknown and that both measurements have errors. The B-A plot enables the easy identification of any systematic  
258 bias between the measurements or possible outliers, and is the reason B-A plots are extensively used in analytical  
259 chemistry and biomedicine to evaluate agreement between measurement methods (Doğan, 2018). The mean  
260 difference between the measurements, (represented by the blue line in the figures), is the estimated bias between  
261 the two observations. The spread of error values around this average line indicates if the error shows purely  
262 random fluctuations around this mean, or if it has structure across the observed concentration range.

~~263 In contrast to the regression plot, Bland Altman (B-A) plots essentially display the difference between  
264 measurements, enabling more information on the nature of the error to be communicated. B-A plots (Altman &  
265 Bland, 1983) are extensively used in analytical chemistry and biomedicine to evaluate the differences between  
266 two measurement techniques (Doğan, 2018). The B-A is a scatter plot, in which the abscissa represents the average  
267 of these measures (e.g. LCS and a reference measurement), acknowledging that the true value is unknown and that  
268 both measurements have errors, and the ordinate shows the difference between the two paired measurements.~~

269 In the case where all the error is assumed to be in one of the measurements, e.g. comparing a LCS to a reference  
270 grade measurement, there is an argument that the B-A abscissa could be the agreed reference value instead of the  
271 average of two measurements. However, in this work we use the average of the two values as per the traditional

272 B-A analysis. To illustrate the B-A interpretation, from the error model (Eq. (1)) we can derive the following  
273 expression:

$$274 \quad y_i - x_i = x_i (b_1 - 1) + b_0 + \varepsilon \quad (2)$$

275 From Eq. (2) it can be seen that if  $b_1 \neq 1$  or if the error term ( $\varepsilon$ ) variance is non-constant (e.g. heteroscedasticity)  
276 the difference will not be normally distributed. The B-A plot (with  $x_i$  as the reference instrument results) allows a  
277 quick visual assessment of the error distribution without the need to calculate the model parameters. In the case  
278 the differences are normally distributed, the so-called “agreement interval” (usually defined as  $\pm 2\sigma$  around the  
279 mean) will hold 95% of the data points. Even though the estimated limits of agreement will be biased if the  
280 differences are not normally distributed, it can still be a valuable indicator of agreement between the two  
281 measurements.

282 If the ultimate goal of studying measurement errors is to diagnose the measurement uncertainty in a particular  
283 target measurement range, then visualising the uncertainty in pollutant concentration space can be very  
284 informative. The REU (GDE, 2010) provides a relative measure of the uncertainty interval about the measurement  
285 within which the true value can be confidently asserted to lie. The abscissa in an REU plot represents the agreed  
286 reference pollutant concentration, whose error is taken into account, something not considered by the other metrics  
287 or visualisations discussed. The REU is regularly used to assess measurement compliance with the Data Quality  
288 Objective (DQO) of the European Air Quality Directive 2008/50/EC, and is mandatory for the demonstration of  
289 equivalence of methods other than the EU reference methods. For LCS the REU is widely used as a performance  
290 indicator (Bagkis et al., 2021; Bigi et al., 2018; Castell et al., 2017; Cordero et al., 2018; Spinelle et al., 2015).  
291 However, the evaluation of this metric is perceived as arduous and cumbersome and it is not included in the  
292 majority of sensor studies (Karagulian et al., 2019). There is now a new published European Technical  
293 Specification (TS) for evaluating the LCS performance for gaseous pollutants (CEN/TS 17660-1:2021). It  
294 categorises the devices in 3 classes according to the DQO (Class 1 for “indicative measurements”, Class 2 for  
295 “objective estimations”, and Class 3 for non-regulatory purposes, e.g. research, education, citizen science, etc.).  
296 In the following sections, we use these established methods for assessing measurement uncertainty, alongside  
297 simple time series and regression plots, to explore different error sources and their implications for air pollution  
298 measurements.

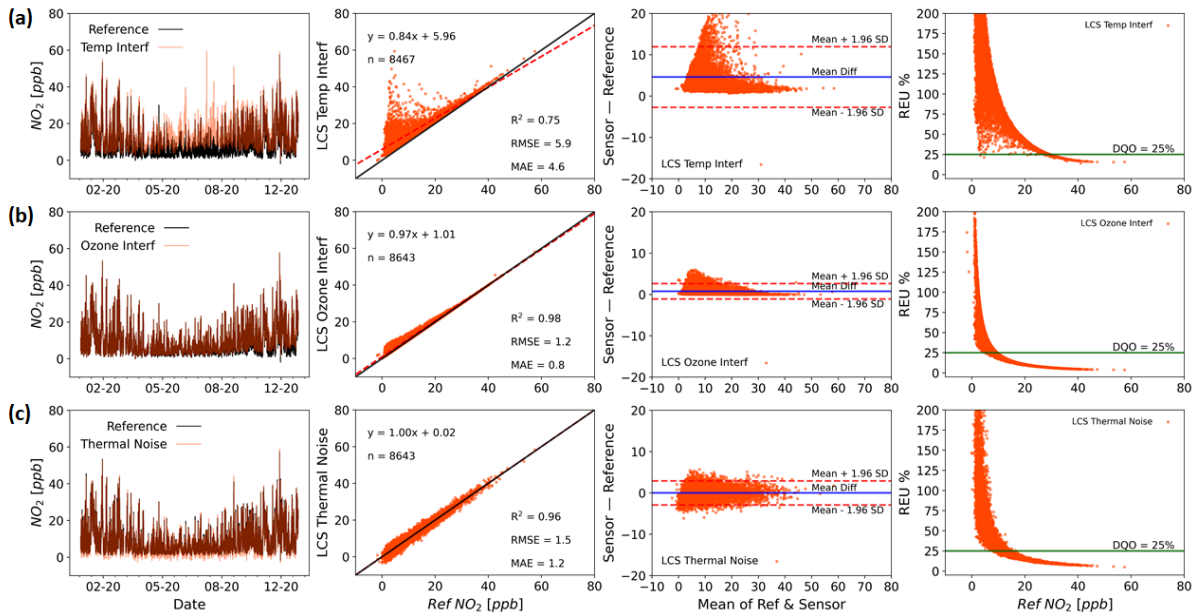

## 299 **4. Case studies**

### 300 **4.1 Simulated instruments**

301 In order to investigate the impact of different origins of measurement error on measurement performance, a set of  
302 simulated datasets have been created. These data are derived using real-world reference data as the true values,  
303 with the subsequent addition of errors of different origins to generate the simulated measurement data. Error  
304 origins were chosen for which examples have been described in the LCS literature. Performance metrics along  
305 with visualisation methods are then used to assess measurement performance.

306 As the complexity of the error increases, the impact of the assumption of statistical stationarity can become more  
307 difficult to satisfy, with the magnitude of the errors becoming less uniform across the observed concentration, and

308 hence spatial, or time domains. Figure 3 shows examples of modelled sources of errors on NO<sub>2</sub> measurements:  
 309 temperature interference (correction model taken from (Popoola et al., 2016), a-panels), a non-target gas (ozone)  
 310 interference (correction model taken from (Peters et al., 2021), b-panels) and thermal electrical noise (white noise,  
 311 c-panels).

312  
 313 **Figure 3. Time series (left panels), regression plots (middle-left panels, including R<sup>2</sup>, RMSE & MAE), Bland-Altman**  
 314 **plots (middle-right panels) and REU (right panels, DQO for NO<sub>2</sub> = 25%) for temperature (a-panels), ozone (b-panels)**  
 315 **and thermal electrical noise (c-panels) modelled interferences on NO<sub>2</sub> measurements (time res 1 h).**

316 The above simulations show examples of how individual sources of error can impact measurement performance.  
 317 Figure S1 shows some more examples, this time for different drift effects (baseline drift, temperature interference  
 318 drift and instrument sensitivity drift). This set of error origins is not exhaustive, with countless others potentially  
 319 impacting the measurement, such as those coming from (i) hardware (sensor-production variability, sampling,  
 320 thermal effects due to materials expansion, drift due to ageing, RTC lag, Analog-to-Digital conversion,  
 321 electromagnetic interference, etc.), (ii) software (signal sampling frequency, signal-to-concentration conversion,  
 322 concept drift, etc.), (iii) sensor technology/measurement method (selectivity, sensitivity, environmental  
 323 interferences, etc.) and (iv) local effects (spatio-temporal variation of concentrations, turbulence, sampling issues  
 324 etc.).

325 Each error source impacts the uncertainty of the measurement, which in turn impacts its ability to provide useful  
 326 information for a particular task. For example, the form of the temperature interference shown in Fig. 3 (a-panels)  
 327 results in the largest errors being seen at the lower NO<sub>2</sub> values. This is because NO<sub>2</sub> concentrations are generally  
 328 lowest during the day, due to photolytic loss when temperatures are highest. Thus this device would be better  
 329 suited to an end-user intending to assess daily peak NO<sub>2</sub> concentration compared with the daytime hourly exposure  
 330 values, providing the environment the device was deployed in showed a similar relationship between temperature  
 331 and true NO<sub>2</sub> as that used here. The O<sub>3</sub> interference shown in Fig. 3 (b-panels) is similar, due again to a general  
 332 anti-correlation observed between ambient O<sub>3</sub> and NO<sub>2</sub> concentrations. This type of interference can often be

333 interpreted incorrectly as a proportional bias, and a slope correction applied to the data. However, this type of  
 334 correction will ultimately fail as O<sub>3</sub> concentrations are dependent on a range of factors, such as hydrocarbon  
 335 concentrations and solar radiation, and as these change the O<sub>3</sub> concentration relative to the NO<sub>2</sub> concentration will  
 336 change. To further complicate matters, multiple error sources can act simultaneously, meaning that the majority  
 337 of measurements will contain multiple sources of error. Figure 4 shows a simple linear combination of the  
 338 modelled errors shown in Fig 3, and the impact this has on the performance metrics.

339  
 340 **Figure 4. Time series (left panel), regression plot (middle-left panel, including R<sup>2</sup>, RMSE & MAE), Bland-Altman**  
 341 **plot (middle-right panel) and REU (right panel, DQO for NO<sub>2</sub> = 25%) for a linear combination of temperature, ozone**  
 342 **and thermal electrical noise modelled interferences (time res 1 h).**

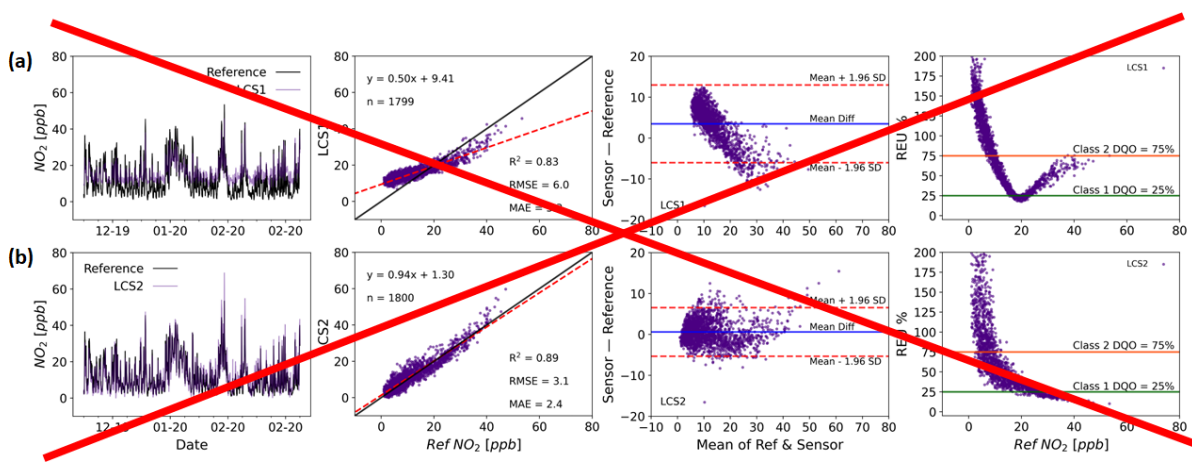

343 As the simulations show, the nature of the errors determine the observed effect on the measurement performance.  
 344 In an ideal situation, like those shown in figures 3 and 4, the error sources would be well characterised, allowing  
 345 the error to be modelled and approaches such as calibrations (for bias) and smoothing (for random errors)  
 346 employed to minimise the total uncertainty. Unfortunately, in scenarios where sources of error and their  
 347 characteristics are not known, modelling the error becomes more difficult and a more empirical approach to  
 348 assessing the measurement performance and uncertainty may be required. The growing use of LCS represents a  
 349 particular challenge in this regard. The susceptibility of LCS to multiple, often unknown or poorly characterised,  
 350 error sources means that in order to determine if a particular LCS is able to provide data with the required level  
 351 of uncertainty for a given task, a relevant uncertainty assessment is required. The following section explores the  
 352 uncertainty characteristics of several LCS, with unknown error sources, deployed alongside reference  
 353 instrumentation in UK urban environments as part of the QUANT study.

#### 354 4.2 Real-world instruments

355 The difficulty in generating representative laboratory error characterisation data means for many measurement  
 356 devices the error sources are essentially unknown. This, combined with the use of imperfect algorithms that are  
 357 not available to the end-user (i.e. “black-box” models) to minimise errors, means that, collocation data is often the  
 358 best option available to end-users in order to assess the applicability of a measurement method for their desired  
 359 purpose. This is particularly the case for LCS air pollution measurement devices. In this section, we show  
 360 collocation data collected as part of the UK Clean Air program funded QUANT project, and use the tools described  
 361 above to investigate the impact of the observed errors on end-use.

362 ~~Figure 5 shows two colocated NO<sub>2</sub> measurements, from two different LCS devices using only their out of box~~  
 363 ~~calibrations (i.e. no collocation data from that site was used to improve performance), compared with colocated~~  
 364 ~~reference measurements at an urban background site in the city of Manchester. Unlike the modelled instruments~~  
 365 ~~in Sect. 4.1, the combination of error sources is unknown in this case and we can thus only assess the LCS~~

366 measurement performance through comparison with the reference measurements using metrics and visual tools.  
 367 There are obvious differences in the performance of both LCS instruments shown in Fig. 5. LCS1 (a panels)  
 368 shows an appreciable difference in the time series baseline, which can be interpreted from both the regression (b1  
 369  $< 1$ ) and the B-A plots as a proportional bias. This bias also impacts the REU plot, with a minimum in the region  
 370 where the regression best fit line crosses the 1:1 line ( $\sim 17$ ppb). It is worth noting that these plots do not directly  
 371 identify the source of the proportional bias, with sensor response to the target compound or another covarying  
 372 compound possible, but provides information on how much it impacts the data. For LCS2 (Fig. 5, b panels) any  
 373 proportional bias is significantly smaller, with the B-A plot showing a much more symmetrical distribution of  
 374 points around the central line across the observed mixing ratio range, although this is not a normal distribution as  
 375 evidenced by the heteroscedastic nature of the differences, indicating the cause is not entirely random in nature.  
 376 The lack of a large proportional bias also results in the REU plot showing a continued reduction in relative  
 377 uncertainty as the true NO<sub>2</sub> concentration increases. Interestingly, both LCS's also show an additional bias at the  
 378 highest NO<sub>2</sub> values observed. This does not significantly impact the REU, due to its relative nature, but can be  
 379 seen in the regression and B-A plots. Correcting for the observed proportional bias in LCS1 and LCS2 improves  
 380 the observed performance by providing the errors with a more symmetrical distribution (LCS1\* and LCS2\* shown  
 381 in Fig. S2).

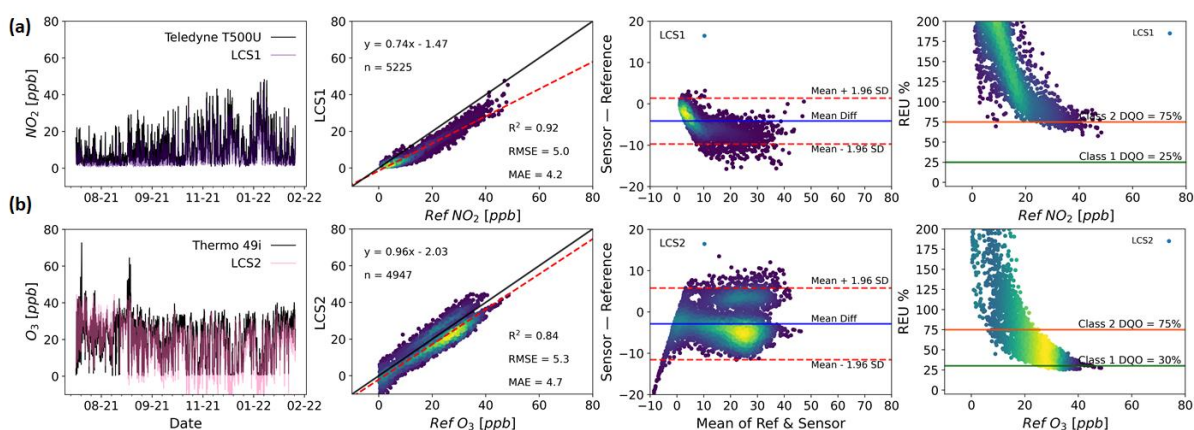

382  
 383 **Figure 5. Time series (left panels), regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and**  
 384 **REU (right panels; NO<sub>2</sub>-Class 1 DQO = 25% & Class 2 DQO = 75%) for NO<sub>2</sub> measurements by two LCS systems of**  
 385 **different brands (a and b panels) in the same location (Manchester Supersite, December 2019 to February 2020. Time**  
 386 **res 1 h).**

387 Figure 5 shows two colocated measurements from two different LCS devices: one measuring NO<sub>2</sub> (a-panels) and  
 388 the other O<sub>3</sub> (b-panels). Both measurements are compared with colocated reference measurements at an urban  
 389 background site in the city of Manchester. Unlike the modelled instruments in Sect. 4.1, the combination of error  
 390 sources is unknown in this case, and we can thus only assess the LCS measurement performance through  
 391 comparison with the reference measurements using global metrics and visual tools.

392 Single value metrics indicate an acceptable performance for both measurements: high linearity (both R<sup>2</sup> are higher  
 393 than 0.8) and relatively low errors (RMSE  $\sim$  5ppb). However, the plots present the data in a variety of ways that  
 394 enable the user to identify patterns in the measurement errors that would be less obvious if only global metrics

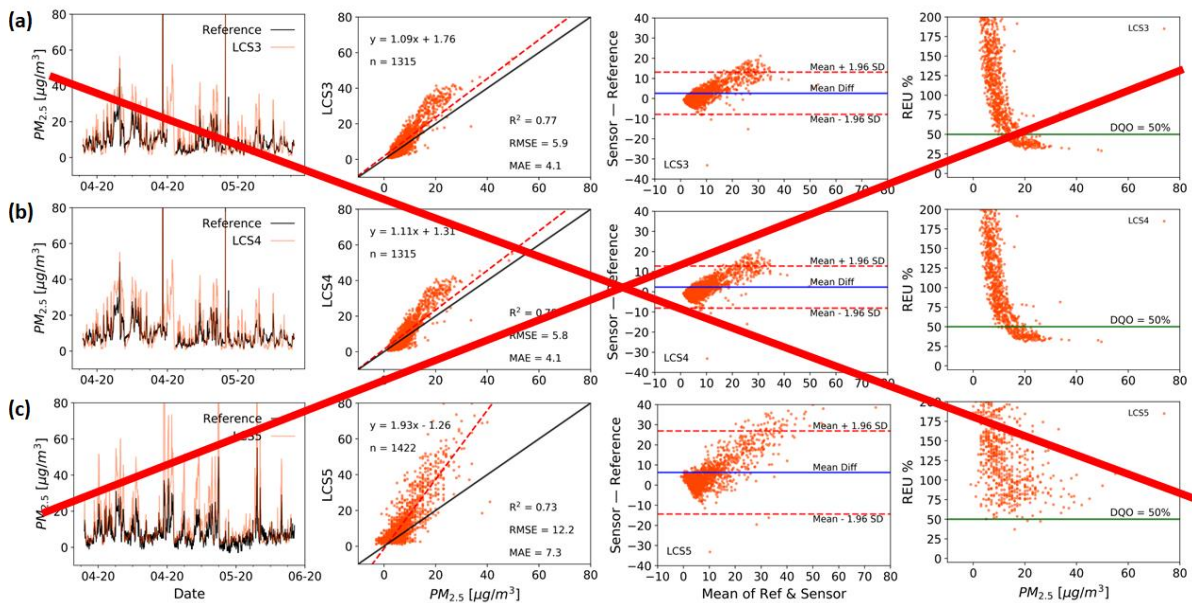

395 were used. For example, the NO<sub>2</sub> sensor (LCS1, a-panels) has a non-linear response that is almost imperceptible  
 396 from the regression plot but stands out in the B-A plot. Furthermore (despite the high R<sup>2</sup> and relatively low  
 397 RMSE), the REU plot shows high relative errors that do not meet the Class 2 DQO for the measured concentration  
 398 range. Regarding the O<sub>3</sub> sensor (LCS2, b-panels), the B-A plot shows two high density measurement clusters, one  
 399 with positive absolute errors (over-measuring) and a larger one with negative errors (under-measuring). These are  
 400 the result of a step change in the correction algorithm applied by the manufacturer and could easily have been  
 401 missed if only summary metrics and a regression plot were used, especially if the density of the data points was  
 402 not coloured.

403 It is worth noting that these plots do not directly identify the source of the proportional bias, with sensor response  
 404 to the target compound or another covarying compound possible, but provides information on how much it impacts  
 405 the data.

406  
 407 **Figure 5. Time series (left panels), regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and**  
 408 **REU (right panels; NO<sub>2</sub> Class 1 DQO = 25% & Class 2 DQO = 75% ; O<sub>3</sub> Class 1 DQO = 30% & Class 2 DQO = 75%)**  
 409 **for NO<sub>2</sub> (a-panels) and O<sub>3</sub> (b-panels) measurements by two LCS systems of different brands in the same location and**  
 410 **time span (Manchester Supersite, July 2021 to February 2022. Time res 1 h). All but the time-series plots, have coloured**  
 411 **by data density.**

412 ~~Figure 6 shows three out of the box PM<sub>2.5</sub> measurements made by three devices from the same brand in spring,~~  
 413 ~~located at two sites: the first two at an urban background (LCS3 & LCS4, a and b panels) and the third at a roadside~~  
 414 ~~(LCS5, c panels). As the regression and the B-A plots show, all LCS measurements in Fig. 6 have a proportional~~  
 415 ~~bias compared with the reference, with the LCS over predicting the reference values. Both LCS's at the urban~~  
 416 ~~background site show very similar performance, indicating that the devices are similarly affected by errors. This~~  
 417 ~~internal consistency is highly desirable, especially when LCS's are to be deployed in networks, as although mean~~  
 418 ~~absolute measurement error may be high, differences between identical devices are likely to be interpretable.~~

419  
420  
421  
422  
423

**Figure 6. Time series (left panels), regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and REU (right panels, DQO for  $PM_{2.5} = 50\%$ ) for  $PM_{2.5}$  measurements by three LCS systems of the same brand (panels a, b and c) in different locations: an urban background (Manchester Supersite, panels a and b) and a roadside site (York, panel c) (April & May 2020, time res 1 h).**

424  
425  
426  
427

Figure 6 shows three out-of-the-box  $PM_{2.5}$  measurements made by two devices (LCS3 & LCS4) from the same brand in spring (LCS3: a-panels; LCS4: c-panels) and in autumn (b-panels, only LCS3). The collocation shown correspond to two different sites: an urban background site (LCS3, a and c-panels) and a roadside site (LCS4, c-panels).

428  
429  
430  
431  
432  
433  
434  
435

As the regression and the B-A plots show, all LCS measurements in Fig. 6 have a proportional bias compared with the reference, with the LCS over predicting the reference values. The device at the urban background site (LCS3) show a dissimilar performance in spring and autumn, indicating that the errors this device suffers are differently influenced by local conditions in the two seasons (all the duplicates at the urban background show the same pattern). While for LCS3 during spring the error have a more linear behaviour, in autumn a non-linear pattern is clearly observed in the regression and B-A plots. Despite the utility that single metrics can have in certain circumstances, the non-linear pattern goes completely unnoticed by them: while for the two different seasons RMSE and the MAE are almost constant the  $R^2$  indicates a higher linearity for autumn.

436  
437  
438  
439

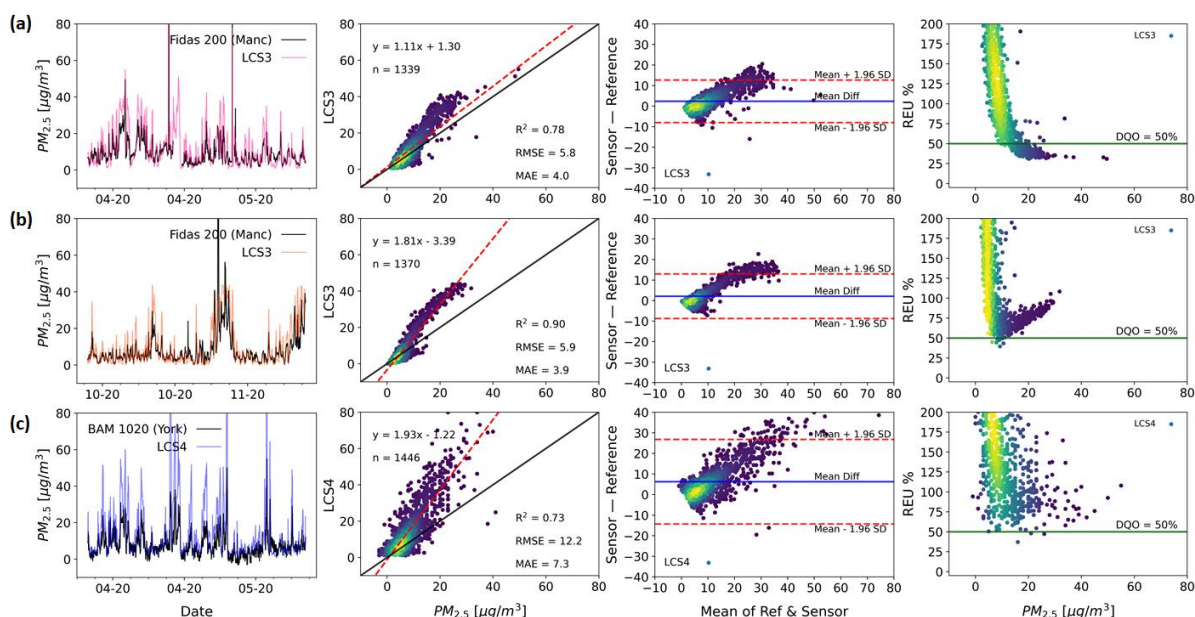

A number of duplicates were deployed at both sites showing a very similar performance in terms of the single metric values but also in regard to the more visual tools (not shown here). This internal consistency is highly desirable, especially when LCS's are to be deployed in networks, as although mean absolute measurement error may be high, differences between identical devices are likely to be interpretable.

440  
441  
442  
443  
444

Having prior knowledge of the nature of the measurement errors allows informed experimental design prior to data collection. This is key if an end user is to maximise the power of a dataset, and the information it provides, to answer a specific question. For example, if an end-user wanted to identify pollution hotspots within a relatively small geographical area, then using a dense network of sensor devices that posses errors large and variable enough to make quantitative comparisons with limit values difficult (possibly due to an interference from a physical

445 parameter like relative humidity) but show internal consistency could be a viable option. Providing the hotspot  
 446 signal is large enough relative to any random error magnitude.

447

448  
 449 **Figure 6. Two LCS systems (LCS3 & LCS4, same brand) measuring PM<sub>2.5</sub> (Time res 1 h). While LCS3 is shown for**  
 450 **the same location (Manchester) but unfolded in two different seasons (a-panels: Apr to May 2020; b-panels: Oct to Nov**  
 451 **2020), LCS4 is at a different location (c-panels: York, Apr to May 2020). Time series (left panels), regression plots**  
 452 **(middle-left panels), Bland-Altman plots (middle-right panels) and REU (right panels; DQO<sub>PM<sub>2.5</sub></sub> = 50%) are used to**  
 453 **characterise the device's error structure. All but the time-series plots have been coloured by data density.**

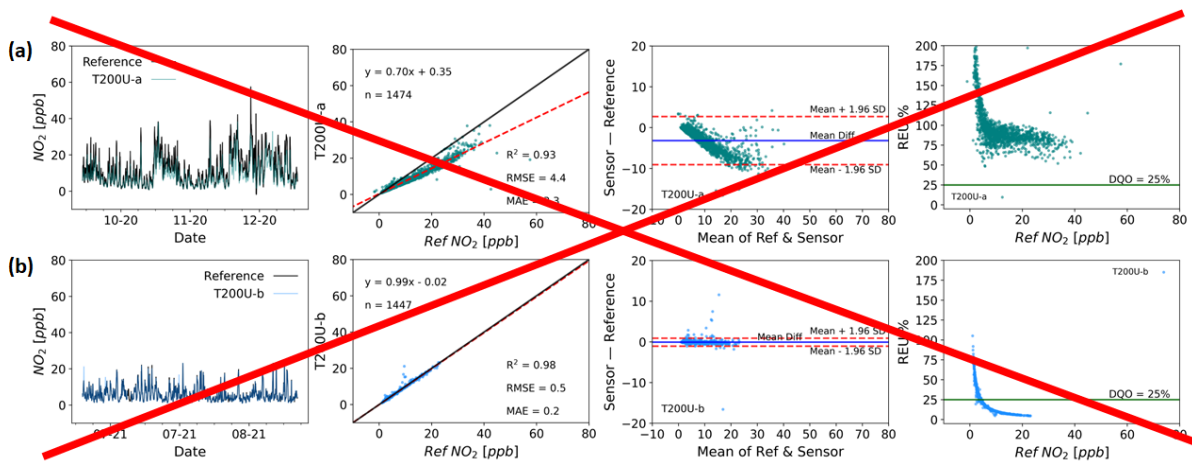

454  
 455 The LCS data from the roadside location (LCS4) show significantly lower precision than those at the urban  
 456 background site, as seen in the B-A plot. This could be caused by differences in particle properties and size  
 457 distributions between the two sites (Gramsch et al., 2021), and by the high frequency variation of transport  
 458 emissions close to the roadside ~~site side~~ and turbulence effects (Baldauf et al., 2009; Makar et al., 2021). Duplicate  
 459 measurements show that all sensors of this type responded similarly in this roadside environment (not shown  
 460 here), supporting the high internal consistency of this device, but indicating a spatial heterogeneity in some key  
 461 error sources. It is also worth noting that the gold standard instruments at the two sites are not “reference method”  
 462 but “reference equivalent methods” (GDE, 2010), each using a different measurement technique: while an optical  
 463 spectrometer (Palas Fidas 200) is used in Manchester, the York instrument uses a Beta attenuation method (Met  
 464 One BAM 1020), which could also potentially lead to some of the observed differences. The increased apparent  
 465 random variability for LCS4, combined with the proportional bias, results in significantly higher measurement  
 466 uncertainty across the observed range, as can be seen by the REU plots, with LCS4 never reaching an acceptable  
 467 DQO level (50% for PM<sub>2.5</sub>). **As with the NO<sub>2</sub> sensors (Fig. 5).** If the observed proportional bias is corrected the  
 468 linearly bias-corrected sensors (Fig. S3) show a much improved comparison with the reference measurement,  
 469 specially **LCS3\* in autumn and LCS4\*.** The error distribution for the LCS3 (autumn) shown by the B-A plot is

470 greatly narrowed (~3x times) and now the sensor is accomplishing the DQO below  $10 \mu\text{g m}^{-3}$  as the REU plot  
 471 indicates. For LCS4 In this case the B-A plot shows an error characteristic more dominated by random errors, and  
 472 the REU plots shows a significant reduction of the relative uncertainty, with the REU at  $10 \mu\text{g m}^{-3}$  reducing from  
 473 ~75 to ~50%.

474 As a comparison for the LCS data shown above, Fig. 7 shows two identical  $\text{NO}_2$  reference grade instruments,  
 475 Teledyne T200U (Chemiluminescence method) at the Manchester urban background site (panels a and b) during  
 476 two different time periods, with a Teledyne T500U (CAPS detection method) used as the “ground truth”  
 477 instrument. Instrument “a” manifests a significant proportional bias, in contrast to instrument “b”, but both show  
 478 differences that could be non-negligible depending on the application. The deviations observed in instrument “a”  
 479 was due to the cell pressure being above specification by ~20%, unnoticed while the instrument was in operation.  
 480 This demonstrates the importance of checking instrument parameters regularly in the field even if the data appears  
 481 reasonable.

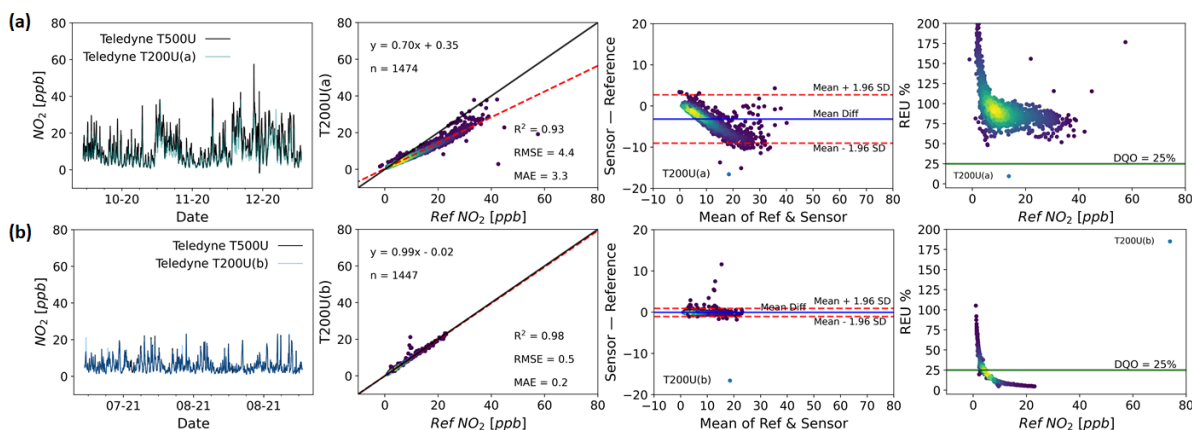

482 As the LCS error structure is determined relative to the performance of a reference measurement, if the reference  
 483 instrument suffers from significant errors this will affect the outcomes of the performance assessment, due to the  
 484 assumption that all the errors reside with the LCS. As Fig. 7 shows, however, this assumption is not necessarily  
 485 always valid and potentially argues that reference instruments used in collocation studies should be subject to  
 486 further error characterisation, including possible collocation with other reference instruments. As a similar  
 487 comparison of reference instruments, Fig. S3 shows two ozone research grade instruments (a Thermo 49i and a  
 488 2B).

489 It is worth noting that even when using reference, or reference equivalent, grade instrumentation, inherent  
 490 measurement errors mean that relative uncertainty, as shown in the REU plot, increases asymptotically at lower  
 491 values. This is not unexpected, but is potentially important as ambient target concentration recommendations  
 492 continue to fall based on updated health evidence (World Health Organization, 2021).

493

494

495 **Figure 7. Time series (left panel), regression plots (middle-left panel), Bland-Altman plots (middle-right panel) and**  
 496 **REU (right panel, DQO for NO<sub>2</sub> = 25%) for two identical (Teledyne T200U) reference NO<sub>2</sub> instruments (panels a and**  
 497 **b) colocated at the Manchester Supersite (1h time res). The first instrument between October & November 2020 and**  
 498 **the second between July & August 2021. All but the time-series plots have been coloured by data density.**

499 **5. Discussion**

500 The widespread use of collocation studies to assess measurement device performance, means many examples exist  
 501 in the LCS literature where different devices are compared using summary metrics for field or laboratory studies  
 502 (Broday, 2017; Duvall et al., 2016; Hofman et al., 2022; Karagulian et al., 2019; Mueller et al., 2017; Rai et al.,  
 503 2017; van Zoest et al., 2019). Although these comparisons do provide useful information, they can be misleading  
 504 for end users wanting to compare the performance of different devices, as they are often carried out under different  
 505 conditions and do not present the data or experimental design in full. Even in the case where comparisons have  
 506 been done under identical conditions, the data still needs to be treated with caution, as inevitable differences  
 507 between assessment environment and proposed application environment, as well as any changes to  
 508 instrument/sensor design or data processing, mean that past performance does not guarantee future performance.

509 All measurement devices suffer from measurement errors, many of which are potentially significant depending  
 510 on the application, with devices and their error susceptibility covering a broad spectrum. As evidenced by Fig. 7,  
 511 reference instruments are not immune from this phenomena, with the proportional bias of one of the NO<sub>x</sub>  
 512 instruments clearly affecting its measurements resulting in the absolute error increasing with concentration. As  
 513 the requirements on measurement devices continue to increase, driven in part by new evidence supporting the  
 514 reduction of air pollutant target values, the devices currently being used for a particular application could no longer  
 515 be fit-for-purpose in the situation where the limit value has decreased to the point where it is small relative to the  
 516 device's uncertainty.

517 Single value performance metrics, such as R<sup>2</sup> and RMSE, can seem convenient when comparing multiple co-  
 518 located devices as they facilitate decision making when a threshold criterion is defined. However, these scalar  
 519 values hide important information about the scale and / or distribution of the errors within a dataset; graphical  
 520 summaries of the measurements themselves can offer significantly more insight into the impact of measurement  
 521 errors on device performance and ultimate capabilities. Of particular use in air pollution measurements is the  
 522 ability to see how the errors manifest themselves in relation to our best estimate of the true pollutant concentration,

523 as often applications have specific target pollutant concentration ranges of interest. For example, the two  $\text{NO}_2$   
524 LCS devices shown in Fig. 5 have ~~similar  $R^2$  values of 0.83 and 0.89, but one is suffering from a strong~~  
525 ~~proportional bias that impacts on measurements either side of the 18ppb crossing point~~ considerably high  $R^2$   
526 values (0.92 and 0.84) and relatively low RMSE and MAE, but one suffering of non-linear errors (LCS1) and the  
527 other with data coming from two different calibration states (LCS2).

528 Errors, or combinations of errors, frequently result in varying magnitude of the observed measurement  
529 inaccuracies across the concentration space observed, and it is often useful to assess both the absolute and relative  
530 effects of the errors. By getting a more complete picture of the device performance, decisions can be made on the  
531 effectiveness of simple corrections, such as correcting for an apparent proportional bias using an assumption of a  
532 linear error model. Ultimately end users need to identify the data requirements a priori and design quantifiable  
533 success criteria by which to judge the data. For example, rather than just wanting to measure the 8-hour average  
534  $\text{NO}_2$ , be more specific and require that this needs to be accurate to within 5 ppb, have demonstrated approximately  
535 normally distributed errors in a representative environment for the period of interest, and no statistical evidence  
536 of deviation from a linear correlation with the reference measurement over the target concentration range for the  
537 period of interest.

538 A major challenge comes from complex errors, such as interferences from other compounds or with environmental  
539 factors, that vary temporally and/or spatially. Similar graphical techniques to those presented above can be used  
540 to identify the existence of such relationships, but correcting for them remains a challenge. ~~For example, the~~  
541 ~~correlation between measurement errors and relative humidity could be explored by replacing the abscissa with~~  
542 ~~measured relative humidity in both the B-A and REU plots. This would visualise the relationship between absolute~~  
543 ~~and relative errors with relative humidity, but would not be able to confirm causality. The complex and covarying~~  
544 ~~nature of the atmosphere means that the best way to identify a device error source is through controlled laboratory~~  
545 ~~experiments, where confounding variables can be controlled, although these experiments are often difficult and~~  
546 ~~expensive to perform in a relevant way.~~

547 This brings into question the power of colocation studies, as they can ultimately never be performed under the  
548 exact conditions for every intended application. The  $\text{PM}_{2.5}$  sensors shown in Fig. 6 demonstrate this, as if a  
549 colocation dataset generated at the urban background site was used to inform a decision about the applicability of  
550 these devices to a roadside monitoring task, then an overly optimistic assessment of the scale of the errors to be  
551 expected would be likely. It is therefore always desirable that colocation studies are as relevant as possible to the  
552 desired application, and this is even more paramount in the case where the error sources are poorly specified. For  
553 this reason, complete meta-data on the range of conditions over which a study was conducted is key information  
554 in judging its applicability to different users.

555 Although there is no strict definition on what makes a device a LCS, we often make the categorization based on  
556 the hardware used. Standard reference measurement instruments are generally based on well-characterised  
557 techniques developed and improved over years, based primarily on the progressive refinement of hardware (e.g.  
558 materials used for the detection elements, electronic circuits to filter noise, refinement of production methods,  
559 etc.). Although LCS sensor technologies are improving, it is interesting that many of the significant improvements  
560 that have been made to LCS performance have been through software, rather than hardware advances. As more

561 colocation data ~~are~~ ~~is~~ generated in different environments, many LCS manufacturers have been able to develop  
562 data correction algorithms that minimise the scale of the errors that are present on the LCS hardware. This can  
563 greatly improve the performance of LCS devices, and has been a large factor in the improvements seen in these  
564 devices over recent years. These algorithms are, however, inevitably imperfect and can suffer from concept drift  
565 (De Vito et al., 2020), caused by the lack of available colocation data over a full spectrum of atmospheric  
566 complexity. Furthermore, any kind of statistical model introduces a new error source that can work in conjunction  
567 with the pre-existing measurement errors to drastically change the observed error characteristics, making it much  
568 more difficult for users to interpret and extrapolate from colocation study performance to intended application. ~~If~~  
569 ~~end users are to be able to make well informed decisions about device applicability to a particular task, then an~~  
570 ~~argument can be made for information on the scale of the error corrections made to a reported measurement to be~~  
571 ~~made available, ideally alongside and a demonstration of its benefits in a relevant environment.~~ If end users are  
572 to be able to make well informed decisions about device applicability then information on the scale of the  
573 measurement errors, and the impact of corrections made to minimise these, should be made available. Exemplar  
574 case studies in a range of relevant environments would also be highly valuable. Unfortunately, this colocation  
575 data ~~are~~ ~~is~~ costly to generate, meaning relevant data often does not exist, and when it does is often not  
576 communicated in such a way that enables the user to make a fully informed decision.

## 577 6. Conclusions

578 In situ measurements of air pollutants are central to our ability to identify and mitigate poor air quality.  
579 Measurement applications are wide ranging, from assessing legal compliance to quantifying the impact of an  
580 intervention. The range of available measurement tools for key pollutants is also increasingly broad, with  
581 instrument price tags spreading several orders of magnitude. In order for a measurement device to be of use for a  
582 particular application it must be fit-for-purpose, with cost, useability and data quality all needing to be considered.  
583 Understanding measurement uncertainty is key in choosing the correct tool for the job, but in order for this to be  
584 assessed the job needs to be fully specified a priori. The specific data requirements of each measurement  
585 application need to be understood and a measurement solution chosen that is capable of providing data with  
586 sufficient information content.

587 In order to aid end users in extrapolating from colocation study performance to potential performance in a specific  
588 application, performance metrics are often used. Although single value performance metrics do convey some  
589 useful information about the agreement between the data from the measurement device being assessed and the  
590 reference data, they can often be misleading in their evaluation of performance. This dictates a more rigorous and  
591 empirical approach to data uncertainty assessment in order to determine if a measurement is fit for purpose. The  
592 ability to assess device performance across the observed concentration range, as in the B-A and REU plots, enables  
593 an end-user to make an informed decision about the capabilities of a measurement device in the target  
594 concentration range. These visual tools also help identify any simple corrections that can be applied to improve  
595 performance. In contrast, if an end-user was only provided with a single value metric, such as  $R^2$  or RMSE then  
596 it would be significantly more difficult to understand the likely implications of the measurement uncertainties.

597 All measurement devices suffer from errors, which result in deviations between the reported and true values.  
598 These errors can come from a multitude of sources, with the scale of the deviation from the true value being

599 dependent on the nature of the error. Although a known measurement uncertainty for all applications would be  
600 ideal for end users to be able to assess measurement device suitability for purpose, in many cases, especially for  
601 LCS, this is not possible due to the presence of poorly characterised, or sometimes unknown, error sources. In the  
602 absence of this, useful information on likely measurement performance can be obtained using colocation data  
603 compared with a measurement with a quantified uncertainty. It is important that such a colocation study is carried  
604 out in an environment as similar as possible to the application environment, as the unknown nature of many error  
605 sources means their magnitude can change significantly between different locations and/or seasons (e.g. Fig. 6).  
606 Ideally, depending on the measurement task, the user could use the colocation data to model the error causes and  
607 use this to develop strategies to minimise final measurement uncertainty. Unfortunately, relevant colocation study  
608 **are is** often not available, and to generate the data would be prohibitively costly, which limits the user's ability to  
609 make a realistic assessment of likely uncertainties. The presence of, often complex, error minimisation post  
610 processing or calibration algorithms further complicates things. This additional uncertainty is most likely to bias  
611 any performance prediction if the end user is unaware of the purpose or scale of the data corrections, and their  
612 applicability to the target environmental conditions. Ideally, long term colocation data sets demonstrating the  
613 performance of measurement hardware and software, in a range of relevant locations, over multiple seasons, and  
614 carried out by impartial bodies would be available to inform measurement solution decisions.

615 In order for end users to take full advantage of the ever increasing range of air pollution measurement devices  
616 available, the questions being asked of the data must be consummate with the information content of the data.  
617 Ultimately this information content is determined by the measurement uncertainty. Thus, providing end users with  
618 as accurate an estimate as possible of the likely measurement uncertainty, in any specific application, is essential  
619 if end users are to be able to make informed decisions. Similarly, end users must specify the data uncertainty  
620 requirements for each specific task if the correct tool for the job is to be identified. This requirement for air quality  
621 management strategies to acknowledge the capabilities of available devices, both in the setting and monitoring of  
622 limits, will only become increasingly important as target levels continue to decrease.

634 **Acknowledgements**

635 This work was funded as part of the UKRI Strategic Priorities Fund Clean Air program (NERC NE/T00195X/1),  
636 with support from Defra. We would also thank the OSCA team (Integrated Research Observation System for  
637 Clean Air) at the Manchester Air Quality Supersite (MAQS), for help in data collection for the regulatory-grade  
638 instruments. The secondary research grade instruments used here (Thermo ozone 49i, 2B Technologies 202 ozone,  
639 and Teledyne T200U NO<sub>x</sub>) are provided through the Atmospheric Measurement and Observation Facility  
640 (AMOF) and the calibrations were carried out in the COZI Laboratory, a facility housed at the Wolfson  
641 Atmospheric Chemistry Laboratories (WACL). Both funded through the National Centre for Atmospheric Science  
642 (NCAS). Special thanks to Elena Martin Arenos, Chris Anthony, Killian Murphy, Stuart Young, Steve Andrews  
643 and Jenny Hudson-Bell from WACL for the help and support to the project. Also thanks to Stuart Murray and  
644 Chris Rhodes from the Department of Chemistry Workshop for their technical assistance and advice. Thanks to  
645 Andrew Gillah and Michael Golightly from the York Council who assisted with site access.

1 **Table S1. Research grade instrumentation used for this study.**

Analyte	Manchester			York
NO <sub>2</sub>	*Teledyne T500U (CAPS)	**Teledyne T200U (Chemiluminescence)	**Teledyne T200U (Chemiluminescence)	-----
O <sub>3</sub>	*Thermo 49i (UV photometry)	**Thermo 49i (UV photometry)	**2B (UV photometry)	-----
PM <sub>2.5</sub>	-----	-----	-----	*Met One BAM 1020 (Beta attenuation)

2 \*Instruments permanently deployed at the site.

3 \*\*Instruments temporarily deployed as part of the QUANT study.

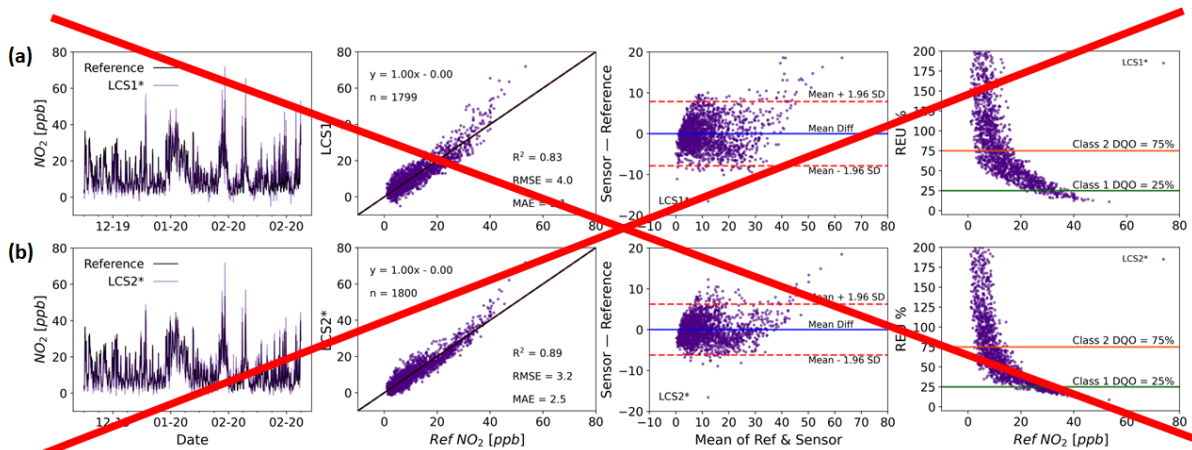

4

5

6 **Figure S1. Time series (left panels), regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and**  
 7 **REU (right panels, DQO for NO<sub>2</sub> = 25%) for baseline drift (a-panels), temperature interference drift (b-panels), and**  
 8 **instrument sensitivity drift (c-panels) simulated errors.**

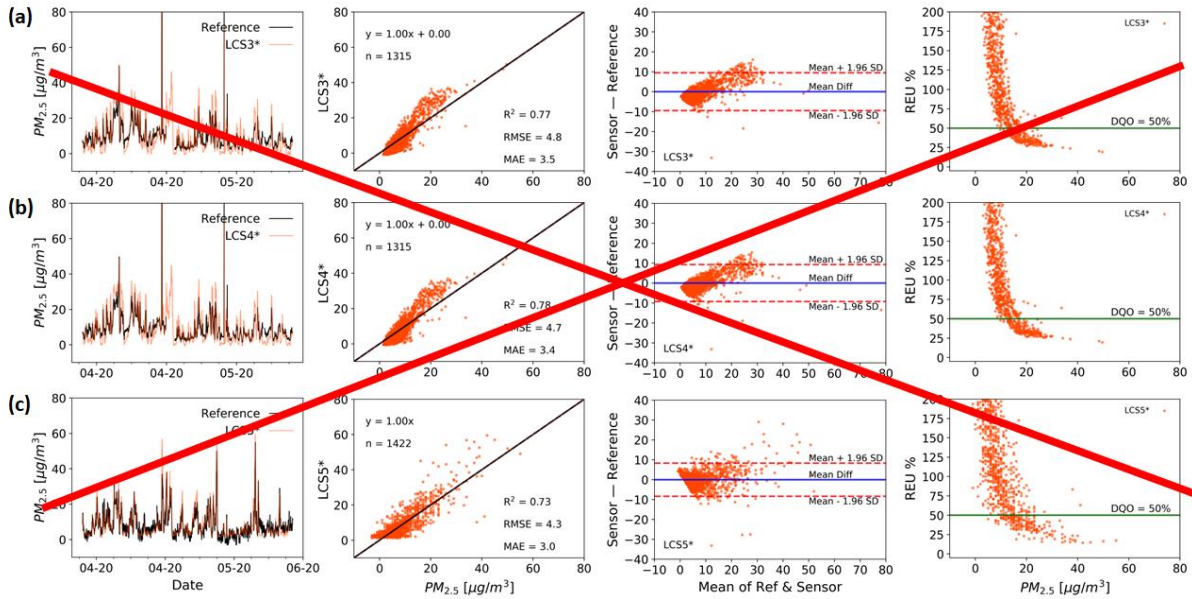

9

10

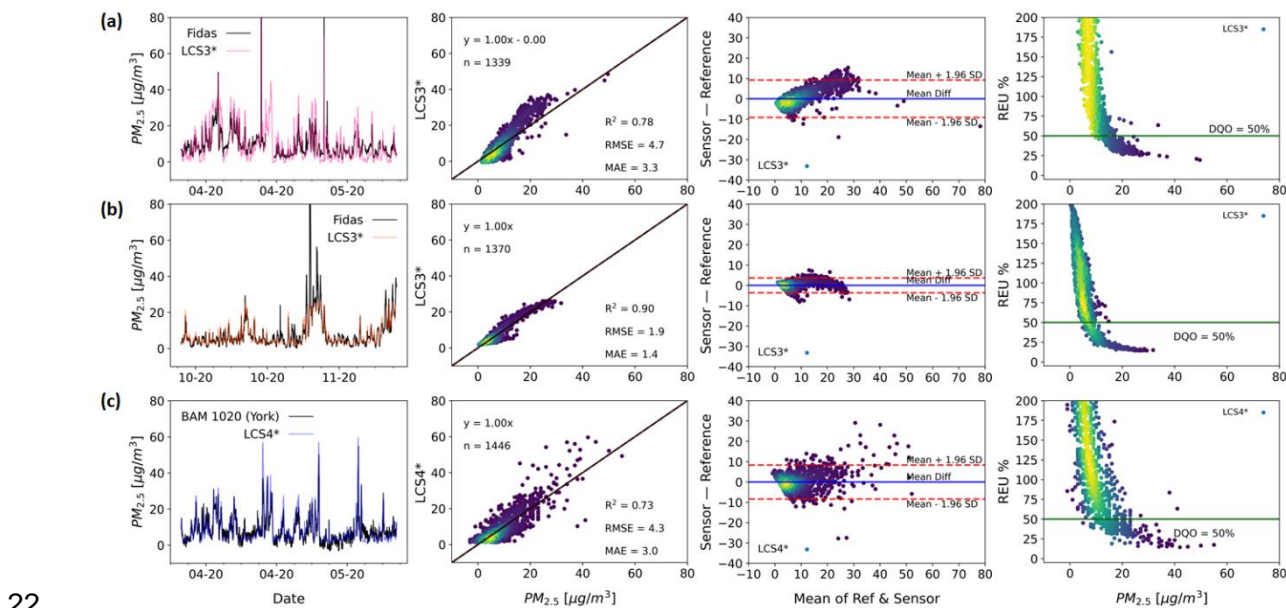

11 **Figure S2. Time series (left panels), regression plots (middle-left panels), Bland-Altman-plots (middle-right panels) and**  
 12 **REU (right panels; NO<sub>2</sub> Class 1 DQO = 25% & Class 2 DQO = 75%) for NO<sub>2</sub> measurements by two LCS bias-corrected**  
 13 **systems of different brands (panels a and b) in the same location (Manchester Supersite, December 2019 to February**  
 14 **2020, 1hr time res):**

15

16 **Figure S3. Time series (left panels), regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and**  
 17 **REU (right panels, DQO for PM<sub>2.5</sub> = 50%) for PM<sub>2.5</sub> measurements by three LCS bias-corrected systems of the same**  
 18 **brand (panels a, b and c) in different locations (April & May 2020, 1hr time res): an urban background (Manchester**  
 19 **Supersite, a and b panels) and a roadside site (York, c panels).**

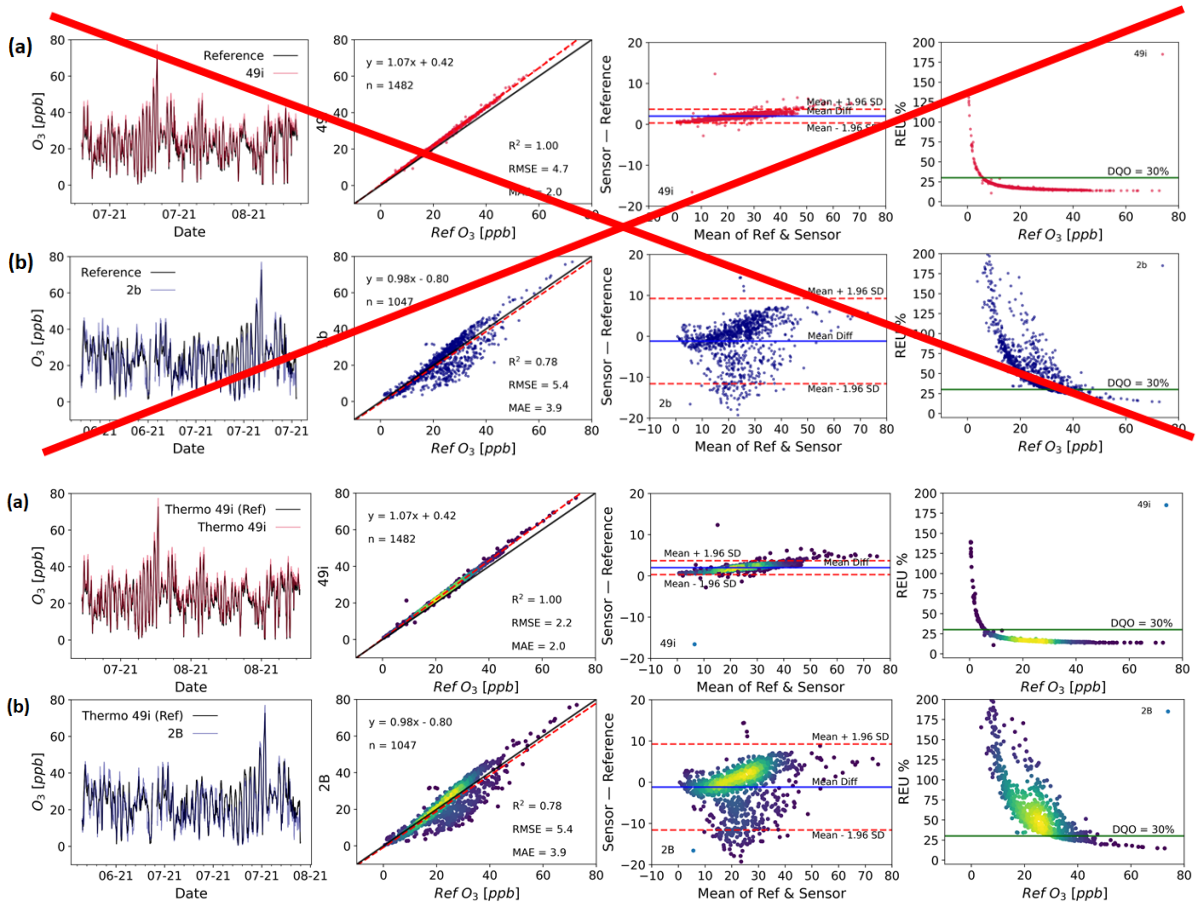

20

22 **Figure S2. Two bias corrected LCS systems (LCS3 & LCS4, same brand) measuring PM<sub>2.5</sub> (Time res 1 h). While LCS3**  
 23 **is shown for the same location (Manchester) but unfolded in two different seasons (a-panels: Apr to May 2020; b-**  
 24 **panels: Oct to Nov 2020), LCS4 is at a different location (c-panels: York, Apr to May 2020). Time series (left panels),**  
 25 **regression plots (middle-left panels), Bland-Altman plots (middle-right panels) and REU (right panels; DQO<sub>PM<sub>2.5</sub></sub> =**  
 26

27 50%) are used to characterise the device's error structure. All but the time-series plots have been coloured by data  
28 density.
