6 **Abstract.**

7 Studying precipitation at very high latitudes is difficult because of the harsh environmental conditions that limit the external
8 activity of humans and instruments, especially in the polar winter. The direct monitoring of ice crystal habits and size
9 distribution in antarctic precipitation is important for the validation of the algorithms used for retrieving precipitation from
10 ground-based and satellite-borne radar instruments, and for the improvement of the climatological modeling of polar areas.
11 The paper describes an automated device (ICE-CAMERA) specifically developed for the imaging, measurement and
12 classification of ice precipitation on the Antarctic high plateau. The instrument gives detailed information on precipitation on
13 an hourly basis. The article provides a description of the device and its image processing software. Starting in 2014, the
14 instrument operates *almost* unattended all year round at Concordia station, Antarctica (75°S, 123°E, 3220 m altitude).

15

16 **1. Introduction.**

17 In Antarctica, the characteristics of ice precipitation depend greatly on the region. In coastal areas, precipitation is influenced
18 by synoptic scale features, such as cyclones and fronts (Bromwich, 1988). In the interior (> 2500 m), a significant part of the
19 precipitation falls in the form of small ice crystals (“diamond dust”, DD) under clear-sky conditions (Fujita and Abe, 2006).
20 Snow particles over Antarctica are generally smaller compared to other regions of the world. The largest particles are found
21 close to the coast, where more water vapour is available and diameters up to 10 mm are recorded (Konishi et al., 1992) with
22 particle shapes similar to mid-latitude ones (Satow, 1983). Most of the bigger particles are aggregates (some can be found in
23 the dataset of Grazioli et al., 2022). More inland stations record snowflakes of much smaller sizes, ranging from particles
24 smaller than 100 µm at South Pole (Walden et al., 2003, Lawson et al., 2006) till hundreds of µm at other inland stations
25 (Lachlan-Cope et al., 2001).

26 In situ measurements of precipitation are rare in Antarctica and affected by large uncertainties. This is particularly true in the
27 high plateau, where less than 20 cm of snow accumulates every year (Palermo et al., 2014). As a result, the global precipitation
28 products that rely on these observations (i.e. the Global Precipitation Climatology Centre (GPCC), (Schneider et al., 2017))
29 have no coverage over this region. Other observational products, such as the Global Precipitation Climatology Project (GPCP)
30 (Huffman et al., 2001), that uses GPCC for bias correction over land, has relied on satellite-only precipitation estimates.
31 Satellite products also face large uncertainties over cold regions such as Antarctica due to insufficient sensitivity of sensors to
32 detect and estimate precipitation signals, complex surface emissivities, and poor understanding of precipitation microphysics.
33 Ground based K-band radars (~1-cm wavelength) are robust instruments successfully employed for studying precipitation in
34 coastal Antarctic sites (Souverijns et al., 2017) but are quite blind to the sub-millimetre ice particles encountered on the plateau,
35 due to the relationship D^6 between the radar scattering cross-section and the particle diameter (D).

36 The satellite-borne radar CloudSat (Liu, 2008) did provide a quantum leap in observing ice in the Antarctic atmosphere (up
37 to 82 °S), but being a single-frequency radar (like K-band radars), the retrieval of precipitation quantities relies on many
38 assumptions about the properties of particles, resulting into $\pm 50\%$ uncertainties for IWC (Heymsfield et al., 2008). The
39 microphysical assumptions (shapes and size distribution of particles) are the biggest causes for IWC, IWP, and snowfall rate
40 retrieval uncertainty (Hiley et al., 2011, Wood et al., 2015). Moreover, CloudSat bins close to the ground cannot be used for
41 precipitation retrieval, resulting into a severe underestimation of the diamond-dust and blowing-snow contribution to Antarctic
42 snow balance (Palm et al., 2018). Despite these uncertainties, in absence of ground validation CloudSat data are now used as

43 independent data set for the validation of precipitation models in Antarctica (Palermo et al.,2014, Palermo et al.,2017).
44 The direct observation and the continuous monitoring of habit and size distribution of precipitation is therefore required in
45 order to validate both precipitation models, CloudSat and radar algorithms on the Antarctic plateau.
46 Disdrometers are robust *in-situ* devices, increasingly used in Antarctic coastal areas (Souverijns et al., 2017, Bracci et al.,2022).
47 They provide the size distribution and falling speed of hydrometers, but they give no direct information about the shape. The
48 evolution of disdrometers into 2D-disdrometers gave access to some shape indications about hydrometeors (Grazioli et
49 al.,2014). A further evolution of disdrometers into Imaging-disdrometers, such as the Snowflake Video Imager (SVI) (Newman
50 et al., 2009), provided realistic images of the crystals. Grazioli et al., (2017), as part of a multidisciplinary field campaigns,
51 deployed a multi-angle snowflake camera (MASC) to take photographs of individual snow particles. This instrument,
52 representing a further advance in the field of imaging disdrometers, collects high-resolution stereoscopic photographs of
53 snowflakes in free fall while they cross the sampling area (Garrett et al., 2012), thus providing information about snowfall
54 microphysics (Praz et al., 2017). The optical structure of the imaging-disdrometer and the MASC makes these instruments
55 reliable in the presence of millimetre-sized hydrometeor precipitation. In Antarctica, their practical application is mostly
56 limited to coastal zones where particles are coarse (e.g. MASC resolution is 33 μm).
57 The direct observation of inner Antarctic particles requires imaging techniques with resolution of a few microns. Photographic
58 studies of precipitation in the interior of the Antarctic are quite rare, carried out primarily at the South Pole Station (SPS)
59 through formvar replicas. In early works with formvar, Hogan (1975) identified at SPS millimetre-sized columnar crystals and
60 column- and bullet-rosettes in cloud precipitation, and smaller ($\cong 100 \mu\text{m}$ diameter) platelike particles in clear-sky
61 precipitation. Satow (1983), working with formvar replicas on Mizuho plateau found prevalently single bullets and
62 combination of bullets. Long solid column crystals were also found (with an air temperature range from -42°C to -56°C) with
63 a mean length of 290 μm and a maximum length of 1.2 mm, with a mean aspect ratio of 18. Small (50-400 μm) hexagonal,
64 triangular, scalene and square plates were also observed. Kikuchi and Hogan (1979) collected formvar replicas of DD in the
65 summer at SPS, finding columnar crystals of 90 μm average lengths and plates as small as 50 μm in diameter. Ohtake and
66 Yogi (1979) classified winter ice crystal precipitation in Antarctica under six categories. These included large rosettes, bullets
67 and columns (millimetre-sized), thin hexagonal plates and columns (200 μm or less), and smaller crystals of various shapes
68 including triangular and polyhedral. Shimizu (1963) observed "long column" crystals in the winter at Byrd Station (80S,
69 120W). Size distributions of Antarctic DD in winter and spring were reported by Smiley et al. (1980) for particles larger than
70 50 μm : they observed the same ice crystal forms that were reported earlier. Walden et al. (2003) studied DD, blowing snow,
71 and cloud precipitation in winter, at SPS, by collecting crystals on slides and analyzing them using microphotography. In their
72 study, columns with an average length of 60 μm and plates with an average diameter of 30 μm were found in DD. The direct
73 observation of ice precipitation on the plateau was typically carried out by means of formvar replicas and/or microphotography,
74 but these techniques take time, are difficult to implement throughout the year and are necessarily limited to short field
75 campaigns and samples of very limited size. Designing automatic instruments for the continuous, photographic study of
76 precipitation in such a harsh environment necessarily require several compromises between the high resolution of
77 microphotography and the robustness of outdoor optical instruments such as disdrometers. Lawson et al. (2006) worked at
78 SPS, in summer, using innovative Cloud Particle Imagers (CPIs), which replaced formvar replicas. This technique allowed the
79 automatic analysis of around 700,000 DD crystal images in terms of caliper size, aspect ratio and other shape parameters. An
80 automatic classification software, based on shape parameters, was used to categorize the images into nine simplified classes:
81 small plates and spheroids, columns, thick plates, plates, budding rosettes, rosettes, complex with side planes, irregulars.
82 Concordia International Station, located on the Dome-C (DC, 75°S , 123°E , 3220 m above sea level) is a special location to test
83 new instruments for precipitation studies. Surface temperatures seldom exceed -25°C in summer, whereas winter temperatures
84 can reach -85°C . The 3 m average wind speed is 3 ms^{-1} for Aristidi (2005) and 4.5
85 ms^{-1} (hourly-averaged) for Argentini et al. (2014). The strongest winds (up to 15 ms^{-1} , hourly-averaged) blow from the

86 continental regions. These winds are due to gravity flows from the inner plateau regions south of Dome C, and are more often
87 observed during the winter, especially in coincidence with warming events. The circulation at the surface during the summer
88 is affected, especially in daytime, by the synoptic circulation. In summer the wind speed oscillates during the day, with values
89 increasing (by a few ms^{-1}) in the afternoon, when a convective layer develops, leading to the increase of the wind speed
90 (Argentini et al., 2014). Relative humidity relative to ice is typically around 55-85% (Genthon et al., 2022). In these conditions,
91 precipitation of ice crystals can be studied by simply collecting them on horizontal surfaces. This is done at DC by hand,
92 starting in 2008, collecting precipitation on flat surfaces ("benches") and visually inspecting it. This analysis is restricted to
93 one observation per day, a rate that is difficult to increase, especially in winter. The analysis of these samples is also time-
94 consuming and often subject to biases due to ice re-processing and sublimation, hoar formation, and subjective judgement of
95 the shape and relative abundance of ice particles. Schlosser et. al (2017) relied on this manual observation and classification
96 of ice particles in his analysis of precipitation isotope data at DC. They classified the ice grains into diamond dust, drifting
97 snow, snow and frost (hoar). The prevalence of hoar in the observed daily precipitation record (with temperatures below -
98 50°C) indicates the limitations of this manual technique if detailed information on DC precipitation particles is desired.

99 Detailed work was carried out in DC on a few individual DD and cloud precipitation crystal replicas by means of SEM electron
100 microscopy by Santachiara et al. (2016). They also analyzed very small particles (10-50 μm), in a size range inaccessible to
101 ordinary optical methods.

102 The purpose of developing ICE-CAMERA was to fill a gap in precipitation monitoring at Concordia with a robust instrument
103 capable of monitoring with continuity, all-year round, habit and size of ice particles in precipitation, while avoiding some of
104 the problems associated with the visual inspection of precipitation. This was achieved through the combined development of
105 robust camera equipment and machine learning techniques for sizing and classifying ice crystals.

106

107

108

109 2. The instrument.

110 2.1 Overview of ICE-CAMERA.

111 ICE-CAMERA is a flatbed scanner (Zheleznyak et al, 2015), whose operating principle is the same as that of ordinary
112 flatbed scanners in offices. In the case of ICE-CAMERA, it specially designed for observing polar precipitation in the harsh
113 environmental conditions of Concordia station (Fig. 1). Within this work, the term "precipitation" will include both
114 "diamond dust" and cloud precipitation.

115

116

117

118

Fig. 1: ICE-CAMERA with its summer sun-shield (left) and with the winter coat (right).

119

120 The principle is simple: at the low temperatures and low wind speeds typically encountered at DC, precipitation falling on a
121 horizontal glass surface ('deposition surface', DS) accumulates with time until it sublimates, leaving enough time for scanning
122 the glass surface for counting and measuring individual ice particles. The scanning, like in ordinary flatbed scanners, is
123 performed by means of a line-scan camera (Sect.2.2). moved by a motorized scan sledge, and looking up at the DS through a
124 45° mirror (Fig. 2). The focus of the camera is adjusted by a small motorized focusing sledge moving the 45° mirror (Sect.2.3).
125 During the scan, the image is sent to the PC, located inside the shelter.
126 After a complete scan of the DS, the glass is heated and the precipitation sublimated (section 2.7). Once cooled down, the
127 clean SD begins to accumulate new particles. This cycle takes place every hour. After each image acquisition, the MATLAB
128 image processing code is called to process the DS image, and a summary-image containing only segmented particles (if
129 present) is stored for post-processing. (Sect. 4.1.3). Every particle is also automatically measured through image processing
130 (Sect. 4.1) and classified through machine learning (Sect.4.2). Individual particle data are stored in rows in a text file, along
131 with weather and housekeeping data, for post-processing and statistical analysis.

132

133

134 **Fig. 2: ICE-CAMERA basics: the scan sledge moves the image-acquisition line along the deposition surface. The focusing sledge**
135 **adjusts the focus.**

136

137 All basic operations of ICE-CAMERA, (with the exception of CAM acquisition) are driven by a custom microprocessor
138 (Microchip PIC) logic board (Fig. 3). The same PIC board reads the housekeeping temperature sensors (attached to the DS
139 and placed inside and outside the instrument), drives the stepper motors of the sledges as well as pumps and fans. The PIC
140 Board communicates with the main computer (located inside the shelter) through RS232. NI Labview software controls image
141 acquisition, reads maintenance data, and monitors PIC operations along the RS232 line. The line-scan camera communicates
142 with the PC via Gigabit Ethernet.

143 The instrument is placed outdoor, on the roof of the "Physique" shelter, approximately 6 m above the ground.

144 ICE-CAMERA was first installed in Concordia in 2012, but replaced in 2014 with its improved version, described here.

145 From then on, the instrument works year-round to produce precipitation data, every hour. Standard meteorological data are
146 automatically obtained from local weather station AWS MILOS 520.

153 2.2 The line scan Camera.

154 A linear scanning GigE Vision monochrome camera (Schafter-Kirchoff SK7500VTF-XB (52.5 mm sensor, 7500 pixels,
 155 $7 \times 7 \mu\text{m}$ pixels, 8.2kHz line frequency), equipped with a 1:1 macro lens (APO-Rodagon D1X, f5.6) is used for the acquisition.
 156 The optics were designed by Schafter-Kirchoff in order to have a resolution equivalent to the $7 \mu\text{m}$ pixel size. The 45 deg
 157 mirror is used to look upward. The illumination is ensured by 850 nm LEDs. A colour filter (Schott RG715, 800-1000 nm
 158 band-pass) was used on the CAM lens, in order to have a fully solar blind instrument. The line-scan camera assembly is moved,
 159 hourly, by a motorized sledge at a speed of 8 mm s^{-1} in order to scan the rectangular DS ($55 \times 200 \text{ mm}$), located at the center
 160 of the window. The final image is 7500×30000 pixel, 12 bits, monochrome. A fine calibration of the actual pixel size of the
 161 DS image was achieved by scanning a calibrated grid (0.1mm spacing) placed on the DS. This is necessary because the
 162 effective resolution of the image produced by the moving linear camera along the sledge direction depends on how fast the
 163 sledge moves. After the correction of this effect, the image pixel size resulted in $6.97 \times 6.9 \mu\text{m}$, which was extremely close to
 164 the simulated size of $7 \times 7 \mu\text{m}$.

165 **2.3 The Focusing.**

166 In working conditions, the focal depth is ± 0.5 mm. A preliminary and accurate alignment of the motorized sledge plane to
167 the DS ensures uniformity of focus across the DS at room temperature. A motorized focusing sledge, moving the bending
168 mirror, allows to adjust the focus in operating conditions (Fig. 2). As ICE-CAMERA works outdoor at DC, it can
169 experience a broad internal temperature range, from $+5^{\circ}\text{C}$ in summer to -45°C in winter, with quite large temperature
170 gradients across the structure. Thermal expansion and changes in optical refractive indexes result in unpredictable changes in
171 the focal plane. The correction of the focus is thus automatically performed, every 6 hours, by bringing the measuring sledge
172 outside the DS, where a focusing spot (a sandpaper strip) is glued to the window (Fig. 4).

173

174

175 **Fig. 4: ICE-CAMERA out-of-the-box. The focus target is fixed onto the DS window**

176

177 The porous structure of the sandpaper has a length-scale of the order of 0.1 mm, comparable with the size of the measured
178 ice particles. While calibrating, the focusing sledge is moved by ± 2 mm around the actual position in 0.25 mm steps.
179 Successive images of the sandpaper are taken and their contrast (defined as the standard deviation of the intensity of the
180 pixels) is measured. After a Gaussian-fit of the contrast as a function of defocusing (Fig. 5), the position corresponding to
181 the maximum contrast is obtained, and the mirror sledge is moved into that position. The typical focal spot adjustment
182 between two consecutive calibrations is 0-0.25 mm. The calibration takes approximately 5 minutes. For this reason, it is not
183 done after each measurement, so as to save PC resources for data processing.

184

185

186

187 **Fig. 5: Typical focus calibration: Contrast is calculated in three sectors of the image: center, left and right. The contrast**
 188 **throughout the image is also displayed (red). The slight difference in focus (0.2mm) between the center of the image and the side**
 189 **wings is a normal lens effect.**

190

191 2.4 Illumination.

192 Lighting is supplied by two 850 nm LED (TSHG6200) strips. Both arrays illuminate the scan line symmetrically and
 193 approximately 45° from the optic axis in order to minimize multiple reflections in the double window and within the camera
 194 lens. Infrared illumination was chosen in order to work in solar-blind conditions. This is particularly important, as the linear
 195 scanning camera always looks upward, to the sky. The uniformity of lighting along the linear CCD image was tested by taking
 196 an image of the same sandpaper used in the focus. The intensity profile along the CCD image was measured, and the intensity
 197 of the LEDs eventually changed to have a final intensity uniformity across the entire frame of less than 15%.

198

199 2.5 The Deposition Surface (DS).

200 The DS is a 10 mm thick, electrically-heated glass (E-GLAS, Saint-Gobain). It is a sandwich with an electrically conductive
 201 layer pressed between two usual glass sheets. This glass is transparent at 850 nm, and is electrically heated with 45 V ac, 1000
 202 Wm⁻² when sublimating the ice particles. A second, 2 mm thick, optically graded glass sheet (an ordinary flatbed scanner
 203 optical glass), placed 13 mm under the DS, makes up with the DS a double window. This arrangement is necessary in order to
 204 keep the DS thermally insulated from the heated, interior of the instrument. A thermocouple is attached to the DS, while other
 205 thermocouples monitor window inter-space temperatures. A DS temperature of (at least) 3 °C above air temperature is enough
 206 to prevent the formation of frost on it in any season, as suggested by Tremblin et al., (2011) (Fig. 6).

208 **Fig. 6: ICECAMERA at -70°C, Concordia station winter: the DS is free of frost**

208

209

210

211

212 During the sublimation period (Sect.2.7), ambient air is pumped for five minutes by means of a 3.5 l m^{-1} miniature pump
 213 through the double window space, in order to keep the internal surfaces of the double window always free of frost. Using
 214 inert gases such as argon in the double window space for the same purpose proved unsuccessful in Concordia at the
 215 extremely low winter temperatures. In order to avoid the eventual accumulation of wind-drifted snow, the DS has no walls or
 216 obstacles all around. Furthermore, the instrument is located on the roof of a shelter, almost 6 meters above the ground, an
 217 altitude where blowing snow is not normally important at Concordia. Libois et al. (2014) identify drifting snow events at
 218 Dome C when the 10-m wind speed exceeds 7 m s^{-1} . Assuming a logarithmic wind speed profile between the surface and
 219 10-m and an aerodynamic roughness length value of 1 mm (Vignon et al., 2016), this corresponds to a wind speed threshold
 220 value of 5 m s^{-1} at 6 m above the ground. Winds below this threshold (near the annual average wind speed in DC) are not
 221 expected to carry blowing snow to the DS. In addition, blowing snow impacts the flat horizontal and smooth DS at very
 222 small angles, with a very limited chance of sticking to it. As a consequence, ice particles collected on the DS can be
 223 considered representative of precipitation. In case of strong winds, not only the attachment of blowing snow to the DS is
 224 very low, but also the collection of eventual precipitation is reduced. Since DS is warmer than air, there is no secondary
 225 growth in deposited ice. Instead, the partial sublimation of ice particles before scanning could not be excluded, especially in
 226 summer. This topic needs additional field work and will be modelled in Sect. 3.2.

227

228 **2.6 The thermal control.**

229 The temperatures measured by the ICE-CAMERA sensors are continuously transferred to the computer. The NI-Labview
 230 software controls the internal temperature of ICE-CAMERA above -40°C (by driving the 200W, ventilated resistance “Heater
 231 2” of Fig. 3), and the DS temperature always under -5° (by eventually disabling the “heated glass” of Fig.3). These conditions
 232 are maintained throughout the year during every phase of the measuring cycle. An independent 200W wired thermostat
 233 (“Heater 1” in Fig. 3) provides emergency temperature control in case of computer or PIC board failure. After a black-out,
 234 when the power is restored, a timer is used to heat the inside of the instrument before turning on the electronics. This is
 235 important at Concordia to prevent damage to standard electronics with typical operating temperatures of -40°C .
 236 In winter, a 40 mm thick Styrofoam coat is added around the instrument for increasing thermal insulation, whereas in summer

237 a Mylar sunscreen prevents overheating of the instrument and allows keeping the DS below -5°C in the warmest days (Fig.
238 1). Additionally, in warm weather, outdoor air is carried inside the box with a tangential fan, for better cooling of the
239 instrument.

240

241 2.7 Sublimation-deposition cycle.

242 After an entire scan of the DS, electricity is applied to the window to sublimate the particles. The heating rate of the DS
243 depends primarily on the electrical power applied to the window and the thermal constants of the heated window, and
244 secondarily on the wind speed. An indoor test (Fig. 7), showed a heating rate of $2.5^{\circ}\text{C min}^{-1}$, and a cooling rate of 1°C
245 min^{-1} .

246

247 **Fig. 7 : Indoor test of DS heating-cooling rates within a 60 min cycle. Sublimation, Deposition and scan periods are shown**

248

249 The cooling rate is at most only about 50% of the heating rate. The cooling is passive by heat transfer to the surrounding air.
 250 The sandwich-like structure of the heating-glass, with the heating layer at the middle, is depicted in Fig. 8. The conductive
 251 heat transfer coefficient of the glass ($k_1=0.8 \text{ W m}^{-1} \text{ K}^{-1}$) is much greater than that of still air ($k_2=0.024 \text{ W m}^{-1} \text{ K}^{-1}$; when
 252 radiative cooling, convection and wind are taken into consideration, the k_2 constant increases). During glass heating, heat is
 253 transferred rapidly to the DS from the electrically-heated inner layer, while during cooling the heat transfers from the DS to
 254 the air occurs slowly, with a thermal constant k_2 . This explains the asymmetrical curve of Fig.7.
 255

256
 257
 258 **Fig. 8: left: The thermal structure of the electrically-heated glass forming the DS. k_1 and k_2 are the thermal conductivities of glass**
 259 **and still air, respectively. Right: The temperature profile during heating is sketched. T_h , T_s and T_{air} are the temperatures of the**
 260 **heated layer, DS and air, respectively.**
 261
 262
 263

264 Outdoor tests carried out in summer at DC (-30°C air temperature) showed a heating rate of 3°C min^{-1} in still air, $2.5^\circ\text{C min}^{-1}$
 265 $^\circ\text{C min}^{-1}$ with 2.5 m s^{-1} wind speed, and $1.8^\circ\text{C min}^{-1}$ with 5 m s^{-1} wind speed. In all cases, the cooling rate was approximately 1.5°C
 266 min^{-1} .

267 An outdoor sublimation test (-30°C air temperature, wind speed $<3 \text{ m s}^{-1}$) performed with snow manually spread on the DS
 268 showed that, after applying heating for 10 minutes (up to a DS temperature of -8°C) the sublimation of the majority of particles
 269 (diameter $<1000 \mu\text{m}$) was complete within 20 minutes after turning off the heating, with just a few big grains (initial
 270 diameter $>1000 \mu\text{m}$) still present after 30 minutes.
 271 After these tests, the glass heating period was set at 10 minutes (the heating is stopped anyway if the DS temperature exceeds
 272 -5°C to avoid melting of the ice in summer). At the peak of the sublimation period, DS resulted warmer than air of about dT
 273 $= 20^\circ\text{C}$. Once the heater is turned off, and after a cooling time of 20 minutes, the DS temperature comes back warmer than
 274 the air by about $dT = 5^\circ\text{C}$. The "sublimation period" is considered complete, and ice particles accumulate again on the DS,
 275 with no relevant sublimation ("deposition period" in Fig. 7). At the end of the deposition period, a scan of the DS is carried
 276 out, for a duration of one minute. If no ice particles were detected on the previous scan, the DS heater is not applied, sublimation

277 is not needed. The effective deposition period depends on the temperature, wind and exposure to the sun in summer. This
278 uncertainty, combined with occasional wind removal and particulate sublimation (Sect. 3.2) during the deposition period,
279 prevents the use of ICE-CAMERA for rigorous quantitative precipitation studies.
280 DS surface temperature is actually measured by using a small thermocouple. This measurement implies great uncertainties due
281 to the radiant warming of the sensor in summer and the difficult thermal coupling with the glass surface. A non-contact
282 measurement of DS temperature by means of IR sensors would also be ineffective in winter conditions.

283

284 **3. Ice particles and the deposition surface.**

285 **3.1 Adhesion of ice particles on the DS.**

286 The adhesion of ice crystals to the smooth DS is caused by two principal reasons: Van der Waals and electrostatic forces.
287 Eidevåg et al (2020) studied the adhesion of dry snow particles after 90° impact to different wall materials. They considered
288 models for normal direction, tangential sliding, and tangential rolling that account for the adhesive Van der Waals interaction
289 of spherical ice particles (25-275 µm diameter) and their aggregates. The Johnson-Kendall-Roberts (JKR) model for adhesion
290 was used. Their findings showed that the maximum normal velocity at which spherical ice particles adhere to a glass surface
291 decreases with particle diameter. Spherical particles of 100 µm would adhere for speeds less than 0.02 m s⁻¹. In the case of
292 agglomerates with a diameter of 315 µm, composed of 1000 spherical ice particles 25 µm diameter each, the sticking velocity
293 for the adhesion of 90% agglomerates normally hitting the surface increased to 0.5 m s⁻¹, just one third of the Stokes
294 sedimentation speed (1.7 m s⁻¹) calculated for the same aggregate at DC conditions (T_{air}=-50°C, air density=1.03 kg m⁻³,
295 dynamic viscosity= 1.44E-5 Pa s). These results show that the 300 µm diameter ice particles could stick to the ICE-CAMERA
296 window for the weak Van der Waals' forces alone. Ryzhkin and Petrenko (1997) showed that static charges, naturally
297 transported by ice crystals, increase adhesion. The electrostatic interaction between the ice and the surface is significantly
298 stronger than the van der Waals forces at distances greater than the inter-molecular forces. This effect explains why the «big»
299 ice crystals (D>300 µm) also adhere to the DS. Once attached to the DS, the weak winds generally observed at DC cannot
300 detach the particles from the DS. Particulates are protected by the boundary layer (BL) that forms on the DS. The 99% thickness
301 of the laminar BL (Blasius solution) at the centre of the DS (0.15 m distance from the window edge) is expected to be 7 mm
302 at -50°C with a wind speed of 1 m s⁻¹, decreasing to 2 mm at 10 m s⁻¹. As a result, the particles deposited on the DS are
303 protected against the wind.

304

305 **3.2 Sublimation of ice particles.**

306 The DS of ICE-CAMERA is always warmer than the surrounding air. This is necessary to eliminate hoar, enabling the device
307 to be used in all DC conditions. The adverse effect is an accelerated natural sublimation of deposited particles. A wide range
308 of experimental and theoretical research efforts has characterized the effects of temperature and super-saturation on ice crystal
309 growth rates and morphology under conditions relevant to atmospheric processes (for example Lamb and Hobbs, 1971;
310 Libbrecht, 2005; Libbrecht, 2017). The wide variety of ice crystals found in nature has sparked an interest. Sublimation was
311 sometimes regarded either as the opposite process, or a less intriguing process, and was less visited in lab studies.
312 Nelson,(1988) sublimated numerous, 100 µm diameter plate crystals (0.1°C>T>-18°C, 0.05% to 5% sub-saturation) showing
313 that the crystals first lost sharp edges, and finally evolved into spheroidal particles, and the aspect ratio remained almost
314 constant. The sublimation rates were accurately predicted by the diffusion equation with the surface vapour density at the
315 equilibrium value for a uniform surface temperature. The sublimating crystal reaches a self-preserving shape that is one of the
316 shape preserving solutions of the diffusion equation. Ham (1959) showed that ellipsoids and thus spheroids preserve shape
317 during growth and sublimation if the grain surface has a uniform temperature. Jambon-Puillet et al.(2018) also showed
318 experimentally and theoretically that sublimation first smooths out regions of sharp curvature, leading to an ellipsoid. The
319 second stage is the sublimation of the self preserved ellipsoid shape. The entire process may be modelled as a vapour diffusion

320 problem, mathematically equivalent to the resolution of the electrical potential around a charged conductor. Using this analogy,
321 they provided a mathematical method for simulating the sublimation of the ice particle. The sublimation of the ellipsoid turned
322 out mathematically simple, and their method was adopted in this work to numerically simulate the second stage of sublimation
323 of ICE-CAMERA particles.

324 Monodispersed oblate spheroids with an aspect ratio (AR) of 5, in thermal equilibrium with the DS, were assumed in the
325 simulations as a surrogate for ice plates. The two major spheroid axes coincide with the «diameter» of the oblate spheroid, D.
326 In the model, D, DS temperature, air temperature and relative humidity with respect to ice (RH_{air}) can be changed. The
327 sublimation time required for full sublimation of a spheroidal ice particle was computed. As sublimation accelerates when the
328 particle is going to vanish, the time necessary for the complete sublimation is only slightly larger than the time necessary to
329 reduce the particle to the minimum particle size (D=60 μm) accepted by ICE-CAMERA image processing. The simulations
330 assume that the preliminary sublimation of the high-curvature parts of the particle (sharp edges, corners, surface irregularities)
331 was already completed, so that the calculated time of sublimation must be considered as a lower limit for real-world crystals,
332 and probably almost one half of the overall duration of sublimation (Jambon-Puillet et al.,2018). Simulations also assume the
333 thermal equilibrium between the particle and DS, a condition which is not necessarily satisfied on the thermally insulating
334 glass surface of the DS. Figure 9a shows the total sublimation time with the DS heated dT=+20°C above air temperature
335 (sublimation period). The humidity resulted irrelevant in this case, and only results for 70% RH_{air} are shown. Results show
336 that at -30°C air temperature (summer conditions in DC) complete sublimation can occur within a few minutes after attaining
337 the DS sublimation temperature, for all particle sizes up to 1 mm. At lower air temperatures, the sublimation time increases:
338 at -70 °C (winter temperature in DC), particles smaller than 100 μm in diameter still disappear within 10 minutes, while larger
339 particles can survive along the sublimation period. Simulations showed that, at -70 °C, dT should be increased to dT=60°C in
340 order to ensure the complete sublimation of ice particles up to 1 mm diameter during the sublimation period. This is actually
341 not possible with the electric heated window glass adopted, but could probably be achieved by microwave heating.
342

Fig. 9: Sublimation time of monodisperse oblate spheroids at varying air temperatures, with a) $dT = 20^\circ\text{C}$ (sublimation period) and b) $dT = 5^\circ\text{C}$ (deposition period).

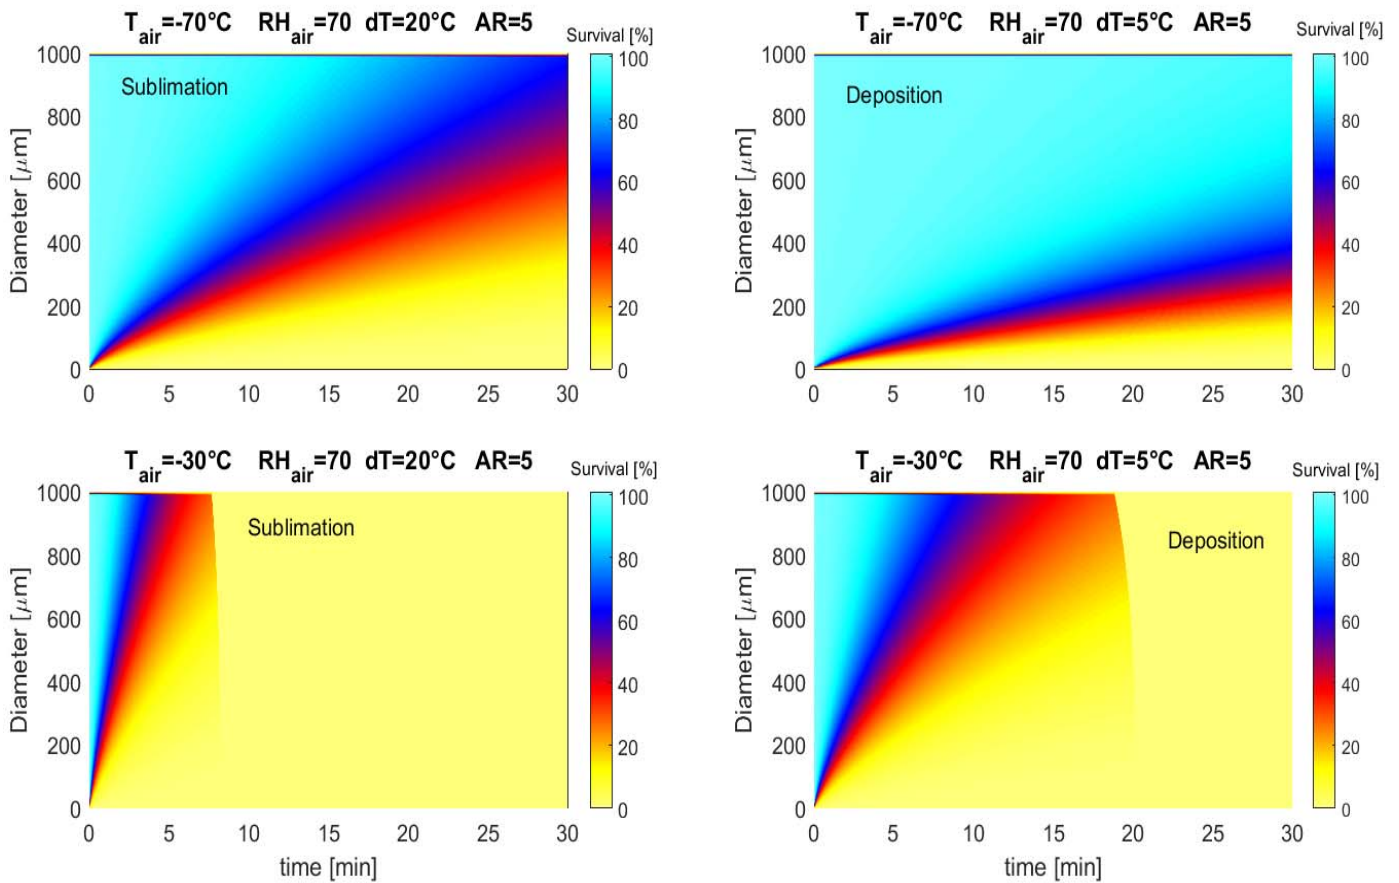

343
344
345
346

347 After the sublimation period, most of the particles previously collected on the DS are sublimated, and a new deposition period
348 begins. Even during this period, sublimation still acts on ice particles, albeit slowly. Figure 9b shows the sublimation time
349 expected for monodisperse spheroids during the deposition period. The DS was considered 5°C hotter than air. As shown,
350 during the deposition period the relative humidity of air also plays a role, even if secondary. In summer ($T_{\text{air}} = -30^\circ\text{C}$),
351 sublimation can take less than a minute for particles smaller than $100\ \mu\text{m}$ and ten minutes for $300\ \mu\text{m}$ particles. During winter
352 ($T_{\text{air}} = -70^\circ\text{C}$), all particles are expected to survive through the deposition period. As a rule-of-the-thumb, simulation showed

353 that working with $dT=+5^{\circ}\text{C}$ resulted in an increase of the rate of sublimation by a factor 2-3 compared with a DS in thermal
354 equilibrium with ambient air ($dT=0$) for the whole range of air temperatures and RH_{air} shown in Fig. 9b.

355 Results of Fig.9b show that the effective lower limit of ICE-CAMERA particle detection is not limited solely to the resolution
356 of the optical system and/or image processing software. In summer, particles smaller than $100\ \mu\text{m}$ may be decimated during
357 deposition, unless they fall just before scanning. Such small particles dominate diamond dust events. As a result, ICE-
358 CAMERA, during the summer period, is best suited to the study of cloud precipitation. Nevertheless, visual screening of ICE-
359 CAMERA images showed only a limited number of small particles revealing signs of partial sublimation, such as rounded
360 corners, smooth edges, or a spheroidal appearance. Some small plates (observed mainly in winter, when sublimation during
361 the deposition period is very slow) showed smoothed corners, but it is not clear if this was induced by sublimation or is a
362 natural feature of these ice grains. Also, even in summer, small DD particles such as plates (with no signs of edge smoothing)
363 were normally observed (Sec.5.2). It is probable that most particles (other than, probably, pristine plates) never achieve thermal
364 equilibrium with the DS glass, and that the results of Fig.10 should be considered as the worst case. Also, the sublimation of
365 the high-curvature parts of the particle prior to assuming the spheroidal form (Jambon-Puillet et al.,2018) could take much
366 more time than the sublimation time calculated here for the spheroid. A series of consecutive DS scans at fixed air temperatures
367 is needed to measure the effective sublimation rate of small particles in deposition conditions ($dT=+5^{\circ}\text{C}$).

368 When a polydisperse particle population is deposited on the DS instead of monodisperse particles, a more complicated
369 sublimation picture arises, because small spheroidal particles, shrinking, are continuously replaced in the size distribution by
370 sublimating, initially bigger ones. An initial uniform particle size distribution (PSD) of the oblate spheroids ($AR=5$) was
371 assumed with diameters between $D=1$ and $2000\ \mu\text{m}$ for the simulations. The evolution over time (1 sec resolution) of the PSD
372 was calculated (Fig. 10) in terms of particle survival (the ratio between the actual number of particles in a certain size bin and
373 the initial number in the same bin). No vapour competition between ice particles was taken into consideration in the
374 simulations. Results are similar to those of monodisperse particles (Fig. 9), with a slightly longer time of sublimation for
375 polydisperse particles compared to monodisperse particles of the same size. Results for an air temperature of -70°C confirm
376 that most particles larger than $500\ \mu\text{m}$ survive, throughout the DS sublimation period ($dT = 20^{\circ}\text{C}$), longer than 30 minutes.
377 This means that sublimating by heating the window is quite inefficient for large particles in winter. During the deposition
378 period, at -70°C losses for sublimation are scarce and limited to particles smaller than $200\ \mu\text{m}$. Consequently, double counting
379 of the same particle ($D>500\ \mu\text{m}$) is possible in two consecutive ICE-CAMERA scans in the cold DC winter. At -30°C air
380 temperature (summer) the heating of the DS with $dT=20^{\circ}\text{C}$ leads to the sublimation of most particles up to 2 mm diameter
381 within 5 minutes. On the other side, during the deposition period particles smaller than $500\ \mu\text{m}$ can undergo sublimation over
382 a period of just 10 minutes in summer, thus limiting the effective period of deposition before a scan. As with monodisperse
383 particles, this introduces bias in the summer because many small particles (typical of DD) can be removed before they are
384 measured.

385

386 **Fig.10: Evolution of a originally uniform PSD of ice spheroids ($D=0-2000 \mu\text{m}$, $AR=5$) under different atmospheric**
 387 **conditions. (RH_{air} is a secondary factor affecting the results, shown here for $RH=70\%$).**
 388 **Left: sublimation period; right: deposition period. Top: winter, bottom: summer.**

389

390 Even if these results could be disappointing for interpreting ICE-CAMERA data, the same problems affect the actual method
 391 of observing precipitation in DC: collecting and observing (every 24 hours) the ice particles deposited on flat surfaces
 392 ('benches') is affected by the same problem as collecting particles on the ICE-CAMERA DS with $dT=0$. Fluctuations in
 393 relative humidity over 24 hours result in sublimation and regrowth of particles on the "benches" in an almost unpredictable
 394 manner. Fig. 11 shows the expected sublimation time for particles (with the same PSD of Fig. 10) placed on 'benches' (or
 395 ICE-CAMERA DS) in equilibrium with air ($dT=0$) for extreme, sub-saturated conditions: winter $T_{\text{air}}=-70^\circ$ ($RH_{\text{air}}=30\%$ and
 396 99%), and summer $T_{\text{air}}=-30$ ($RH_{\text{air}}=30\%$ and 99%). The PSD evolution is computed with a resolution of 1 sec for a total
 397 period of 6 hours. The results show that sublimation also works in winter and with almost saturated air ($99\% RH_{\text{air}}$), leading
 398 to a complete loss of small particles ($D < 200 \mu\text{m}$) in a few hours. In summer conditions and $30\% RH_{\text{air}}$ sublimation happens
 399 much more quickly, with the disappearance of all particles up to $2000 \mu\text{m}$ in 30 minutes. With $RH_{\text{air}}=99\%$, sublimation
 400 removes all particles in just a few hours in summer. In presence of wind and dry air, sublimation rate could even increase, as
 401 observed by Grazioli et al., 2017 in coastal areas. These simulations all refer to sub-saturated conditions: in the case of a
 402 'bench' in thermal equilibrium with super-saturated air, hoar form on the surface, with a possible confusion with precipitation.

403

404 **Fig.11: Evolution of a originally uniform PSD of ice spheroids ($D=0-2000 \mu\text{m}$, $AR=5$) under different atmospheric**
 405 **conditions. The DS (or ‘bench’) is in thermal equilibrium with air ($dT=0$). Top: winter, bottom: summer**

406

407

408 4. Data processing.

409

410 4.1. Image processing.

411 ICE-CAMERA is not just designed to take photographs of ice particles, but to provide automatic morphometry and
 412 classification of polar precipitation. This was accomplished through the use of image processing and machine learning
 413 techniques. The process is divided into two parts: segmentation and measuring, and classification of ice crystals.

414

415 4.1.2 Image segmentation and measurement of ice particles.

416 After acquisition, the raw ICE-CAMERA scans are segmented, using MATLAB software, to isolate all detected particles. The
 417 process follows the workflow of Fig. 12. Refer to Pratt (2007) for image-processing nomenclature, to Walton, 1948 for Feret
 418 measurement, to Russ and Brent Neal (2017) for the nomenclature of standard shape parameters such as Eccentricity, Euler
 419 Number, circularity, roundness, solidity, compactness, form factor, and number of skeletal branches. The normalized central
 420 moments $f1...f7$ were also computed as described by Hu, (1962).

421 The Aspect Ratio (AR) is defined as Feret’s length/ Feret’s width. The Feret-box surface-equivalent diameter (D_f) is defined
 422 as the diameter of the circle of the same area as the Feret bounding box, while the surface-equivalent diameter (D_s) is
 423 defined as the diameter of the circle having the same area as the segmented ice grain. The main steps of Fig. 12 are visually
 424 summarized in Fig.13 for a rimed, columnar particle.

425

426

427

Fig. 12: The image-processing flow chart.

Fig. 13: The original image (in this case a rimer column) is segmented using 'region-growing'. The projected particle area (clear blue) is calculated. The bounding box is determined (green) and the Feret length and width measured. The image is finally rotated to have the major axis horizontal, re-scaled, and resized to the CNN input size.

445

446 4.1.3 Summary-image of detected particles.

447 The bounding boxes of all individual ice particles detected in a scan are sorted by Feret length, and reassembled in a summary-
448 image collecting all segmented particles (Fig 14). Each particle is also associated with a numerical record containing the
449 coordinates of its bounding rectangle on the summary-image, shape parameters, Feret size, time of acquisition and local
450 weather data. In this way, the re-analysis of the summary-image is possible instead of re-processing the original, large image.
451 The original image is ultimately removed.

452

453

454

Fig. 14: Example of a summary-image for a single scan.

455

456

457 4.1.4 Limitations and uncertainties in detecting and sizing ice particles.

458

- 1) The total number of particles measured is limited to 2000 per scan, as a result of MATLAB memory limitations.

459

Extra particles are not treated.

460

- 2) Particles below $3600 \mu\text{m}^2$ in bounding-box surface, 73 pixels minimum size (equivalent to approximately $D < 60 \mu\text{m}$) are not preprocessed (smaller particles could be detected, but most have a seemingly circular shape due to low pixelation or poor focus).

461

462

463

- 3) The segmentation becomes difficult when overlapping particles or aggregates of particles are present. In such situations, double counting of the same particle may occur in up to 12% in a scan in the presence of an intense precipitation event. The same particles can in fact fall inside different segmented areas of the image, because of the

464

465

466 lack, on the original image, of defined boundaries between particles. The process of "region growing" which leads
467 to segmented particles can actually start, independently, from several bright ("seed") regions located in different parts
468 of the image of the overlapping particles. The 'region growing' processes can then propagate through the overlapping
469 particles leading to several 'copies' of the same, segmented image. Overlapping particles are normally classed by the
470 CNN algorithm as "clusters". A few occasional arrangements of three or more overlapping columns are sometimes
471 mistaken for single plates. The Feret measurement of these particles is meaningless. At DC this situation occurs only
472 after heavy cloud precipitation, a relatively rare event.

473 4) Particles close each other in the original image could be segmented into a single particle by region-growing and thus
474 misclassified.

475 5) In the case of defocused images, the particle shapes are all close to a fuzzy, round or elliptical shape, which can cause
476 a misclassification into irregular particles, spheroidal particles or plates. ICE-CAMERA images dominated by this
477 type of particles are normally eliminated during a preliminary manual screening. Also, a few big particles in summer
478 resulted rounded by partial sublimation. A few images containing only rounded or "spheroidal" particles of 500 μm
479 diameter or greater were collected during the warmest part of summer, and were manually discarded before the
480 statistical data analysis.

481 6) Needles and hexagonal plates (typically small, see Fig.26) may be very bright in ICE-CAMERA images due to
482 enhanced light diffusion at preferred angles. For the same reason, hollow columns sometimes have a shiny spot in the
483 middle. In the case of needles, this effect can reduce the apparent aspect ratio, as the width is apparently increased
484 by the scattered light saturating the camera. For plates, the bright specular reflection blurs sometimes the polygonal
485 contour, especially in the case of small plates.

486

487 **4.2 Automated classification of ice particles.**

488 An initial attempt at automatic classification of ICE-CAMERA segmented images was made in 2014 using shape factors. This
489 kind of technique has also been used by others (e.g. Lindqvist et al., 2012) for attempting the classification of ice particles. In
490 the case of ICE-CAMERA this approach resulted extremely unreliable. A much more promising approach was offered after
491 2015 by the rapid development of transfer learning and convolutional neural networks (CNN) (Le Cun et al., 2015;
492 Schmidhuber, 2014). Xiao et al. (2019) successfully applied deep transfer learning to ice particle images obtained with airborne
493 Cloud Particle Imagers (CPI). The CNN approach has added much value to ICE-CAMERA because a reliable classification
494 of ice particles into simplified classes became possible. The CNN used for the ICE-CAMERA particle classification is
495 "GoogleNet" (Szegedy et al. 2015), a variant of the Inception network, a deep convolutional neuronal network developed by
496 Google scientists. GoogleNet is a type of convolutional neural network based on the Inception architecture. It utilises Inception
497 modules, which allow the network to choose between multiple convolutional filter sizes in each block. The GoogleNet
498 architecture consists of 22 layers (27 layers including pooling layers), and part of these layers are a total of 9 inception modules.
499 In this work, GoogleNet was used in MATLAB R2020b environment. The GoogleNet CNN, pretrained on the ImageNet data
500 set (Deng et al. 2009), was used, with its final, fully connected layer changed to size 14. The input layer of the GoogleNet
501 architecture requires images of size 224 x 224.

502

503 **4.2.1 The CNN classification classes.**

504 Low temperatures and humidity on the high Antarctic plateau reduce the diversity of ice particle shapes. This is observed on
505 the field at DC, at South Pole station (Lawson et al., 2006), and suggested by review works such as Bailey and Hallett (2009).
506 Following an initial survey of the ICE-CAMERA image database, a set of 14 types of particles was selected, as shown in Fig.
507 15. When choosing the 14 classes, I assumed that shapes easily recognizable by a human operator could also be easily
508 recognizable by a CNN.

511

512

Fig. 15: A sample of ICE-CAMERA images of the 14 classes of ice particles used to train the CNN.

513

514 In the following scheme I tried to fit the classes chosen for ICE-CAMERA with the classification scheme of the ice particles
 515 of Kikuchi et al. (2013), an updated version of the original classification of Magono and Lee (1966).

516

517 **-Needles:** covering the classes C1a,C1b,C3d (Kikuchi et al. 2013)

518 **-Bullets:** covering the C4b-C4c classes.

519 **-Columns:** columns covering classes C2a, R2b, C3a, C3b.

520 **-Hexagonal plates:** covering classes P1a, P1b, P1c, P4f, G2a, G3a, CP3f, CP3d.

521 **-Trigonal plates:** covering the class G2b.

522 **-Irregular plates:** plate-like particles with irregularities, riming, overgrowing plates, etc. But keeping a basic hexagonal
 523 shape, covering P6a, P6b, P7a, CP6d, R1b, R2b, R2c, R3a, G4b.

524 **-Rosettes:** bullet-rosettes or column-rosettes, with a minimum of two branches, covering C2c, C3e, C4d

525 **-Irregular rosettes:** rosettes with irregularities, riming, but preserving the typical stellar outline of rosettes. Covering
 526 classes P7a,P7b,CP2d ,CP4c,CP5a,CP6e,CP6f,CP6g,R1d

527 **-Irregular grains:** covering CP3e, CP5a, CP6d, G4c,G4a,I3a,I2a,I1a,H1a,H1b

528 **-Spheroidal:** particles with spheroidal or spherical appearance, covering H1a, H1c. (Large particles with $D > 600 \mu\text{m}$)
529 detected as 'spheroidal' in DC are usually artifacts caused by defocused images and are not considered in the statistical
530 analysis.

531 **-Compact columns:** short columns covering classes G1a, C3a

532 **-Clusters of particles:** covering A1a, A3a, H2a, H1b, P8b, CP3e, CP5a, CP6h

533 **-Frost:** frost formed on the DS plate CP7,CP8,CP9

534 **-Fibers:** non-volatile fibrous material (from local human activities, Styrofoam particles, textile particles, dust, etc)

535

536 The last two classes are not considered in the statistical analysis of ICE-CAMERA data: they are just used to detect occasional
537 frost formed on the DS, and man-made, non-evaporable (thus persisting on the DS) materials. Uncommon ice particle
538 typologies present at Concordia were not considered in the present work. Trigonal plates have been included, although they
539 are rare, simply because they are seemingly easy to detect with CNN.

540

541 **4.2.2 The training data-set.**

542 For the first CNN training, a set of 5500 ICE-CAMERA segmented images of single particles, sampled randomly from the
543 2014-2017 ICE-CAMERA database, have been manually sorted into 14 image data stores, corresponding to the 14 classes.
544 Fourteen of the computer keyboard keys were marked with the symbols of the 14 classes in order to expedite the manual
545 classification of the initial training data set. These images were used for initial CNN training. The resulting CNN was used to
546 classify the ICE-CAMERA data set for the years 2014 to 2017. Correctly classified, selected images from this CNN-produced
547 image dataset were manually added to the 14 training image data set as new training images for a second CNN training. Even
548 if many of the images used for the next CNN training and testing had already been classified by the CNN, these images should
549 be considered as ordinary, supervised training images. This process has been repeated recursively three times in order to
550 expand the training database and thus increase the accuracy of the CNN classifier.

551 Figure 16 shows the final number of training and test images selected for each class. The total number of images used for the
552 training was 81800. Trigonal plates were rare, and their number in the training dataset was thus artificially augmented by
553 duplicating the training images, in order to avoid their absence in the small (64-images) training mini-batches.

Fig. 16: The final number of images used for CNN training + validation + test.

555

556

557

558

559

560 4.2.3 CNN training details.

561 To meet Google's input requirements, all images of single particles were resized to 224*224 pixels. In the training process,
 562 'data augmentation' was applied to the original data set. Artificially 'augmenting' the image data set has been shown to be
 563 effective in CNN training (Shorten and Khoshgoftaar, 2019). Images inside each mini-batch are automatically, randomly
 564 'augmented' in order to reduce CNN overfitting. The following transformations were used in augmentation:

565

- X, Y reflection
- random X, Y translations ± 30 pixels
- Random scaling 80-120%

566

567

568

Other changes such as rotation have not been introduced since the ICE-CAMERA images to be classified are typically oriented horizontally by the image processing procedure (e.g. Fig. 14)

569

570 The following learning options were utilized in GoogleNet training:

571

572 Solver: stochastic gradient descent with momentum (SGDM)

573

activation: softmax

574

Number of Epochs=5

575

Learn Rate=0.001

576

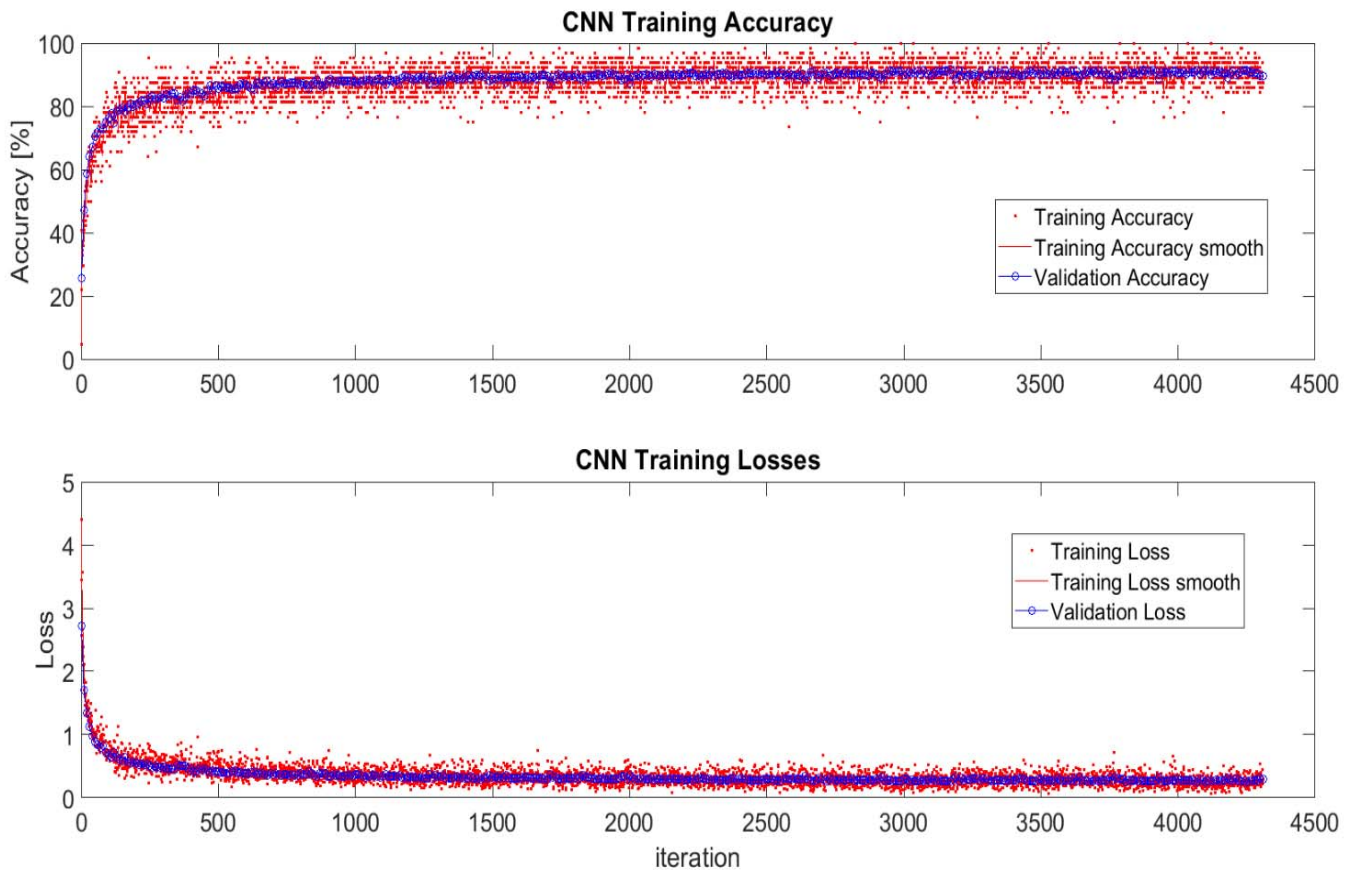

Batch Size=64

577 L2 weight regularization factor=0.005

578 Validation frequency= every 30 iterations

579 Shuffle of the data set at every epoch

580 10% of the image data set of Fig. 16 was dedicated to validating, 10% for testing, and the remaining 80% of the training. The
581 evolution of the CNN training in terms of accuracy and losses is presented in Fig. 17. The validation line closely tracks the
582 training line, showing the absence of overfitting.

583

584

Fig. 17: Evolution of the CNN training.

585

586 4.2.4. Testing the CNN classifier.

587 CNN's performance test results are summarized in confusing matrix graphs like Fig. 18a. Each row corresponds to a
588 predicted class (Output Class) and each column corresponds to a true class (Target Class). Diagonal cells refer to correctly
589 classified observations. Off-diagonal cells are improperly classified observations (red color markings increasing
590 misclassification). The column on the far right of the plot shows the percentages of all the examples predicted to belong to
591 each class that are correctly and incorrectly classified (positive predictive value and false discovery rates, respectively). The
592 row at the bottom of the plot shows the percentages of all the examples belonging to each class that are correctly and
593 incorrectly classified (true positive rate and false negative rate, respectively).

594

595

596 **4.2.5 Accuracy of the classifier.**

597 In the column-normalized summary (Fig. 18a), the percentages along the i-th column shows the probability (P) of a "true"

598 particle in class i-th being classified in each of the 14 output classes.

599

600

Fig. 18: Confusion plot of the CNN : a) column-normalized, b) row-normalized

601 Reading the columns of Fig 18a from left to right, the accuracy of the CNN in properly classifying a particle belonging to the
602 i -th true class (bottom row) can be assessed. The results are summarized below:

603

604 -Good accuracy ($P > 90\%$) in identifying needles, spheroidal, bullets, trigonal plates.

605 -Compact columns are misclassified into columns (3% of the time) and bullets (3% of the time).

606 -Hexagonal and irregular plates are confused approximately 10% of the time. This is expected since the edges of the plates
607 (usually small) are sometimes blurred in the image.

608 -Irregular rosettes are misclassified in 5% of cases as pristine rosettes and in 5% of cases as irregular plates.

609 -Irregular plates are confused with hexagonal plates 10% of times.

610 -Irregular grains are sometimes mistaken with irregular plates (10%) and hex plates (6%).

611 -Columns are misclassified as bullets 15% of the times.

612 The three-dimensional structure of the ice particles is lost in the ICE-CAMERA images, so that some thick ice forms such as
613 C4a, P1b, G3b, CP1a, etc. (Kikuchi et al, 2013), if any, are likely to be misclassified by this CNN.

614 A different view to read the CNN test is the row-normalized summary of the confusion matrix (Fig. 18b).

615 Percentages along the i -th row now show the probability for a particle classified into the i -th class to effectively belong to
616 each of the 14 true classes. Reading the rows of Fig. 18b from top to bottom, results are:

617 -Particles classified as needles, spheroidal, trigonal plates, bullets, pristine rosettes and irregular grains effectively ($P > 90\%$)
618 belong to their class.

619 -Particles classified as irregular rosettes have a 5% chance of being regular rosettes

620 -Particles classified as compact columns have a 6% chance of being columns.

621 -Particles classified as columns have a 4% chance of being a 2-branch rosette and 3% of being bullets or compact columns.

622 -Particles classified as pristine plates have a 4% chance of being irregular grains.

623 -Particles classified as irregular plates have a 7% chance of being irregular grains, 9% hex. plates, and 5% of being irregular
624 rosettes

625 **5. Results.**

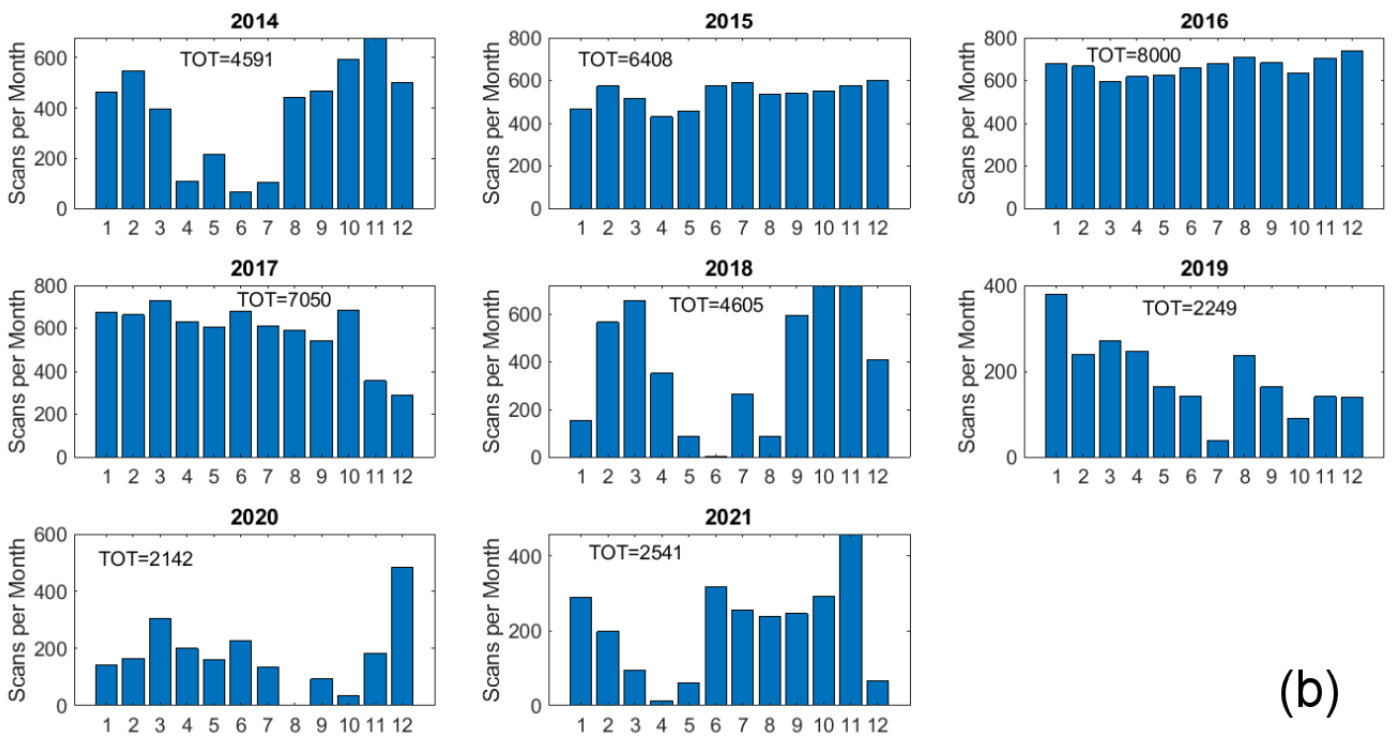

626 **5.1 Overview of ICE-CAMERA data set.**

627 From January 2014 to December 2021, ICE-CAMERA has segmented a total of 11,007,543 particles. This gross count includes
628 particulates successively rejected for the statistical analysis. Some whole scans were eventually ignored because of poor focus,
629 sledge motor failures, or the presence of layers of snow or frost. Individual particles were omitted from the analysis due to
630 their small size or defocus. The distribution of the number of particles observed during the months is shown on Fig. 19a. The
631 number of scans per month is shown in Fig. 19b. Under optimal conditions, one scan per hour is planned, with a typical total
632 of 740 scans per month. Some months, problems with ICE-CAMERA, focusing, or processing software resulted in the small
633 number of scans or particles observed. In most other cases, scans were not recorded when fewer than ten particles were detected
634 on the DS.

635

(a)

(b)

636

637 **Fig. 19: Statistics per month for the years 2014 to 2021. a) Ice particle counts per month (total counts per year are also**
 638 **reported). (b) Number of scans per month (total number per year is also reported)**

639

640 The number of particles per scan (NpS) is a rough indicator of the intensity of the collected precipitation, but it could be
 641 affected by sublimation, because in condition of ‘warm’ air the smallest particles could disappear from the DS before being
 642 detected (sec.3.2). Figure 20a shows the NpS in relation to the air temperature for the whole period 2014-2021, in box and
 643 whisker format. On each box, the middle mark indicates the median, and the lower and upper edges indicate the 25th and 75th
 644 percentiles, respectively. The lower and upper whiskers indicate an interquartile below the 25th percentile and an interquartile
 645 above the 75th percentile.

646 Most ice particles were detected at temperatures between -60°C and -45°C , characteristic temperatures in spring and autumn.
 647 The NpS at -70°C is not statistically different from the NpS at -30°C . This result suggests that sublimation on the DS during
 648 the deposition period is less important than the natural variability of precipitation intensity in determining the number of
 649 particles detected during the acquisition. This is confirmed by the DC air temperature statistics (fig.20d): most particles were
 650 detected at temperatures above the median DC temperature, whereas, in the case of significant sublimation, we would expect
 651 more particles in the lower temperature range (Sect.3.2).

652 A similar consideration can be made when looking at NpS statistics with relative humidity (Fig. 20b). Most particles were
 653 detected with relative humidity ranging from 35% to 60%. NpS for $\text{RH}=20\%$ does not differ statistically from NpS at 80%
 654 RH. Even if RH is less important than temperature in determining the sublimation rate, also this result suggests that sublimation
 655 does not affect dramatically the *number* of particles finally detected by ICE-CAMERA.

656 Figure 20c shows NpS in relation to wind velocity: ice particles were collected by ICE-CAMERA under all wind conditions
 657 encountered in DC. Ice particles were numerically more abundant when the wind was between 7 m s^{-1} and 15 m s^{-1} . As the
 658 average surface wind speed at DC resulted around $\approx 6\text{ m s}^{-1}$ for the measurement period (Fig.20f), particles were collected on
 659 the DS preferentially with winds stronger than the average, a condition typically encountered in winter in coincidence with
 660 warming events (Argentini et al.,2014). These winds exceed the threshold value of 5 m s^{-1} for blowing snow at ICE-CAMERA
 661 altitude, and may ultimately contain some drifting snow. The drop of NpS for wind speeds above 15 m s^{-1} (very rare in DC)
 662 is probably due to the limited attachment of snow to the DS with strong winds.

663

664

665 **Fig. 20: NpS statistics in relation to a) Tair, b) RH , c) wind speed.**

666 **For comparison, the statistics for d) Tair, e) RHy, and f) wind speed are shown for the same period (2014-2021).**

668 **5.2 Image processing and CNN used on ICE-CAMERA data.**

669 MATLAB post-processing software, including the CNN classifier (Sect.4.2) and measurement tools (Sect.4.1) has been
 670 applied to the 2014-2017 ICE-CAMERA dataset. Even if the detailed analysis of these data is the task of a separate paper, a
 671 sample of the capacity of the instrument is presented in this section for the first two years of measurement (2014-2015). The
 672 total particles analyzed resulted in $N=553.358$. The number of particles classified in the 14 classes is reported in Fig. 21. The
 673 relative rarity of trigonal plates and spheroid particles is evident.

674

675

Fig. 21: Total numbers of particles classified in the 14 classes for years 2014-2015 .

676

677 Figure 22 shows the Feret length statistics in box and whisker format. Particles classified as plates, needles, compact columns,
 678 spheroidal and irregular grains gave an average length lower than 300 μm . Bullets and columns mean length resulted in the
 679 400-500 μm range, while for rosettes and irregular rosettes was in the 350-550 μm range.

680

681

682

683

685

686

Fig. 22: Feret length statistics for the years 2014-2015

687 Figure 23 shows in detail the probability distribution of the Feret length for plates and rosettes. For plates (Fig23b), the peak
 688 of the distribution is for $L_{\text{feret}}=100 \mu\text{m}$, similar to the peak of the diamond dust (maximum) size distribution measured by
 689 Lawson et al. (2006) at SPS in summer (it must be pointed out that Lawson et al. (2006) measured also particles as small as
 690 $30 \mu\text{m}$, while particles below $60 \mu\text{m}$ are not processed by the ICE-CAMERA software, and are therefore missing from the
 691 probability distribution of Fig23b). This finding indicates that the possible sublimation of particles less than $100\text{-}200 \mu\text{m}$ during
 692 the deposition time, suggested in Section 3.2, is not relevant for the final particle size statistics. The results obtained from ICE-
 693 CAMERA for pristine rosettes (Fig23a), differ considerably from those of Lawson et al (2006), because the peak of the
 694 probability distribution resulted $L=480 \mu\text{m}$, to be compared with $L=120 \mu\text{m}$ of Lawson et al (2006). This difference is not
 695 explicable with the eventual sublimation of the smallest rosettes on the DS. Instead, this result is a realistic feature, sustained
 696 by the direct visual observation of rosettes in DC precipitation.

697

698 **Fig. 23: Feret length probability distribution for a) rosettes and b) hex. plates. The relevant presence of small plates**
 699 **($D < 200 \mu\text{m}$) suggests that sublimation on the DS is not relevant. years 2014-2015**

700 Figure 24 shows the trend of the mean Feret length of hexagonal plates with air temperature (sample size=121166 plates).

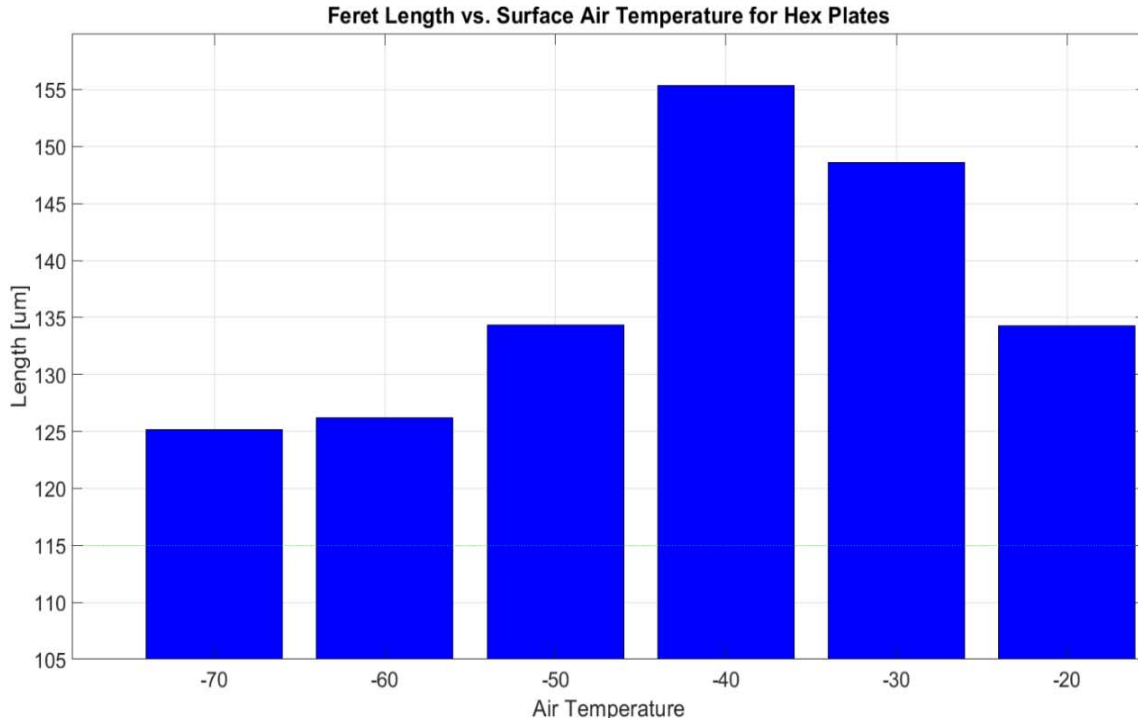

701 The maximum plate size is observed at temperatures of -30 to -40°C . If sublimation on the DS dominated the size

702 distribution of the plates observed by ICE-CAMERA, an inverse relationship between size and temperature would be

703 expected. This finding again suggests that sublimation on the DS (even in summer, and up to -40°C air temperature) is not as

704 important as numerical simulations might suggest.

705

706

Fig. 24: Average Feret length for hex. plates with respect to air temperature – years 2014 to 2015.

707 Figure 25a shows Feret's aspect ratio per class. Not surprisingly, many "rounded" classes (plates, rosettes, etc.) have an $AR < 2$.

708 Compact columns show a median AR close to 2.4, while columns and bullets are close to 3. The average AR for the needles

709 was 3.2, which is lower than expected for the reasons outlined in section 4.1.4.

710

711 **Fig. 25: Statistics of : (a) Aspect Ratio, (b) Projected surface-equivalent diameter (Ds), (c) ratio between surface-**
 712 **equivalent (Ds) and Feret box-equivalent (Df) diameters for the years 2014-2015.**

714 Figure 25b shows the surface-equivalent diameter D_s of the particles. Figure 25c shows the ratio between the surface
715 equivalent diameter (D_s) and the bounding box equivalent diameter (D_f). The difference between the two diameters is relevant
716 for "fluffy" particles like rosettes and clusters. For those particles, D_s/D_f gave values of 0.6 to 0.65. For comparison, a round
717 particle is expected to have a ratio of $D_s/D_f=0.78$.

718

719 **6. Conclusions.**

720 ICE-CAMERA, although very similar to a simple flatbed scanner in its basic design, has represented a technical challenge for
721 its implementation at DC. Hardware and software have been continuously and extensively modified at DC over the past five
722 summer campaigns. The result is now a reliable instrument, running throughout the year on an hourly basis, for the statistical
723 study of precipitation in internal polar areas. Particle size and morphology are automatically obtained, and some semi-
724 quantitative precipitation estimates can be derived. The collected data are automatically pre-analyzed, but they can be post-
725 processed at any time, in order to follow the continuous improvements of the image processing and machine learning
726 algorithms. The GoogleNet CNN, trained specifically for this instrument, has succeeded in classifying ICE-CAMERA images
727 into 14 form classes, with an accuracy of more than 80% for most of them. The instrument is particularly useful for
728 automatically measuring the size of individual ice particles in precipitation, a process virtually impossible manually, and
729 certainly impossible on the field in DC and elsewhere on the Antarctic plateau in winter. ICE-CAMERA scans are carried out
730 every hour. Keeping the surface of the instrument free of frost all the time and cleaning it by heating the deposition surface
731 after each scan is paid with the possible loss of small ice particles. Particles less than 100-200 μm can disappear by sublimation
732 before being recorded, especially in summer. This problem is complementary to the problem encountered when observing
733 precipitation manually: when observing precipitation manually every 24 hours, (as is the case of DC) the reprocessing of
734 particles, or the formation of ice and hoar artifacts cannot be prevented. In ICE-CAMERA, frost and ice regrowth are
735 suppressed, but small particles may disappear for sublimation. ICE-CAMERA data, collected since 2014, have already been
736 statistically processed and the results will be described in a specialized paper. Results from a subset of data (years from 2014
737 to 2015), was presented in this work. These results demonstrated the capability of the instrument to classify and size individual
738 ice particles in DC precipitation, apparently without dramatic losses of small particles for sublimation. Cloud precipitation
739 particles (rosettes) were found to be significantly larger (480 μm) than those observed at SPS by Lawson et al (2006), while
740 plates resulted of similar size (120 μm). Unfortunately, only non-polluted, very cold, low humidity, low precipitation
741 environments (like high mountain tops, dry polar environments) could house a similar instrument. In the presence of pollution,
742 marine aerosols or dust, manual cleaning of the DS would be required to remove solid particles and salts escaping sublimation.
743 For coastal zones, the temperature is generally close to zero, making the thermal cleaning of the DS by sublimation
744 problematic. In these environments, if an instrument like ICE-CAMERA were installed, a mechanical wiper would replace the
745 heated window of the current instrument. Furthermore, the CNN presented in this paper should be re-trained with different
746 classes of ice crystals.

747

748 **7. Technical issues.**

749 Using ICE-CAMERA at DC, as well as other automated instruments, was difficult. The instrument had several failures along
750 years, and each one was difficult to fix, at least in winter, when the instrument had to be dismantled from the roof of the
751 shelter at -70°C and eventually fixed in the local lab by the winter-over crew, with remote assistance from Europe. Until a few
752 years ago, communicating with DC was limited to email with small attachments, making remote assistance a lengthy task.
753 Even today, connecting the rest of the world remotely with the ICE-CAMERA PC, to operate with the instrument software, is

754 virtually impossible. Most hardware failures in DC were due to software bugs or computer failures. Rather than having trouble
755 with low temperatures, operating in DC means dealing with limited heat-dissipation of PC parts such as power supply and
756 hard disks, electrostatic discharge issues in low-humidity, heated environments, lack of spare parts for most of the year, a
757 varied skill-ness of winter-over personnel. Failures in the thermal control of ICE-CAMERA caused some mechanical stress
758 and failures in the focusing sledge, while water condensation eventually rusted the bearings of the stepper motors (all bearing
759 were de-greased for a better low temperature operation). The CNN used to classify ICE-CAMERA images is continually
760 changing and improving and the CNN training data set increases with time, as new images collected by ICE-CAMERA are
761 used as new training ones.

762

763

764 **8. Code and Data availability.**

765 The CNN developed as part of this work (under Mathworks MATLAB R2020B), along with the image data set (224*224
766 images for the 14 classes of particles) used for training, validation and testing the CNN are available in the ZENODO
767 repository (Del Guasta, 2022)

768

769

770 **Acknowledgements.**

771 I am grateful to the Italian Antarctic Project PNRA for supporting this work with the projects ICE-CAMERA (PNRA
772 2009/A4.1) and PRE-REC (PNRA 2013/AC3.05). I am also grateful to the ‘Osservatorio Meteo-Climatologico Antartico’
773 (PNRA 14_00100) for the Meteo data, and to all the logistics staff and winter-over crews of Concordia station, all working
774 hard to permit our scientific activity. I am also grateful to Francesco Castagnoli (INO CNR) for the initial design of the
775 instrument.
