Abstract

Ambient fine particulate matter (PM_{2.5}) pollution is a major health risk. Networks of low-cost sensors (LCS) are increasingly being used to understand local-scale air pollution variation. However, measurements from LCS have uncertainties that can act as a potential barrier to effective decision-making. LCS data thus need adequate calibration to obtain good quality PM_{2.5} estimates. In order to develop calibration factors, one or more LCS are typically co-located with reference monitors for short- or long -periods of time. A calibration model is then developed that characterizes the relationships between the raw output of the LCS and measurements from the reference monitors. This calibration model is then typically *transferred* from the co-located sensors to other sensors in the network. Calibration models tend to be evaluated based on their performance only at co-location sites. It is often implicitly assumed that the conditions at the relatively sparse co-location sites are representative of the LCS network overall, and that the calibration model developed is not overfitted to the co-location sites. Little work has explicitly evaluated how transferable calibration models developed at co-location sites are to the rest of an LCS network, even after appropriate cross-validation. Further, few studies have evaluated the sensitivity of key LCS use-cases such as hotspot detection to the calibration model

40 applied. Finally, there has been a dearth of research on how the duration of co-location
41 (short-term/long-term) can impact these results. This paper attempts to fill these gaps
42 using data from a dense network of LCS monitors in Denver deployed through the city's
43 Love My Air program. It offers a series of transferability metrics for calibration models that
44 can be used in other LCS networks and some suggestions as to which calibration model
45 would be most useful for achieving different end goals.

46

47 **Key words:** low-cost sensors, PM_{2.5}, calibration, LoveMyAir

48 **1 Introduction**

49 Poor air quality is currently the single largest environmental risk factor to human health in
50 the world, with ambient air pollution responsible for approximately 6.7 million premature
51 deaths every year (State of Global Air, 2020). Having accurate air quality measurements
52 is crucial for tracking long-term trends in air pollution levels, identifying hotspots, and for
53 developing effective pollution management plans. The dry-mass concentration of fine
54 particulate matter (PM_{2.5}), a criterion pollutant that poses more of danger to human health
55 than other widespread pollutants (Kim et al., 2015), can vary over distances as small as ~
56 10's of meters in complex urban environments (Brantley et al., 2019; deSouza et al.,
57 2020a). Therefore, dense monitoring networks are often needed to capture relevant
58 spatial variations. Due to their costliness, Environmental Protection Agency (EPA) air
59 quality reference monitoring networks are sparsely positioned across the US (Apte et al.,
60 2017; Anderson and Peng, 2012).

61

62 Low-cost sensors (LCS) (<USD \$2500 as defined by the US EPA Air Sensor Toolbox)
63 (Williams et al., 2014) have the potential to capture concentrations of PM in previously
64 unmonitored locations and to democratize air pollution information (Castell et al., 2017;
65 Crawford et al., 2021; Kumar et al., 2015; Morawska et al., 2018; Snyder et al., 2013;
66 deSouza and Kinney, 2021; deSouza, 2022). However, LCS measurements have several
67 sources of greater uncertainty than reference monitors (Bi et al., 2020; Giordano et al.,
68 2021; Liang, 2021).

69

70 Most low-cost PM sensors rely on optical measurement techniques. Optical instruments
71 face inherent challenges that introduce potential differences in mass estimates compared
72 to reference methods (Barkjohn et al., 2021; Crilley et al., 2018; Giordano et al., 2021;
73 Malings et al., 2020):

74

75 1. Optical methods do not directly measure mass concentrations; rather, they estimate
76 mass based on calibrations that convert light scattering data to particle number and mass.
77 LCS come with factory-supplied calibrations, but in practice must be re-calibrated in the
78 field to ensure accuracy, due to variations in ambient particle characteristics and
79 instrument drift.

80

81 2. High relative humidity (RH) can produce hygroscopic particle growth, leading to dry
82 mass overestimation unless particle hydration can accurately be taken into account or the
83 particles are desiccated by the instrument.

84
85 3. LCS are not able to detect particles with diameters below a specific size, which is
86 determined by the wavelength of laser light within each device, and is generally in the
87 vicinity of 0.3 μm , whereas the peak in pollution particle number size distribution is
88 typically smaller than 0.3 μm .

89
90 4. The physical and chemical parameters describing the aerosol (particle size
91 distribution, shape, indices of refraction, hygroscopicity, volatility etc.), that might vary
92 significantly across different microenvironments with diverse sources, impact light
93 scattering; this in turn affects the aerosol mass concentrations reported by these
94 instruments.

95
96 The need for field calibration to correct LCS measurements is particularly important. This
97 is typically done by co-locating a small number of LCS with one or a few reference
98 monitors at a representative monitoring location or locations. The co-location could be
99 carried out for a brief period before and/or after the actual study or may continue at a
100 small number of sites for the duration of the study. In either case, the co-location provides
101 data from which a calibration model is developed that relates the raw output of the LCS as
102 closely as possible to the desired quantity as measured by the reference monitor.
103 Thereafter, the calibration model is transferred to other LCS in the network, based upon
104 the presumption that ongoing sampling conditions are within the same range as those at
105 the collocation site(s) during the calibration period.

106
107 Calibration models typically correct for 1) systematic error in LCS by adjusting for bias
108 using reference monitor measurements, and 2) the dependence of LCS measurements
109 on environmental conditions affecting the ambient particle properties such as relative
110 humidity (RH), temperature (T), and/or dewpoint (D). Correcting for RH, T and D is carried
111 out through either a) a physics-based approach that accounts for aerosol hygroscopic
112 growth given particle composition using κ -Köhler's theory, or b) empirical models, such as
113 regression and machine learning techniques. In this paper, we focus on the latter, as it is
114 currently the most widely used (Barkjohn et al., 2021). Previous work has also shown that
115 the two approaches yield comparable improvements in the case of $\text{PM}_{2.5}$ LCS (Malings et
116 al., 2020).

117
118 Prior studies have used multivariate regressions, piecewise linear regressions, or higher-
119 order polynomial models to account for RH, T and D in these calibration models (Holstius
120 et al., 2014; Magi et al., 2020; Zusman et al., 2020). More recently, machine learning
121 techniques such as random forests, neural networks, and gradient boosted decision trees
122 have been used (Considine et al., 2021; Liang, 2021; Zimmerman et al., 2018).

123 Researchers have also started including additional covariates in their models besides

124 what is directly measured by the LCS, such as time of day, seasonality, wind direction,
125 and site-type, which have been shown to yield significantly improved results (Considine et
126 al., 2021).

127
128 Past research has shown that there are several important decisions, in addition to the
129 choice of calibration model, that need to be made during calibration and that can impact
130 the results (Bean, 2021; Giordano et al., 2021; Hagler et al., 2018). These include a) the
131 kind of reference air quality monitor used, b) the time-interval (e.g., hour/day) over which
132 to average measurements used when developing the calibration model, c) how cross-
133 validation (e.g., leave one site out/10-fold cross-validation) is carried out, and d) how long
134 the co-location experiment takes place.

135
136 Calibration models are typically evaluated based on how well the corrected data agree
137 with measurements from reference monitors at the corresponding co-location site. A
138 commonly used metric is the Pearson correlation coefficient, R , which quantifies the
139 strength of the association. However, it is a misleading indicator of sensor performance
140 when measurements are observed close to the limit of detection of the instrument.
141 Therefore, Root Mean Square Error (RMSE) is often included in practice. Unfortunately,
142 neither of these metrics captures how well the calibration method developed at the co-
143 located sites *transfers* to the rest of the network in both time and space.

144
145 If the conditions at the co-location sites (meteorological conditions, pollution source mix)
146 for the period of co-location are the same as for the rest of the network during the total
147 operational period, the calibration model developed at the co-location sites can be
148 assumed to be transferable to the rest of the network. In order to ensure that the sampling
149 conditions at the co-location site are representative of sampling conditions across the
150 network, most researchers tend to deploy monitors in the same general sampling area as
151 the network (Zusman et al., 2020). However, it is difficult to definitively test if the co-
152 location site during the period of co-location is representative of conditions at all monitors
153 in the network; ambient PM concentrations can vary on scales as small as a few meters.
154 Furthermore, LCS are often deployed specifically in areas where the air pollution
155 conditions are poorly understood, meaning that representativeness cannot be assessed in
156 advance.

157
158 In order to evaluate whether calibration models are transferable in time, we test if models
159 generated using typical short-term co-locations at specific co-location sites perform well
160 during other time periods at all co-location sites. Where multiple co-location sites exist,
161 one way to evaluate how transferable calibration models are in space is to leave out one
162 or more co-location sites and test if the calibration model is transferable to the left-out
163 sites. This method was used in recent work evaluating the feasibility of developing a US-
164 wide calibration model for the PurpleAir low-cost sensor network (Barkjohn et al., 2021;
165 Nilson et al., 2022).

166

167 Although these approaches are useful, co-location sites are sparse relative to other sites
168 in the network. Even in the PurpleAir network (which is one of the densest low-cost
169 networks in the world) there were only 39 co-location sites in 16 US states, a small
170 fraction of the several thousand PurpleAir sites overall (Barkjohn et al., 2021). It is thus
171 important to develop metrics to test how *sensitive* the spatial and temporal trends of
172 pollution derived from the entire network are to the calibration model applied. Finally, a
173 key use-case of LCS networks is to identify hotspots. It is important to also evaluate how
174 sensitive the hotspot identified in an LCS network is to the calibration model applied.

175
176 Examining the reliability of calibration models is timely because more researchers are
177 opting to use machine learning models. Although in most cases, such models have
178 yielded better results than traditional linear regressions, it is important to examine if these
179 models are overfitted to conditions at the co-location sites, even after appropriate cross-
180 validation, and how transferable they are to the rest of the network. Indeed, because of
181 concerns of overfitting, some researchers have explicitly eschewed employing machine
182 learning calibration models altogether (Nilson et al., 2022). It is important to test under
183 what circumstances such concerns might be warranted.

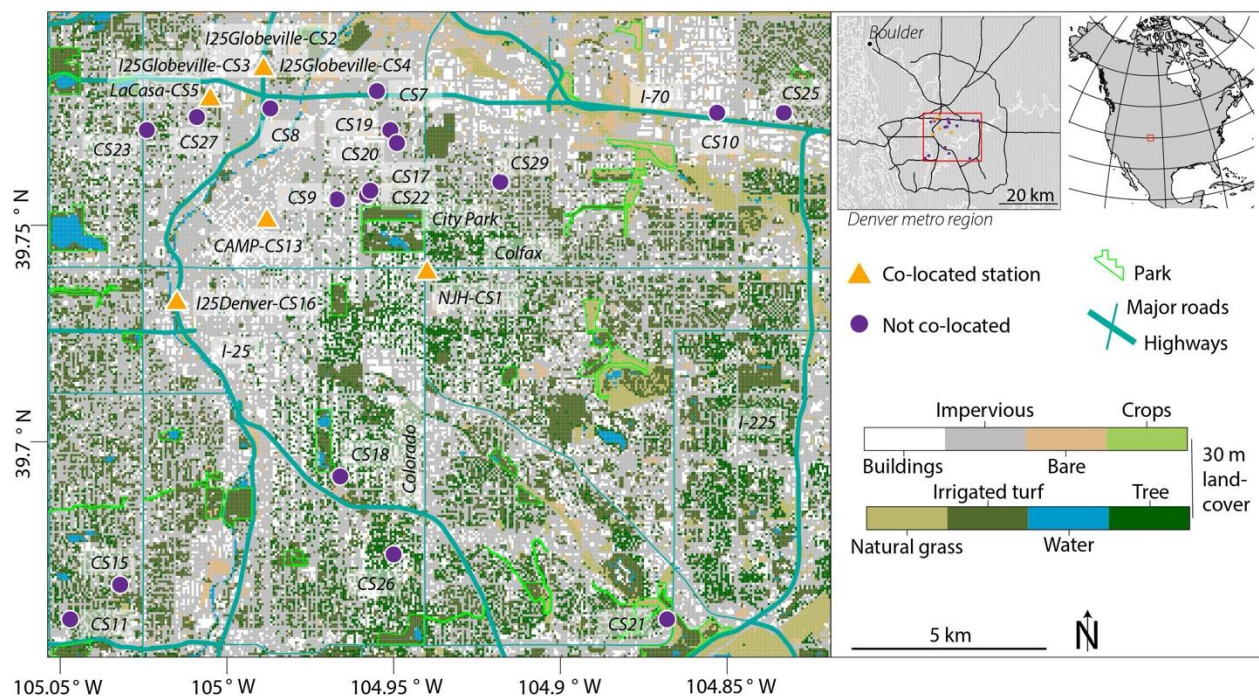

184
185 This paper uses a dense low-cost PM_{2.5} monitoring network deployed in Denver, the
186 “Love My Air” network deployed primarily outside the city’s public schools, to evaluate the
187 transferability of different calibration models in space and time across the network. To do
188 so, new metrics are proposed to quantify the Love My Air network spatial and temporal
189 trend uncertainty due to the calibration model applied. Finally, for key LCS network use-
190 cases such as hotspot detection, tracking high pollution events and evaluating pollution
191 trends at a high temporal resolution, the sensitivity of the results to the choice of
192 calibration model is evaluated. The methodologies and metrics proposed in this paper can
193 be applied to other low-cost sensor networks, with the understanding that the actual
194 results will vary with study region.

195 **2 Data and Methods**

196 **2.1 Data Sources**

197 Between Jan 1 and Sep 30, 2021, Denver’s Love My Air sensor network collected minute-
198 level data from 24 low-cost sensors deployed across the city outside of public schools and
199 at 5 federal equivalent method (FEM) reference monitor locations (**Figure 1**). The Love
200 My Air sensors are Canary-S models equipped with a Plantower 5003, made by Lunar
201 Outpost Inc. The Canary-S sensors detect PM_{2.5}, T, and RH, and upload minute-
202 resolution measurements to an online platform via cellular data network.

203
204 We found that RH and T reported by the Love My Air sensors were well correlated with
205 that reported by the reference monitoring stations. We used the Love My Air LCS T and
206 RH measurements in our calibration models as they most closely represent the conditions
207 experienced by the sensors.

208 **Figure 1:** Locations of all 24 Love My Air sensors. Sensors displayed with an orange
 209 triangle indicate that they were co-located with a reference monitor. The labels of the co-
 210 located sensors include the name of the reference monitor with which they were co-
 211 located after a hyphen.
 212

2.1.1 Data cleaning protocol for measurements from the Love My Air network

214 A summary of the data cleaning and data preparation steps carried out on the Love My
 215 Air data from the entire network are listed below:

- 217 1) Removed data for time-steps where key variables: $PM_{2.5}$, T and RH measurements
 218 were missing
- 219 2) Removed unrealistic RH and T values ($RH < 0$ and $T \leq -30^{\circ}C$)
- 220 3) Removed $PM_{2.5}$ values above $1,500 \mu g/m^3$ (outside the operational range of the
 221 Plantower sensors used) from the Canary-S sensors (Considine et al., 2021)
- 222 4) We were left with 8,809,340 minute-level measurements and then calculated
 223 hourly-average $PM_{2.5}$, T, and RH measurements for each sensor. We had a total of
 224 147,101 hourly-averaged measurements
- 225 5) From inspection, one of the monitors, CS13, worked intermittently in Jan and Feb,
 226 before resuming continuous measurement in March (**Figure S1 in Supplementary**
 227 **Information**). When CS13 worked intermittently, large spikes in the measurements
 228 were observed, likely due to power surges. We thus retained measurements taken
 229 after March 1, 2021 for this monitor. The total number of hourly measurements was
 230 thus reduced to 146,583.

232 Love My Air sensors (indicated by Sensor ID) were co-located with FEM reference
 233 monitors from which we obtained high quality hourly $PM_{2.5}$ measurements at (**Table 1**):

- 234 1) La Casa (Sensor ID: CS5)
- 235 2) CAMP (Sensor ID: CS13)
- 236 3) I25 Globeville (Sensor ID: CS2, CS3, CS4)
- 237 4) I25 Denver (Sensor ID: CS16)
- 238 5) NJH (Sensor ID: CS1) for the entire period of the experiment

239 **2.1.2 Data preparation steps for preparing a training dataset used to develop** 240 **the various calibration models**

241 A summary of the data preparation steps for preparing a training dataset used to develop
242 the various calibration models are described below:

- 243 1) We joined hourly averages from each of the seven co-located Love My Air
244 monitors with the corresponding FEM monitor. We had a total of 35,593 co-located
245 hourly measurements for which we had data for both the Love My Air sensor and
246 the corresponding reference monitor. **Figure S2** displays time-series plots of $PM_{2.5}$
247 from all co-located Love My Air sensors. **Figure S3** displays time-series plots of
248 $PM_{2.5}$ from the corresponding reference monitors.
- 249 2) The three Love My Air sensors co-located at the I25 Globeville sites (CS2, CS3,
250 CS4) agreed well with each other (Pearson correlation coefficient = 0.98) (**Figures**
251 **S4** and **Figure S5**). To ensure that our co-located dataset was well balanced
252 across sites, we only retained measurements from CS2 at the I25 Globeville site.
253 We were left with a total of 27,338 co-located hourly measurements that we used
254 to develop a calibration model. **Figure S6** displays the time-series plots of $PM_{2.5}$
255 from all other Love My Air sensors in the network.
256

257
258 Reference monitors at La Casa, CAMP, I25 Globeville and I25 Denver, also reported
259 minute-level $PM_{2.5}$ concentrations between April 23 11:16 and Sep 30, 22:49. We also
260 joined minute-level Love My Air $PM_{2.5}$ concentrations with minute-level reference data at
261 these sites. We had a total of 1,062,141 co-located minute-level measurements during
262 this time period. As with the hourly-averaged data, we only retained data from one of the
263 Love My Air sensors at the I25 Globeville site and were thus left with 815,608 minute-level
264 measurements from one LCS at each of the four co-location sites.

265
266 **Table S1** has information on the minute-level co-located measurements. The data at the
267 minute-level displays more variation and peaks in $PM_{2.5}$ concentrations than the hourly-
268 averaged measurements (**Figure S7**), likely due to the impact of passing sources. It is
269 also important to mention that minute-level reference data may have some additional
270 uncertainties introduced due to the finer time resolution. We will use the minute-level data
271 in supplementary analyses, only. Thus, unless explicitly referenced, we will be reporting
272 results from hourly-averaged measurements.

273 **2.1.3 Deriving additional covariates**

274 We derived dew-point (D) from T and RH reported by the Love My Air sensors using the
 275 *weathermetrics* package in the programming language R (Anderson and Peng, 2012), as
 276 D has been shown to be a good proxy of particle hygroscopic growth in previous research
 277 (Barkjohn et al., 2021; Clements et al., 2017; Malings et al., 2020). Some previous work
 278 has also used a nonlinear correction for RH in the form of $RH^2/(1-RH)$, that we also
 279 calculated for this study (Barkjohn et al., 2021).

280
 281 We extracted hour, weekend, and month variables from the Canary-S sensors and
 282 converted hour and month into cyclic values to capture periodicities in the data by taking
 283 the cosine and sine of $hour * 2\pi/24$ and $month * 2\pi/12$, which we designate as *cos_time*,
 284 *sin_time*, *cos_month* and *sin_month*, respectively. Sinusoidal corrections for seasonality
 285 have been shown to improve accuracy of $PM_{2.5}$ measurements in machine learning
 286 models (Considine et al., 2021).

287
 288 **Table 1:** Site location of each Love My Air sensor, as well as summary statistics of hourly
 289 measurements from each sensor

| Sensor ID | Co-location Information | Latitude | Longitude | Hours operational | $PM_{2.5}$ ($\mu g/m^3$) | | | Temperature ($^{\circ}C$) | RH (%) | Dewpoint ($^{\circ}C$) |
|-----------|------------------------------|----------|-----------|-------------------|----------------------------|--------|---------|-----------------------------|--------|--------------------------|
| | | | | | Mean | Median | Min-Max | Mean | Mean | Mean |
| CS1 | Co-located at NJH | 39.739 | -104.940 | 5,478 | 13 | 8 | 0 - 121 | 14.9 | 57.4 | 4.4 |
| CS2 | Co-located at I25 Globeville | 39.786 | -104.989 | 5,818 | 14 | 9 | 0 - 142 | 16.4 | 63.6 | 7.6 |
| CS3 | Co-located at I25 Globeville | 39.786 | -104.989 | 2,490 | 18 | 13 | 0 - 159 | 9.3 | 62.5 | 0.1 |
| CS4 | Co-located at I25 Globeville | 39.786 | -104.989 | 5,765 | 12 | 8 | 0 - 137 | 15.8 | 67.6 | 8.0 |
| CS5 | Co-located at La Casa | 39.779 | -105.005 | 5,761 | 12 | 8 | 0 - 129 | 13.4 | 69.6 | 6.0 |

2.2 Defining the Calibration Models Used

The goal of the calibration model is to predict, as accurately as possible, the ‘true’ PM_{2.5} concentrations given the concentrations reported by the Love My Air sensors. At the co-located sites, the FEM PM_{2.5} measurements, which we take to be the “true” PM_{2.5} concentrations, are the dependent variable in the models.

We evaluated 21 increasingly complex models that included T, RH, D as well as metrics that captured the time-varying patterns of PM_{2.5} to correct the Love My Air PM_{2.5} measurements (**Tables 2** and **3**).

Sixteen models were multivariate regression models that were used in a recent paper (Barkjohn et al., 2021) to calibrate another network of low-cost sensors: the PurpleAir, that rely on the same PM_{2.5} sensor (Plantower) as the Canary-S sensors in the current study. As T, RH, and D are not independent (**Figure S8**), the 16 linear regression models include adding the meteorological conditions considered as interaction terms, instead of additive terms. The remaining five calibration models relied on machine learning techniques.

Machine learning models can capture more complex nonlinear effects (for instance, unknown relationships between additional spatial and temporal variables). We opted to use the following machine learning techniques: Random Forest (RF), Neural Network (NN), Gradient Boosting (GB), SuperLearner (SL) that have been widely used in calibrating LCS. A description of each technique is described in detail in **section S1** in *Supplementary Information*. All machine learning models were run using the *caret* package in R (Kuhn, 2015).

316 We used both Leave-One-Site-Out (LOSO) (**Table 2**) and Leave-Out-By-Date, where we
317 left out a 3-weeks period of data at a time at all sites (LOBD) (**Table 3**) cross-validation
318 (CV) methods to avoid overfitting in the machine learning models. For more details on the
319 cross-validation methods used to avoid overfitting in the machine learning models refer to
320 **section S2** in *Supplementary Information*.

321 **2.2.1 Corrections generated using different co-location time periods (long-** 322 **term, on-the-fly, short-term)**

323 As described earlier, co-location studies in the LCS literature have been conducted over
324 different time periods. Some studies co-locate one or more LCS for brief periods of time
325 before or after an experiment, whereas others co-locate a few LCS for the entire duration
326 of the experiment. These studies apply calibration models generated using the co-located
327 data to measurements made by the entire network over the entire duration of the
328 experiment. We attempt to replicate these study designs in our experiment to evaluate the
329 transferability of calibration models across time by generating four different corrections:
330

331 (C1) *Entire data set correction*: The 21 calibration models were developed using data at
332 all co-location sites for the entire period of co-location.

333 (C2) *On the fly correction*: The 21 calibration models to correct a measurement during a
334 given week were developed using data across all co-located sites for the same week of
335 the measurement.

336 (C3) *2-week winter correction*: The 21 calibration models were developed using co-
337 located data collected for a brief period (2 weeks) at the beginning of the study (Jan 1 -
338 Jan 14, 2021). They were then applied to measurements from the network during the rest
339 of the period of operation.

340 (C4) *2-week winter + 2-week spring*: The 21 calibration models were developed using co-
341 located data collected for two 2-week periods in different seasons (Jan 1 - Jan 14, 2021
342 and May 1 - May 14, 2021). They were then applied to measurements from the network
343 during the rest of the period of operation.

344
345 Although models developed using co-located data over the entire time period (C1) tend to
346 be more accurate over the entire spatiotemporal data set, it is inefficient to re-run large
347 models frequently (incorporating new data). On-the-fly corrections (such as C2) can help
348 characterize short-term variation in air pollution and sensor characteristics. The duration
349 of calibration is a key question that remains unanswered (Liang, 2021). We opted to test
350 corrections C3 and C4 as many low-cost sensor networks rely on developing calibration
351 models based on relatively short co-location periods (deSouza et al., 2020b; West et al.,
352 2020; Singh et al., 2021). Each of the 21 calibration models considered was tested under
353 four potential correction schemes (C1, C2, C3 and C4).

354
355 For C1, the five machine-learning models were trained using two CV approaches: LOSO
356 and LOBD, separately. For C2, C3 and C4 only LOSO was conducted, as model
357 application is already being performed on a different time period from the training (for

358 more details refer to **section S2**). Overall, we test 89 calibration models (21 (C1,
359 CV=LOSO) + 5 (C1, CV=LOBD) + 21 × 3 (C2, C3, C4) = 89) listed in **Tables 2** and **3**.

360 **2.3 Evaluating the calibration models developed under the four** 361 **different correction schemes**

362 We first qualitatively evaluate transferability of the calibration models from the co-location
363 sites to the rest of the network by comparing the distribution of T and RH at the co-
364 location sites during time-periods used to construct the calibration models with that
365 experienced over the entire course of network operation (**Figure 2**).

366
367 We then evaluate: How well different calibration models perform when using the
368 traditional methods of model evaluation (**Tables 2, 3, S2**). We attempt to quantify the
369 degree of transferability of the calibration models in time by asking: How well do
370 calibration models developed during short-term co-locations (corrections: C3 and C4)
371 perform when transferred to long-term network measurements? In order to answer this
372 question, we evaluated calibration models using corrections C3 and C4 only for the time-
373 period over which the calibration models were developed, which was Jan 1 - Jan 14,
374 2021, for C3 and Jan 1 - Jan 14, 2021, and May 1 - May 14, 2021, for C4 (**Table S2**). We
375 compared the performance of C3 and C4 corrections during this time period with that
376 obtained from applying these models over the entire time period of the network (**Table 2**).

377
378 We next ask how well calibration models developed at a small number of co-locations
379 sites transfer in space to other sites using the methodology detailed in the next
380 subsection.

381 **2.3.1 Evaluating transferability of calibration models over space**

382 To evaluate how transferable the calibration technique developed at the co-located sites
383 was to the rest of the network we left out each of the five co-located sites in turn and
384 using data from the remaining sites ran the models proposed in **Tables 2** and **3**. We then
385 applied the models generated to the left-out site. We report the distribution of RMSE from
386 each calibration model considered at the left-out sites using box-plots (**Figure 3**). For
387 correction C1, we also left out a three-week period of data at a time and generated the
388 calibration models based on the data from the remaining time periods at each site. For the
389 machine learning models (Models 17 – 21), we used CV = LOBD. We plotted the
390 distribution of RMSE from each model considered for the left-out three week period
391 (**Figure 3**).

392
393 We statistically compare the errors in predictions on each test dataset with errors in
394 predictions from using all sites in our main analysis. Such an approach is useful to
395 understand how well the proposed correction can transfer to other areas in the Denver
396 region. To compare statistical differences between errors, we used t-tests if the
397 distribution of errors were normally distributed (as determined by a Shapiro–Wilk test),
398 and Wilcoxon signed rank tests, if not, using a significance value of 0.05.

399
 400 We have only five co-location sites in the network. Although evaluating the transferability
 401 among these sites is useful, as we know the true $PM_{2.5}$ concentrations at these sites, we
 402 also evaluated the transferability of these models in the larger network by predicting $PM_{2.5}$
 403 concentrations using the models proposed in **Tables 2** and **3** at each of the 24 sites in the
 404 Love My Air network. For each site, we display time series plots of corrected $PM_{2.5}$
 405 measurements in order to visually compare the ensemble of corrected values at each site
 406 (**Figure 4**).

407
 408 We next propose different metrics to quantify the uncertainty in spatial and temporal
 409 trends in $PM_{2.5}$ reported by the LCS network introduced by the choice of calibration model
 410 applied in the subsection below.

411 **2.3.2 Evaluating sensitivity of the spatial and temporal trends of the low-cost** 412 **sensor network to the method of calibration**

413 We evaluate the spatial and temporal trends in the $PM_{2.5}$ concentrations corrected using
 414 the 89 different calibration models using similar methods to that described in (Jin et al.,
 415 2019; deSouza et al., 2022) by calculating:

416
 417 (1) The spatial root mean square difference (RMSD) (**Figure 5**) between any two

418 corrected exposures at the same site: $SRMSD_{h,d} = \sqrt{\frac{1}{N} \sum_{i=1}^N (Conc_{hi} - Conc_{di})^2}$,

419 where $Conc_{hi}$ and $Conc_{di}$ are Jan 1- Sep 30, 2021 averaged $PM_{2.5}$ concentrations
 420 estimated from correction h and d for site i . N is the total number of sites.

421 (2) The temporal RMSD (**Figure 6**) between pairs of exposures: $TRMSD_{h,d} =$

422 $\sqrt{\frac{1}{M} \sum_{t=1}^M (Conc_{ht} - Conc_{dt})^2}$, where $Conc_{ht}$ and $Conc_{dt}$ are hourly corrected $PM_{2.5}$

423 concentrations averaged over all operational Love My Air sites estimated from
 424 correction h and d for time t . M is the total number of hours of operation of the
 425 network.

426
 427 We characterized the uncertainty in the ‘corrected’ $PM_{2.5}$ estimates at each site across the
 428 different models using two metrics: a normalized range (NR) (**Figure 7a**) and uncertainty,
 429 calculated from the 95% confidence interval (CI) assuming a t-statistical distribution
 430 (**Figure 7b**). NR for a given site represents the spread of $PM_{2.5}$ across the different
 431 correction approaches.

432 (3) $NR = \frac{1}{M} \sum_{t=1}^M \frac{\max_{k \in K} C_{kt} - \min_{k \in K} C_{kt}}{\bar{C}_t}$

433
 434 C_{kt} is the $PM_{2.5}$ concentration at hour t from the k th model from the ensemble of K (which
 435 in this case is 89) correction approaches. \bar{C}_t represents the ensemble mean across the K
 436 different products at hour t . M is the total number of hours in our sample for which we
 437 have $PM_{2.5}$ data for the site under consideration.

438

439 For our sample ($K = 89$), we assume the variations in $PM_{2.5}$ across multiple models
440 follows the Student-t distribution with the mean being the ensemble average. The
441 confidence interval (CI) for the ensemble mean at a given time t is:

442

$$443 \quad (4) \quad CI_t = \bar{C}_t + t^* \frac{SD_t}{\sqrt{K}}$$

444 Where \bar{C}_t represents the ensemble mean at time t ; t^* is the upper $\frac{(1 - CI)}{2}$ critical value for
445 the t-distribution with $K-1$ degrees of freedom. For $K=89$, t^* for the 95% double tailed
446 confidence interval is 1.99. SD_t is the sample standard deviation at time t .

$$447 \quad (5) \quad SD_t = \sqrt{\frac{\sum_{k=1}^K (C_{k,t} - \bar{C}_t)^2}{K-1}}$$

448

449 We define an overall estimate of uncertainty as follows:

$$450 \quad (6) \quad uncertainty = \frac{1}{M} \sum_{t=1}^M t^* \frac{SD_t}{\bar{C}_t \sqrt{K}}, \text{ which can also be expressed as}$$

$$451 \quad (6) \quad uncertainty = \frac{1}{M} \sum_{t=1}^M \frac{CI_t - \bar{C}_t}{\bar{C}_t}$$

452 Finally, we evaluate the impact of the choice of calibration model on key LCS network
453 use-cases detailed in the sections below.

454 **2.3.3 Evaluating the sensitivity of hotspot detection across the network of** 455 **sensors to the calibration method**

456 One of the key use-cases of low-cost sensors is hotspot detection. We report the labels of
457 sites that are the most polluted using calibrated measurements from the 89 different
458 models using hourly data. We repeat this process for daily, weekly and monthly-averaged
459 calibrated measurements. We ignore missing measurements from the network when
460 calculating time averaged values for the different time periods considered. We report the
461 mean number of sensors that are ranked 'most polluted' across the different correction
462 functions for the different averaging periods (**Figure 8**). We do this to identify if the choice
463 of the calibration model impacts the hotspot identified by the network (i.e. depending on
464 the calibration model different sites show up as the most polluted).

465 **2.3.4 Supplementary Analysis: Evaluating transferability of calibration** 466 **models developed in different pollution regimes**

467 We evaluated model performance for true/reference $PM_{2.5}$ concentrations $> 30 \mu\text{g}/\text{m}^3$ and
468 $\leq 30 \mu\text{g}/\text{m}^3$, as Nilson et al. (2022) has shown that calibration models can have different
469 performances in different pollution regimes. We chose to use $30 \mu\text{g}/\text{m}^3$ as the threshold,
470 as these concentrations account for the greatest differences in health and air pollution
471 avoidance behavior impacts (Nilson et al., 2022). Lower concentrations ($PM_{2.5} \leq 30$
472 $\mu\text{g}/\text{m}^3$) represent most measurements observed in our network; better performance at
473 these levels will ensure better day-to-day functionality of the correction. High $PM_{2.5}$ (> 30
474 $\mu\text{g}/\text{m}^3$) concentrations in Denver typically occur during fires. Better performance of the
475 calibration models in this regime will ensure that the LCS network can accurately capture

476 pollution concentrations under smoky conditions. In order to compare errors observed in
477 the two different concentration ranges, in addition to reporting R and RMSE of the
478 calibration approaches, we also report the normalized RMSE (normalized by the mean of
479 the true concentrations) (**Tables S3** and **S4**).

480 **2.3.5 Supplementary Analysis: Evaluating transferability of calibration** 481 **models developed across different time aggregation intervals**

482 One of the key advantages of LCS is that they report high frequency (timescales shorter
483 than an hour) measurements of pollution. As reference monitoring stations provide hourly
484 or daily average pollution values, most often the calibration model is developed using
485 hourly averaged data and then applied to the unaggregated, high-frequency LCS
486 measurements. We applied the calibration models described in **Tables 2** and **3** developed
487 using hourly-averaged co-located measurements on minute-level measurements from the
488 co-located LCS described in **Table S1**. We evaluated the performance of the corrected
489 high-frequency measurements against the ‘true’ measurements from the corresponding
490 reference monitor using the metrics R and RMSE (**Tables S5** and **S6**).

491 **3 Results**

492 We first report how representative meteorological conditions at the co-located sites were
493 of the overall network. Temperature at the co-located sites across the entire period of the
494 experiment (from Jan 1 – Sep 30, 2021) were similar to those at the rest of Love My Air
495 network (**Figure 2a**). The sensor CS19 is the only one that recorded lower temperatures
496 than those at any of the other sites, likely due to it being in the shade. Relative humidity
497 at the co-located sites (three of the four co-located sites have a median RH close to 50 %
498 or higher) is higher than at the other sites in the network (7 of the 12 other sites have a
499 median RH < 50%) (**Figure 2b**). The similarity in meteorological conditions at the co-
500 located sites with those experienced by the rest of the network suggests that models
501 developed using long-term data (C1) are likely to be transferable to the overall network.
502

503 We also compared meteorological conditions during the development of corrections C3
504 (Jan 1 - Jan 14, 2021) and C4 (Jan 1 - Jan 14, 2021, and May 1 - May 14, 2021), to those
505 measured during the duration of network operation (C3: **Figures S10** and **S11**; C4:
506 **Figures S12** and **S13**). Unsurprisingly, temperatures at the co-located sites during the
507 development of C4 were more representative of the network than C3, although they were
508 on average lower (median temperatures ~ 10 - 17°C) than the average temperatures
509 experienced by the network (median temperatures ~ 5 - 23°C). RH values at co-located
510 sites during C3 and C4 tend to be higher than conditions experienced by Love My Air
511 sensors: CS8, CS10, CS15, CS16, CS17, CS18, CS20 likely due to the different
512 microenvironments experienced at each site. The differences in meteorological conditions
513 at the co-located sites for the time-period of calibration model developed with those
514 experienced by the rest of the network suggests that models developed using short-term
515 data (C3, C4) are not likely to be transferable to the overall network.

517 **Figure 2:** (a) Distribution of temperature recorded by each Love My Air sensor, (b)
518 Distribution of RH recorded by each Love My Air sensor. The distribution of temperature
519 and RH recorded by co-located LCS is shown on the left. The distribution of temperature
520 and RH recorded by all LCS not used to construct the calibration models are displayed on
521 the right

522

523 When we evaluate the performance of applying each of the 89 calibration models on all
524 co-located data, we find that based on R and RMSE values, the on-the-fly C2 correction
525 performed better overall than the C1, C3 and C4 corrections for most calibration model
526 forms (**Tables 2 and 3**).

527

528 Within corrections C1 and C2, we found that an increase in complexity of model form
529 resulted in a decreased RMSE. Overall, Model 21 yielded the best performance (RMSE =
530 1.281 $\mu\text{g}/\text{m}^3$ when using the C2 correction, 1.475 $\mu\text{g}/\text{m}^3$ when using the C1 correction with
531 a LOSO CV and 1.480 $\mu\text{g}/\text{m}^3$ when using a LOBD correction). In comparison, the simplest
532 model yielded an RMSE of 3.421 $\mu\text{g}/\text{m}^3$ for the C1 correction, and 3.008 $\mu\text{g}/\text{m}^3$ when
533 using the C2 correction. For correction C1, using a LOBD CV (**Table 3**) with the machine
534 learning models resulted in better performance than using a LOSO CV (**Table 2**), except
535 for Model 21 which is an RF model with additional time-of-day and month covariates, for
536 which performance using the LOSO CV was marginally better (RMSE: 1.475 $\mu\text{g}/\text{m}^3$
537 versus 1.480 $\mu\text{g}/\text{m}^3$).

538

539 We also found that for corrections of short-term calibrations, C3 and C4, more complex
540 models yielded a better performance (for example the RMSE for Model 16: 2.813 $\mu\text{g}/\text{m}^3$,
541 RMSE for Model 2: 3.110 $\mu\text{g}/\text{m}^3$ generated using the C3 correction) when evaluated
542 during the period of co-location, alone (**Table S2**). However, when models generated
543 using the C3 and C4 corrections were transferred to the entire time period of co-location,
544 we find that more complex multivariate regression models (Models 13-16) and the
545 machine learning model (Model 21) that include \cos_time , performed significantly worse
546 than the simpler models (**Table 2**). In some cases, these models performed worse than
547 the uncorrected measurements. For example, applying Model 16 generated using C3 on
548 the entire dataset resulted in an RMSE of 32.951 $\mu\text{g}/\text{m}^3$ compared to 6.469 $\mu\text{g}/\text{m}^3$ for the
549 uncorrected measurements.

550

551 Including data from another season, spring in addition to winter, in the training sample
552 (C4), resulted in significantly improved performance of calibration models over the entire
553 dataset compared to C3 (winter), although it did not result in an improvement in
554 performance for all models compared to the uncorrected measurements. For example,
555 Model 16 generated using C4 yielded an RMSE of 6.746 $\mu\text{g}/\text{m}^3$. Among the multivariate
556 regression models, we found that models of the same form that corrected for RH instead
557 of T or D did best. The best performance was observed for models that included the
558 nonlinear correction for RH (Model 12) or included an $RH \times T$ term (Model 5) (**Table 2**).

559

560 **Table 2:** Performance of the calibration models as captured using root mean square error
561 (RMSE), and Pearson correlation (R). LOSO CV was used to prevent overfitting in the
562 machine learning models. All corrected values were evaluated over the entire time-period
563 (Jan 1 - Sep 30, 2021)

| ID | Name | Model | C1 Correction developed on data during the entire period of network operation | | C2 On-the-fly correction developed using data for the same week of measurement | | C3 Correction developed using measurements made in the first two weeks of Jan | | C4 Correction developed using measurements from the first two weeks of Jan and the first two weeks in May | |
|--|-------------|---|--|---------------------------|---|---------------------------|--|---------------------------|--|---------------------------|

568 3.1.1 Evaluating transferability of the calibration algorithms in space

569 Large reductions in RMSE are observed when applying simple linear corrections (Models
570 1 - 4) developed using a subset of the co-located data to the left-out sites (**Figures 3a, c,**
571 **d, e**) or time-periods (**Figure 3b**) across C1, C2, C3, and C4. Increasing the complexity of
572 the model does not result in marked changes in correction performance on different test
573 sets for C1 and C2. Although the performance of the corrected datasets did improve on
574 average for some of the complex models considered (Model 17, 20, 21 for example, vis-a-
575 vis simple linear regressions when using the C1 correction) (**Figures 3a, 3b**), this was not
576 the case for *all* test datasets considered, as evidenced by the overlapping distributions of
577 RMSE performances (e.g., Model 11 using the C2 correction resulted in a worse fit for
578 one of the test datasets). For C3 and C4, the performance of corrections was worse
579 across all datasets for the more complex multivariate model formulations (**Figures 3d,**
580 **3e**), indicating that using uncorrected data is better than using these corrections and
581 calibration models.

582
583 Wilcoxon tests and t-tests (based on whether Shapiro-Wilk tests revealed that the
584 distribution of RMSEs was normal) revealed significant improvements in the distribution of
585 RMSEs for all corrected test sets vis-a-vis the uncorrected data. There was no significant
586 difference in the distribution of RMSE values from applying C1 and C2 corrections to the
587 test sets, across the different models. For corrections C3 and C4, we found significant
588 differences in the distribution of RMSEs obtained from running different models on the
589 data, implying that the choice of model has a significant impact on transferability of the
590 calibration models to other monitors.

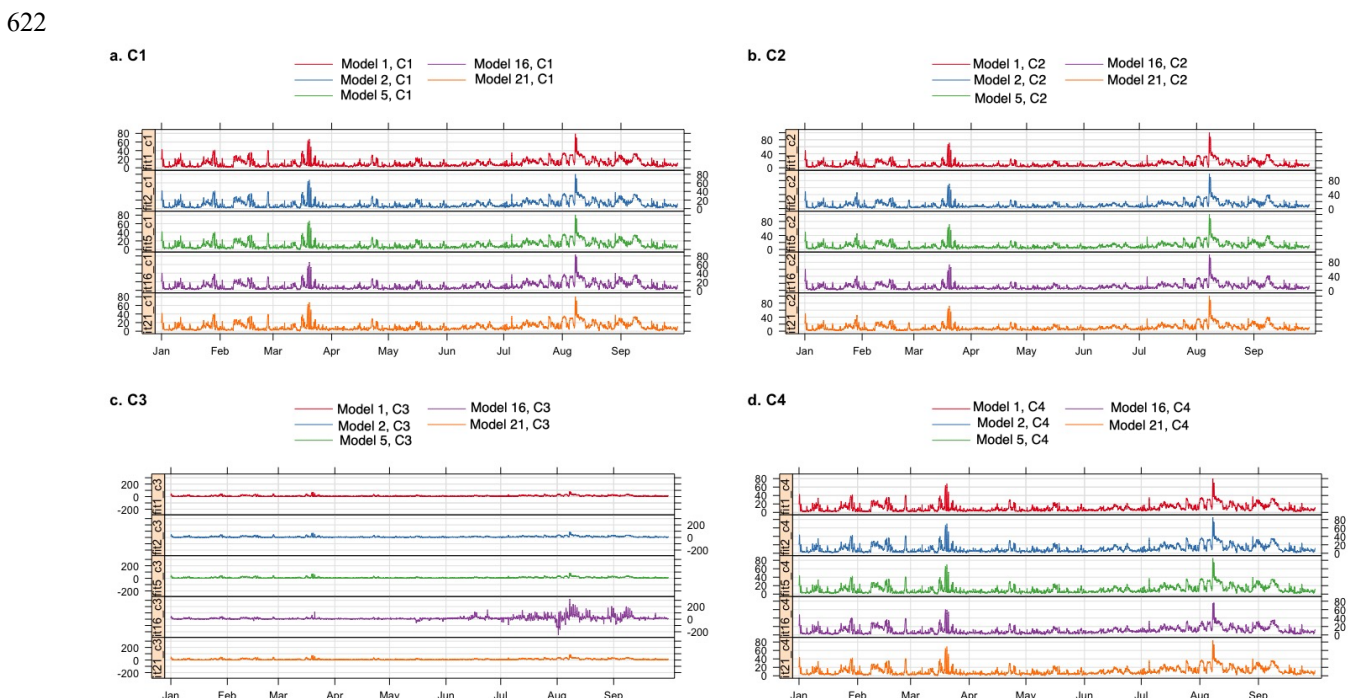

591
 592 **Figure 3:** Performance (RMSE) of corrected Love My Air PM_{2.5} data by generating
 593 corrections based on the 21 models (designated as fit) previously proposed using (a)
 594 Correction C1 when leaving out a co-location site in turn and then running the generated
 595 correction on the test site (Note that for machine learning models (Models 17- 21), we
 596 performed CV using a LOSO CV as well as a LOBD CV approach), (b) Correction C1
 597 when leaving out 3 week periods of data at a time and generating corrections based on
 598 the data from the remaining time periods across each site, and evaluating the
 599 performance of the developed corrections on the held out 3 weeks of data (Note that for
 600 machine learning models (Models 17- 21), we performed CV using a LOBD CV
 601 approach), (c) Correction C2 when leaving out a co-location site in turn and then running
 602 the generated correction on the test site, (d) Correction C3 when leaving out a co-location
 603 site in turn and then running the generated correction on the test site, (e) Correction C4
 604 when leaving out a co-location site in turn and then running the generated correction on
 605 the test site. Each point represents the RMSE for each test dataset permutation. The
 606 distribution of RMSEs is displayed using box-plots and violin-plots.

607
 608 The time-series of corrected PM_{2.5} values for Models 1, 2, 5, 16, and 21 (RF using
 609 additional variables) (using CV = LOSO for the machine learning Models 17 and 21) for

610 corrections generated using C1, C2, C3 and C4 are displayed in **Figure 4** for Love My Air
 611 sensor CS1. These subsets of models were chosen as they cover the range of model
 612 forms considered in this analysis.

613
 614 From **Figure 4**, we note that although the different corrected values from C1 and C2 track
 615 each other well, there are small systematic differences between the different corrections.
 616 Peaks in corrected values using C2 tend to be higher than those using C1. Peaks in
 617 corrected values using machine learning methods using C1 are higher than those
 618 generated from multivariate regression models. **Figure 4** also shows marked differences
 619 in the corrected values from C3 and C4. Specifically Model 16 yields peaks in the data
 620 that corrections using the other models do not generate. This pattern was consistent
 621 when applying this suite of corrections to other Love My Air sensors.

623
 624 **Figure 4:** Time-series of the different $PM_{2.5}$ corrected values for Models 1, 2, 5, 16 and 21
 625 across corrections (a) C1, (b) C2, (c) C3 and (d) C4 for the Love My Air monitor CS1.
 626 Note that the scales are the same for C1, C2 and C4, but not for C3.

627 **3.1.2 Evaluating sensitivity of the spatial and temporal trends of the low-cost**
 628 **sensor network to the method of calibration**

629 The spatial and temporal RMSD values between corrected values generated from
 630 applying each of the 89 models using the four different correction approaches across all
 631 monitoring sites in the Love My Air network are displayed **Figures 5** and **6**, respectively.
 632 There is larger temporal variation (max $32.79 \mu\text{g}/\text{m}^3$), in comparison to spatial variations
 633 displayed across corrections (max: $11.95 \mu\text{g}/\text{m}^3$). Model 16 generated using the C3
 634 correction has the greatest spatial and temporal RMSD in comparison with all other
 635 models. Models generated using the C3 and C4 corrections displayed the greatest spatial
 636 and temporal RMSD vis-a-vis C1 and C2.

637
638
639
640
641
642
643
644

Figures S14- S17 display spatial RMSD values between all models corresponding to corrections C1-C4, respectively, to allow for a zoomed in view of the impact of the different model forms for the 4 corrections. Similarly, **Figures S18- S21** display temporal RMSD values between all models corresponding to corrections C1-C4, respectively. Across all models the temporal RMSD between models is greater than the spatial RMSD.

645

647
648
649
650

Figure 5: Spatial RMSD ($\mu\text{g}/\text{m}^3$) calculated using the method detailed in section 2.3.5 from applying each of the 89 calibration models using the four different correction approaches to all monitoring sites in the Love My Air network.

651
 652 **Figure 6:** Temporal RMSD ($\mu\text{g}/\text{m}^3$) calculated using the method detailed in section 2.3.5
 653 from applying each of the 89 calibration models using the four different correction
 654 approaches to all monitoring sites in the Love My Air network.

655
 656 The distribution of uncertainty and the NR in hourly-calibrated measurements over the 89
 657 models by monitor are displayed in **Figure 7**. Overall, there are small differences in
 658 uncertainties and NR of the calibrated measurements across sites. The average NR and
 659 uncertainty across all sites are 1.554 (median: 0.9768) and 0.044 (median: 0.033),
 660 respectively. We note that although the uncertainties in the data are small, the average
 661 normalized range tends to be quite large.

662

663
 664 **Figure 7:** Distribution of (a) uncertainty and (b) normalized range (NR) in hourly-calibrated
 665 measurements across all 89 calibration models at each site using the methodology
 666 described in Section 2.3.5.

667 **3.1.3 Evaluating the sensitivity of hotspot detection across the network of**
 668 **sensors to the calibration method**

669 Mean (95% CI) PM_{2.5} concentrations across the 89 different calibration models listed in
 670 **Tables 1 and 2**) at each Love My Air site for the duration of the experiment (Jan 1 - Sep
 671 30, 2021) are displayed in **Figure S22**. Due to overlap between the different calibrated
 672 measurements across sites, the ranking of sites based on pollutant concentrations is
 673 dependent on the calibration model used.

674
 675 Every hour, we ranked the different monitors for each of the 89 different calibration
 676 models, in order to evaluate how sensitive pollution hotspots were to the calibration model
 677 used. We found that there were on average 4.4 (median = 5) sensors that were ranked
 678 most polluted. When this calculation was repeated using daily-averaged calibrated data,
 679 there were on average 2.5 (median = 2) sensors that were ranked the most polluted. The
 680 corresponding value for weekly-calibrated data was 2.4 (median = 1), and for monthly
 681 data was 3 (median = 3) (**Figure 8**).

682
 683 **Figure 8:** Variation in the number of sites that were ranked as ‘most polluted’ across the
 684 89 different calibration models for different time-averaging periods displayed using box-
 685 plots

686 **3.1.4 Supplementary Analysis: Evaluating transferability of calibration**
 687 **models developed in different pollution regimes**

688 When we evaluated how well the models performed at high PM_{2.5} concentrations (> 30
 689 µg/m³) versus lower concentrations (≤ 30 µg/m³), we found that multivariate regression
 690 models generated using the C1 correction did not perform well in capturing peaks in PM_{2.5}
 691 concentrations (normalized RMSE > 25%) (**Tables S3** and **S4**).

692
 693 Multivariate regression models generated using the C2 correction performed better than
 694 those generated using C1 (normalized RMSE ~ 20 -25 %). Machine learning models
 695 generated using both C1 and C2 corrections captured PM_{2.5} peaks well (C1: normalized
 696 RMSE ~ 10 - 25%, C2: normalized RMSE ~ 10 - 20%). Specifically, the C2 RF model
 697 (Model 21) yielded the lowest RMSE values (4.180 µg/m³, normalized RMSE: 9.8%), of all
 698 models considered. The performance of models generated using C1 and C2 corrections
 699 in the low-concentration regime was the same as that over the entire dataset. This is
 700 because most measurements made were < 30 µg/m³.

701
 702 Models generated using C3 and C4 had the worst performance in both concentration
 703 regimes and yielded poorer agreement with reference measurements than even the
 704 uncorrected measurements. As in the case with the entire dataset, more complex
 705 multivariate regression models and machine learning models generated using C3 and C4

706 performed worse than more simple models in both PM_{2.5} concentration intervals (**Tables**
707 **S3** and **S4**).

708 **3.1.5 Supplementary Analysis: Evaluating transferability of calibration** 709 **models developed across different time aggregation intervals**

710 We then evaluated how well the models generated using C1, C2, C3 and C4 corrections
711 performed when applied to minute-level LCS data at co-located sites (**Tables S5** and **S6**).
712 We found that the machine learning models generated using C1 and C2 improved the
713 performance of the LCS. Model 21 (CV=LOSO) generated using C1 yielded an RMSE of
714 15.482 µg/m³ compared to 16.409 µg/m³ obtained from the uncorrected measurements.
715

716 The more complex multivariate regression models yielded a significantly worse
717 performance across all corrections. (Model 16 generated using C1 yielded an RMSE of
718 41.795 µg/m³). As in the case with the hourly-averaged measurements, using correction
719 C1, LOBD CV instead of LOSO for the machine learning models resulted in better model
720 performance except for Model 21. Few models generated using C3 and C4 resulted in
721 improved performance when applied to the minute-level measurements (**Tables S5** and
722 **S6**).

723 **4 Discussion and Conclusions**

724 In our analysis of how transferable the correction models developed at the Love My Air
725 co-location sites are to the rest of the network, we found that for C1 (corrections
726 developed on the entire co-location dataset) and C2 (on-the-fly corrections), more
727 complex model forms yielded better predictions (higher R, lower RMSE) at the co-located
728 sites. This is likely because the machine learning models were best able to capture
729 complex, non-linear relationships between the LCS measurements, meteorological
730 parameters and reference data when conditions at the co-location sites were
731 representative of that of the rest of the network. Model 21, which included additional
732 covariates intended to capture periodicities in the data, such as seasonality, yielded the
733 best performance, suggesting that in this study the relationship between LCS
734 measurements and reference data varies over time. One possible reason for this could be
735 the impact of changing aerosol composition in time which has been shown to impact the
736 LCS calibration function (Malings et al., 2020).
737

738 When examining the short-term, C3 (corrections developed on 2-weeks of co-located data
739 at the start of the experiment) and C4 (corrections developed on 2-weeks of co-located
740 data in January and 2-weeks of co-located data in a May) corrections, we found that
741 although these corrections appeared to significantly improve LCS measurements during
742 the time period of model development (**Table S2**), when transferred to the entire time
743 period of operation they did not perform well (**Table 2**). Many of the models, especially the
744 more complex multivariate regression models, performed significantly worse than even
745 the uncorrected measurements. This result indicates that calibration models generated
746 during short time periods, even if the time periods correspond to different seasons, may

747 not necessarily transfer well to other times, likely because conditions during co-location
748 (aerosol-type, meteorology) are not representative of that of network operating conditions.
749 Our results suggest the need for statistical calibration models to be developed over longer
750 time periods that better capture different LCS operating conditions. For C3 and C4, we did
751 however find models that relied on nonlinear formulations of RH, that serve as proxies for
752 hygroscopic growth, yielded the best performance, as compared to more complex models
753 (**Table 2**). This suggests that physics-based calibrations are potentially an alternative
754 approach, especially when relying on short co-location periods and need to be explored
755 further.

756
757 When evaluating how transferable different calibration models were to the rest of the
758 network, we found that for C1 and C2, more complex models that appeared to perform
759 well at the co-location sites did not necessarily transfer best to the rest of the network.
760 Specifically, when we tested these models on a co-located site that was left out when
761 generating the calibration models, we found that some of the more complex models using
762 the C2 correction yielded a significantly worse performance at some test sites (**Figure 3**).
763 If the corrected data were going to be used to make site-specific decisions, then such
764 corrections would lead to important errors. For C3 and C4, we observed a large
765 distribution of RMSE values across sites. For several of the more complex models
766 developed using C3 and C4 corrections, the RMSE values at some left-out sites were
767 larger than observed for the uncorrected data, suggesting that certain calibration models
768 could result in even more error-prone data than using uncorrected measurements. As the
769 meteorological parameters for the duration of the C3 and C4 co-locations are not
770 representative of overall operating conditions of the network, it is likely that the more
771 complex models were overfit to conditions during the co-location, leading to them not
772 performing well over the network operations.

773
774 For C1 and C2, we found that there were no significant differences in the distribution of
775 the performance metric RMSE of corrected measurements from simpler models in
776 comparison to those derived from more complex corrections at test sites (**Figure 3**). For
777 C3 and C4, we found significant differences in the distribution of RMSE across test sites,
778 which indicates that these models are likely site-specific and not easily transferable to
779 other sites in the network. This suggests that less complex models might be preferred
780 when short-term co-locations are carried out for sensor calibration, especially when
781 conditions during the short-term co-location are not representative of that of the network.

782
783 We found that the temporal RMSD (**Figure 6**) was greater than the spatial RMSD (**Figure**
784 **5**) for the ensemble of corrected measurements developed by applying the 89 different
785 calibration models to the Love My Air network. One of the reasons this may be the case is
786 that $PM_{2.5}$ concentrations across the different Love My Air sites in Denver are highly
787 correlated (**Figure S5**), indicating that the contribution of local sources to $PM_{2.5}$
788 concentrations in the Denver neighborhoods in which Love My Air was deployed is small.
789 Due to the low variability in $PM_{2.5}$ concentrations across sites, it makes sense that the

790 variations in the corrected PM_{2.5} concentrations will be seen in time rather than space.
791 The largest pairwise temporal RMSD were all seen between corrections derived from
792 complex models using the C3 correction.

793
794 Finally, we observed that the uncertainty in PM_{2.5} concentrations across the ensemble of
795 89 calibration models (**Figure 7**) was consistently small for the Love My Air Denver
796 network. The normalized range in the corrected measurements, on the other hand, was
797 large; however, the uncertainty (95% CI) in the corrected measurements fall within a
798 relatively small interval. The average normalized range tends to be quite large, likely due
799 to outlier corrected values produced from some of the more complex models evaluated
800 using the C3 and C4 corrections. Thus, deciding which calibration model to pick has
801 important consequences for decision-makers when using data from this network.

802
803 Our findings reinforce the idea that evaluating calibration models at all co-location sites
804 using overall metrics like RMSE should not be seen as the only/best way to determine
805 how to calibrate a network of LCS. Instead, approaches like the ones we have
806 demonstrated, and metrics like the ones we have proposed should be used to evaluate
807 calibration transferability.

808
809 We found that the detection of the ‘most polluted’ site in the Love My Air network (an
810 important use-case of LCS networks) was dependent on the calibration model used on
811 the network. We also found that for the Love My Air network, the detection of the most
812 polluted site was sensitive to the duration of time-averaging of the corrected
813 measurements (**Figure 8**). Hotspot detection was most robust using weekly-averaged
814 measurements. A possible reason for this is that temporal variation in PM_{2.5} in Denver
815 varied primarily on a weekly-scale, and therefore analysis conducted using weekly-values
816 resulted in the most robust results. Such an analysis thus provides guidance on the most
817 useful temporal scale for decision-making related to evaluating hotspots in the Denver
818 network.

819
820 In supplementary analyses, when we evaluated the sensitivity of other LCS use-cases to
821 the calibration model applied such as tracking high pollution concentrations during fire or
822 smoke-events, we found that different models yielded different performance results in
823 different pollution regimens. Machine learning models developed using C1, and models
824 developed using C2 were better than multivariate regression models generated using C1
825 at capturing peaks in pollution (> 30 µg/m³). All models using C3 and C4 yielded poor
826 performance results in tracking high pollution events (**Tables S3** and **S4**). This is likely
827 because PM_{2.5} concentrations during the C3 and C4 co-location tended to be low. The
828 calibration model developed thus did not transfer well to other concentrations. When
829 evaluating how well the calibration models developed using hourly-aggregated
830 measurements translated to high-resolution minute-level data (**Tables S5** and **S6**), we
831 observed that machine learning models generated using C1 and C2, improved the LCS
832 measurements. More complex multivariate regression models performed poorly. All C3

833 and C4 models also performed poorly. This suggests that caution needs to be exercised
834 when transferring models developed at a particular timescale to another. Note that in this
835 paper, because pollution concentrations did not show much spatial variation, we focus on
836 evaluating transferability across timescales, only.

837
838 In summary, this paper makes the case that it is not enough to evaluate calibration
839 models based on metrics of performance at co-located sites, alone. We need to:

840
841 1) *Determine how well calibration adjustments can be transferred to other locations.*
842 Specifically, although we found that in Denver some calibration models performed well at
843 co-location sites, the models could result in large errors at specific sites that would create
844 difficulties for site-specific decision making.

845
846 2) *Examine how well calibration adjustments can be transferred to other time periods.* In
847 this study we found that models developed using the short-term C3 and C4 corrections
848 were not transferable to other time periods because the conditions during the co-location
849 were not representative of broader operating conditions in the network.

850
851 3) *Use a variety of approaches to quantify transferability of calibration models in the*
852 *overall network* (e.g., with spatio-temporal correlations and RMSD). The metrics proposed
853 in this paper to evaluate model transferability can be used in other networks.

854
855 4) *Investigate how adopting a certain timescale for averaging measurements could*
856 *mitigate the uncertainty induced by the calibration process for specific use-cases.*
857 Namely, we found that in the Love My Air network, hotspot identification was more robust
858 to using daily-averaged data than hourly-averaged data. Our analyses also revealed
859 which models performed best when needing to transfer the calibration model developed
860 using hourly-averaged data to higher-resolution data, and which models best captured
861 peaks in pollution during fire- or smoke- events.

862
863 In this work, the Love My Air network under consideration is located over a small area in a
864 single city. In this network, for the time period considered, PM_{2.5} seems to be mainly a
865 regional pollutant and the contribution of local sources is small. More work needs to be
866 done to evaluate model transferability in networks in other settings. Concerns about
867 model transferability are likely to be even more pressing when thinking about larger
868 networks that span different cities and should be considered in future research. In this
869 study, we present a first attempt to demonstrate the importance of considering the
870 transferability of calibration models. In future work, we also aim to explore the physical
871 factors that drive concerns about transferability to generalize our findings more broadly.

872 **Author Contributions**

873 PD conceptualized the study, developed the methodology, carried out the analysis and wrote the
874 first draft. PD and BC obtained funding for this study. BC produced Figure 1. All authors helped in
875 refining the methodology and editing the draft.

876 **Acknowledgements**

877 PD and BC gratefully acknowledge a CU Denver Presidential Initiative grant that
878 supported their work. The authors are grateful to the Love My Air team for setting up and
879 maintaining the Love My Air network. The authors are also grateful to Carl Malings for
880 useful comments

881 **Competing Interests**

882 The authors declare that they have no conflict of interest.
