Abstract

An algorithm for aerosol effective height (AEH) was developed for operational use with observations from the Geostationary Environment Monitoring Spectrometer (GEMS). The retrieval technique uses the slant column density of the oxygen dimer (O_2-O_2) at 477 nm, which is converted into AEH after retrieval of aerosol and surface optical properties from GEMS operational algorithms. The AEH retrieval results show significant AEH values and continuously monitor aerosol vertical height information in severe dust plumes over East Asia, and the collection of plume height information for anthropogenic aerosol pollutants over India. Compared to the AEH retrieved from Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP), the retrieval results show insignificant bias with a standard deviation of 1.4 km for the AEH difference over the GEMS observation domain from January to June 2021 due to uncertainty in input parameters for aerosol and surface. The AEH difference depends on aerosol optical properties and surface albedo. Compared to the aerosol layer height obtained from the tropospheric monitoring instrument (TROPOMI), differences of 0.78 ± 0.81 and 1.16 ± 0.92 km were obtained for pixels with single scattering albedo (SSA) < 0.90 and $0.90 < SSA < 0.95$, respectively, with significant dependence on aerosol type.

Keywords: aerosol effective height, aerosol optical depth, environmental satellite, GEMS

1. Introduction

Since the launch of the Total Ozone Mapping Spectrometer (TOMS) on Nimbus-7, ultraviolet (UV)-visible satellite measurements have been used for environmental monitoring of the distribution and reaction processes of pollutants (e.g., anthropogenic aerosols, tropospheric ozone, NO₂, and SO₂). Measurements from environmental satellites have been used to estimate gaseous species in the atmosphere, resulting in vertical column integrated amounts. However, these column-integrated amounts and associated surface concentrations have uncertainty due to simultaneous changes in optical path length associated with the vertical distribution of target species and amounts of scattering materials (clouds and aerosols) present.

Environmental satellite sensors, in particular those that measure UV-visible wavelength range, have been used to detect aerosol and cloud signals by using the aerosol index (e.g., Buchard *et al.*, 2015; Herman *et al.*, 1997; Torres *et al.*, 1998, 2002; Prospero *et al.*, 2000; de Graaf *et al.*, 2005) and scattering radiative index values (Penning de Vries *et al.*, 2009, 2015; Kooreman *et al.*, 2020; Kim *et al.*, 2018), although these indices only have qualitative characteristics and limitations to identify aerosol amounts. In addition, measurements of scattering material amounts, such as aerosol optical depth (AOD) and radiative cloud fraction, have also been retrieved from pixel-based radiance data in UV-visible wavelength range. Recently, various aerosol retrieval algorithms have been developed for use with satellite sensors. These algorithms focus on improved trace gas retrieval as well as direct monitoring of aerosol properties, such as AOD and single scattering albedo (SSA) (e.g., Ahn *et al.*, 2014; Kim *et al.*, 2020; Torres *et al.*, 2020).

Although the algorithms developed for environmental satellite sensors indicate the

presence and amount of scattering materials, the accuracy of these retrieval algorithms for trace gases is significantly affected by the relative vertical distributions between trace gases and scattering materials (e.g., Lorente *et al.*, 2017; Hong *et al.*, 2017). For this reason, estimating cloud and aerosol vertical parameters is very important. For cloud vertical information, cloud height information has been estimated simultaneously with cloud optical depth and radiative cloud fraction data using the rotational Raman scattering (Joiner and Vasilkov, 2006; Vasilkov *et al.*, 2008; Joiner and Bhartia, 1995) and absorption intensity of the oxygen dimer (O_2-O_2) (Accarreta *et al.*, 2004; Vasilkov *et al.*, 2018; Choi *et al.*, 2021) combined with normalized radiance. Similarly, the aerosol vertical distribution can be estimated using the oxygen absorption bands, such as the O_2-O_2 (Park *et al.*, 2016; Chimot *et al.*, 2017; Choi *et al.*, 2019, 2020), O_2-A (Dubisson *et al.*, 2009; Geddes and Boesch, 2015; Sanders *et al.*, 2015; Zeng *et al.*, 2020), and O_2-B (Ding *et al.*, 2016) bands, as well as combinations of these bands (Sanghavi *et al.*, 2012; Chen *et al.*, 2021). In addition, an algorithm for aerosol vertical information has been developed based on hyperspectral UV-visible radiance from satellite observation. Nanda *et al.* (2018) demonstrated the possibility of aerosol height retrieval from the O_2-A band developed an algorithm using Tropospheric Monitoring Instrument (TROPOMI) (Sanders and de Haan, 2016; Nanda *et al.*, 2020) and implemented the algorithm operationally.

However, the vertical distribution of aerosol is difficult to assess because of its large spatio-temporal variability. Although the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) provided the aerosol vertical distribution with high vertical resolution (Omar *et al.*, 2009), other satellites for passive sensors are only able to estimate the representative parameter of aerosol height. Veihelmann *et al.* (2007)

showed that the number of degrees of freedom of signal for aerosol is 2~4 for most of satellite observation conditions by the ozone monitoring instrument (OMI). It means that the number of information for aerosol vertical distribution have a limitation. Because of limitation for describing the aerosol vertical information, aerosol layer height (ALH) (Nanda et al., 2018) or aerosol effective height (AEH) (Park et al., 2016) were defined to retrieve the aerosol vertical information from the passive satellite sensors.

The Geostationary Environment Monitoring Spectrometer (GEMS), which was launched by South Korea in February 2020, retrieves data related to major trace gases and aerosol properties (Kim *et al.*, 2020). The main purpose of GEMS is to monitor air quality, and aerosol properties are targets of such monitoring over East Asia. For this reason, the GEMS aerosol algorithm was developed as multiple operational products. Aerosol properties are obtained for the purposes of monitoring surface air quality and aerosol effects for the air mass factor (AMF) calculation. In addition to the aerosol optical property algorithm, the GEMS aerosol product is additionally applied to the aerosol vertical information, AEH. For the possibility for development of an AEH retrieval algorithm, Park *et al.* (2016) conducted theoretical sensitivity testing of AEH retrieval using solely the O₂-O₂ absorption band along with aerosol and surface properties. Overall, the sensitivity of AEH retrieval was strongly affected by SSA, AOD, and aerosol types including optical and size properties, and the error budget for AEH retrieval using the O₂-O₂ band was 739 ~ 1276 m. In addition, case studies of AEH during dust transport over East Asia were conducted using radiance data from the Ozone Monitoring Instrument (OMI) and aerosol optical properties from the Moderate Resolution Imaging Spectroradiometer (MODIS).

Based on theoretical considerations and case results of previous studies, we introduce an operational retrieval algorithm for AEH. Section 2 describes the details of the AEH retrieval algorithm for GEMS and provides a list of the detailed input parameters. Section 3 introduces the details of satellite sensors for the comparison and validation in this study. Section 4 reports retrieval results based on case studies of aerosol transport, and section 5 contains validation results based on Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) and TROPOMI data. Finally, we show conclusion and summary in section 6.

2. AEH retrieval algorithm

AEH is a layer height parameter that considers the penetration of photons into the aerosol layer. In this study, the AEH product from GEMS is defined as the height with aerosol extinction integrated from the surface of $(1 - \exp^{-1}) \times \text{AOD}$, and a detailed definition of AEH was introduced by Park *et al.* (2016). Numerous previous studies have used the aerosol top layer height (Kohkanovsky and Rozanov, 2010) or middle layer height (i.e. ALH) (e.g., Sanders *et al.*, 2015; Nanda *et al.*, 2020) as the aerosol vertical layer parameter. AEH is similar to the aerosol top layer height but with a slight bias. For AEH retrieval, the vertical distribution assumption is also important. The Gaussian Density Fitting (GDF) distribution, which is a modified Gaussian distribution structure, is assumed for AEH retrieval. The full-width at half-maximum (FWHM) of the aerosol layer is 1 km. Based on the assumptions about the aerosol vertical distribution, the AEH value is greater than the peak height of the Gaussian distribution and lower than the aerosol top layer height. Detailed description of AEH and other aerosol vertical parameters are shown in Figure 1.

Figure 2 shows the overall flowchart of the AEH algorithm for GEMS satellite. The GEMS is onboard the Geostationary Korea multipurpose satellite 2B (GK2B) as orbiting at 128.2°E, and scans from 145°E to 75°E with north-south coverage of 5°S~45°N. The GK2B observation schedule shares the GEMS and the Geostationary Ocean Color Imager 2 (GOCI2). For this reason, the GEMS scan the 30 minutes duration from every hour from 45 minutes to 15 minutes during daytime. The standard spatial resolution of GEMS is 7×8 km. The spectral resolution and sampling are respectively 0.6 nm with full-width and half-maximum (FWHM) and 0.2 nm with spectral range of 300~500 nm. Because the spectral coverage is limited to 300-500 nm, the AEH from GEMS is applied to the O₂-O₂ absorption band. In AEH estimation, other aerosol characteristics, including aerosol amounts and optical properties, affect retrieval accuracy.

The GEMS Level 2 aerosol operational algorithm (L2AERAOD) retrieves the aerosol index (AI) values for UV and visible wavelengths, as well as AOD and SSA with considering the aerosol types (National Institute of Environmental Research, 2020a). The aerosol types are defined as absorbing, non-absorbing, and dust types by using the classification methods based on the UV and visible AIs (e.g., Go et al., 2020). Park *et al.* (2016) noted that the error budget of AEH is significantly affected by uncertainty in AOD and SSA and by the misclassification of aerosol types, which is directly related to the optical property and size information. Main error sources for AEH retrieval can be obtained from the L2AERAOD results. Therefore, the L2AERAOD results for AOD and SSA at 550 nm were adopted as input data for aerosol properties.

Although L2AERAOD retrieved their own surface reflectance for accurate separation of surface signals from total reflectance at the top of the atmosphere (TOA), the

standard product for surface reflectance (L2SFC) (National Institute of Environmental Research, 2020b) was also independently retrieved from GEMS radiance/irradiance data with specific temporal periods. L2SFC is the reference product for spectral surface reflectance. The L2SFC retrieves the surface reflectivity in multiple spectral channels, and retrieves the black surface reflectivity (BSR) and bi-directional reflectance distribution function (BRDF) based on the original pixel resolution. L2SFC was used as reference data for the surface products for all trace gas retrieval algorithms. Similarly, the AEH retrieval algorithm also uses L2SFC as a reference surface property in operation. Specifically, the BSR value at 477 nm is used as the surface reflectance input for AEH retrieval.

Table 1. Details of fitting parameter for O₂-O₂ SCD estimation via the DOAS method.

| Parameter | |
|-----------------------|--|
| Fitting window | 460 – 486 nm |
| Absorption | NO ₂ at 220 and 294 K (Vandaele <i>et al.</i> , 1998) |
| cross section | O ₃ at 223, 243 and 293K (Bogumil <i>et al.</i> , 2001) |
| | O ₂ -O ₂ at 293 K (Thalman and Volkamer, 2013) |
| | Ring |

For AEH retrieval, the basic method is the identification of changes in optical path length caused by effective aerosol layer height variation. To measure the optical path length change, O₂-O₂ slant column density (SCD) retrieved by the differential optical absorption spectroscopy (DOAS) method was used. In the GEMS product, the O₂-O₂ SCD at 477 nm absorption band is most useful absorption band because this absorption band is strongest absorption band within the GEMS spectral observation range. Detailed DOAS fitting parameter and setting information is provided in Table 1 for the

estimation of O₂-O₂ SCD from both the simulation and observation data. For the O₂-O₂ SCD estimation at 477 nm, the fitting window is ranged from 460 to 486 nm to cover the full absorption structure of O₂-O₂. Within the fitting window, the absorption is significantly affected by the absorptions of NO₂ and O₃. To describe these two absorption materials, temperature dependent cross section information are adopted. The temperature dependent cross section setting considers the stratosphere and troposphere, simultaneously.

Table 2. Ratio between SCD error and the SCD of O₂-O₂ according to the polynomial order and offset settings used for DOAS fitting.

| Polynomial | Offset = none | Offset = 0 th |
|-----------------------|---------------|--------------------------|
| 2 nd order | 6.06 ± 2.07 | 6.79 ± 2.31 |
| 3 rd order | 6.32 ± 2.20 | 6.79 ± 2.32 |
| 4 th order | 7.86 ± 2.78 | 7.34 ± 2.85 |

To minimize the noise effect and improve fitting quality, the optimal settings for fitting were also analyzed. Table 2 shows ratios of SCD error to the SCD for various polynomial and bias orders from observed radiance. The polynomial and offset are basic fitting parameters for the DOAS fitting. Both two parameters describe the broadband spectral feature of radiance. The ratio between SCD error and the SCD of O₂-O₂ is important to determine the AEH retrieval quality. When the fitting error increase, the uncertainty of AEH is also enhanced during the retrieval. Although the fitting quality was good overall, the setting with 2nd order of polynomial and none offset was used for

the O₂-O₂ SCD estimation from the GEMS radiance due to the smallest fitting error.

After the estimation of O₂-O₂ SCD, conversion from O₂-O₂ SCD to AEH is an essential process. For this conversion, a look-up table (LUT) approach between O₂-O₂ SCD and AEH was used with consideration of observation geometries, surface conditions, and aerosol optical properties. Table 3 shows the dimension of the LUT for the AEH retrieval algorithm. To calculate the LUT, a linearized pseudo-spherical vector discrete ordinate radiative transfer model (VLIDORT) version 2.6 was used (Spurr, 2013). During the radiative transfer model simulation, the SSA and AOD is assumed to be 440 nm. Although the center of O₂-O₂ absorption is 477 nm, the spectral discrepancy between model assumed wavelength and center wavelength of O₂-O₂ absorption is assumed to be ignored in this study. After calculating spectral radiance with 0.1 nm sampling, we performed the slit response function of GEMS and sampling specification prior to the DOAS fitting. For O₂-O₂ absorption, the absorption cross section used for the radiative transfer model calculation is considered the temperature dependent absorption cross section (e.g., Park *et al.*, 2017).

O₂-O₂ SCD decreases with increasing AEH for all aerosol types and AOD (Park *et al.*, 2016). The O₂-O₂ SCD sensitivity is enhanced at high AOD and absorbing dominant aerosol cases. In addition, the contrast of O₂-O₂ SCD is greater for absorbing dominant aerosols than non-absorbing aerosols. During the radiance passing through the aerosol layer, the absorbing dominant aerosol is more efficiently absorbed the radiance. For this reason, the effective optical path length is significantly shorter for absorbing aerosols. Based on the changes in sensitivity observed for optical path length, aerosol type (in particular in terms of SSA) and AOD are considered as input parameters for AEH retrieval.

Table 3. The dimension of the LUT for the GEMS AEH retrieval algorithm used to estimate AEH from O₂-O₂ SCD. (SZA: solar zenith angle, VZA: viewing zenith angle, RAA: relative azimuth angle, SUR: surface reflectance).

| Variable [unit] | No. of entries | Entries | |
|--|----------------|---|-----------------------|
| Spectral range [nm] | - | 455~491 nm (0.1 nm interval) | |
| SZA [°] | 7 | 0.01, 10, 20, 30, 40, 50, 60 | |
| VZA [°] | 7 | 0.01, 10, 20, 30, 40, 50, 60 | |
| RAA [°] | 10 | 0.01, 20, 40, 60, 80, 100, 120, 140, 160, 180 | |
| SUR | 3 | 0.0, 0.05, 0.2 | |
| AOD at 440 nm | 9 | 0.04, 0.2, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 5.0 | |
| Refractive Index (Imaginary) at 440 nm | 3×3 | Absorbing (Real: 1.45) | 0.000, 0.0074, 0.0314 |
| | | Dust (Real: 1.53) | 0.0, 0.0030, 0.0080 |
| | | Non-Absorbing (Real: 1.41) | 0.0, 0.0040, 0.0156 |
| AEH [km] | 12 | 0.0 (Extrapolate), 0.2, 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 5.0, 10.0 (Extrapolate) | |
| Terrain Height [km] | 2 | 0.0, 2.0 | |

3. Data

3.1. TROPOMI

The TROPOMI is a spectrometer to observe the radiance from UV to near IR onboard the Sentinel-5 Precursor (Sentinel-5P) satellite. The orbit for Sentinel-5P is a polar orbit with ascending node crossing the equator at 13:30 local time. The aerosol layer height product from TROPOMI (AER_LH) retrieves vertically localized aerosol

layers in free troposphere with cloud free condition by using the level 1b earth radiance measurements from 758 to 770 nm (de Graaf *et al.*, 2022). The definition of ALH from TROPOMI is the optical centroid layer height of the plume. Spectral fit estimation of reflectance around the O₂-A band is based on a neural network for the forward model calculation for simulated condition. After cloud masking to avoid the cloud affected pixels, an optimal estimation method was used to retrieve the aerosol layer height parameters for the inversion method from observation. During the radiance fitting, the ALH and AOD are fitted parameters, but other aerosol parameters, such as SSA, layer thickness, and scattering phase function, are assumed to be fixed values (Nanda *et al.*, 2020). The target requirement on the accuracy and precision is 0.5 km or 50 hPa, and the threshold requirement is 1 km or 100 hPa (de Graaf *et al.*, 2022). In this study, we use version 2.0.0 of the TROPOMI offline level 2 AER_LH product with the spatial resolution is 3.5 km × 7 km at nadir viewing geometry.

3.2. CALIOP

The CALIOP is a spaceborne lidar onboard the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) to measure the vertical information of aerosol and cloud with estimating the optical properties. The CALIOP has two different wavelength channels (532 and 1064 nm) by using the Nd:YAG laser to generate the signals (Winker *et al.*, 2009). The orbit for CALIPSO is Sun synchronous orbit constellated to the A-train with ascending node, and also crosses to the equator at 13:30 local time. For the vertical information, the resolution for vertical sampling is 30 m below 8 km altitude, and 60 m from 8 to 20 km altitude, respectively. Although the pixel data can retrieve with extremely high horizontal and vertical resolutions, the spatial

coverage is narrow. In this study, the data of Level 2 aerosol profile product (APro, version 3.41) was used. Representative layer height parameters (ALH and AEH) are directly estimated by using the vertical profile of aerosol extinction coefficient at 532 nm.

4. Case studies

Figure 3 shows retrieval results for AEH, AOD, and SSA from GEMS on March 29 over East Asia. Because the operational schedule is hourly during the daytime, the GEMS retrieval results are shown at 1-hour intervals from 01:00 to 07:00 Universal Time Coordinated (UTC). From Park et al. (2016), thin AOD pixels have large AEH uncertainty due to weak aerosol scattering information. For this reason, only AEH retrieval results with AOD greater than 0.3 are shown in this study. During this case study, a Yellow dust plume was located along the coast of China and South Korea with AOD at 443 nm of 0.8~1.2. Simultaneously, another plume was also present over the northeastern Korean Peninsula with AOD of 1.0~2.0 at 443 nm. SSA at 443 nm was 0.90~0.93 for the plume over South Korea and 0.87~0.90 for the plume over the northeastern Korean Peninsula. Although the AOD and SSA for these plumes are differed significantly, the retrieved AEH results from these different plumes show similar ranges. For both plumes, AEH shows around 1.0~2.0 km in this case.

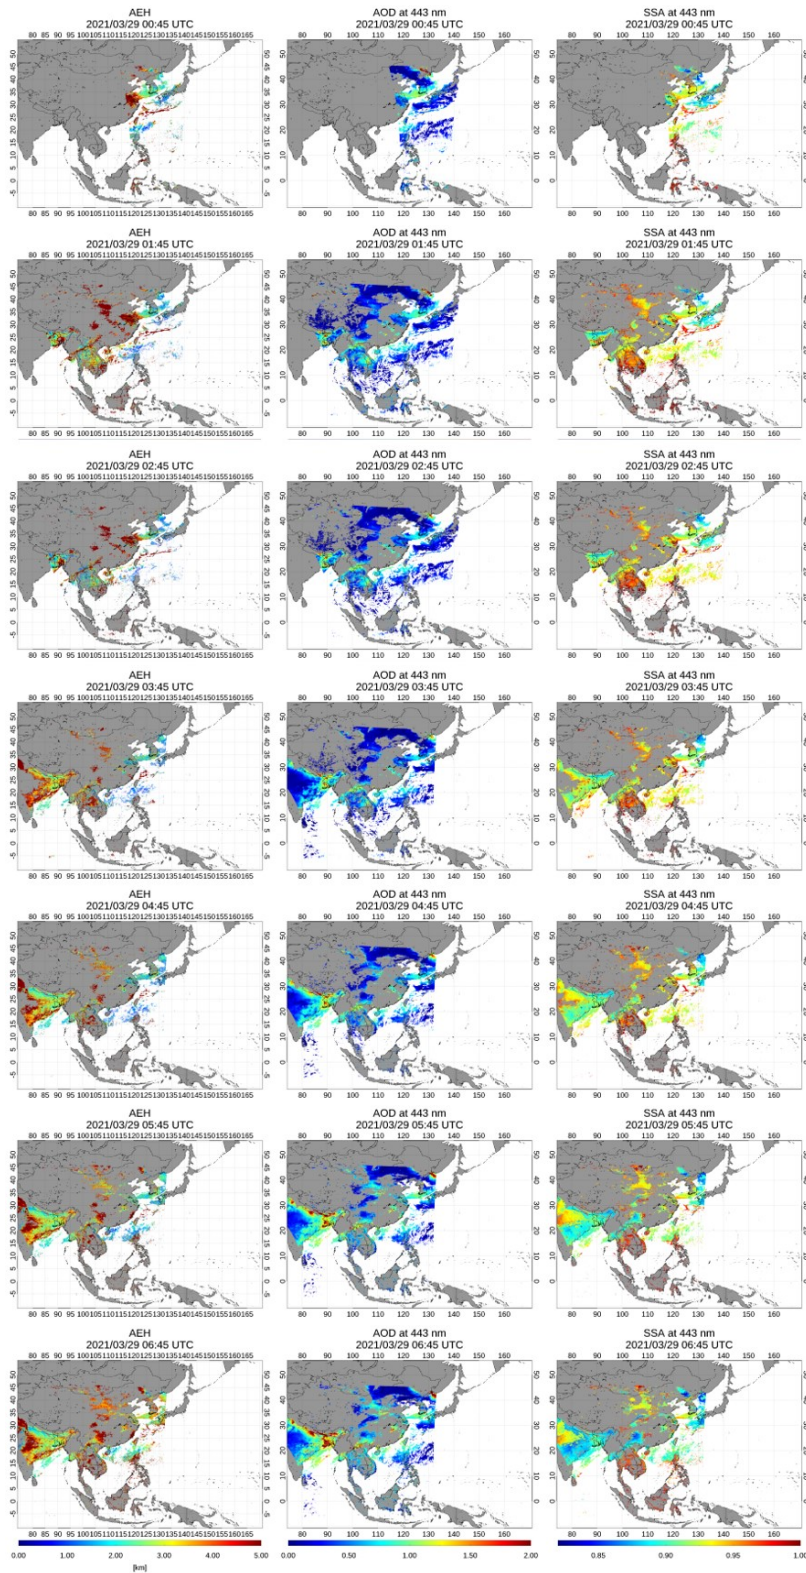

Figure 3. Case study results for AEH, AOD, and SSA based on GEMS observations on March 29, 2021.

As shown in Figure 3, an additional severe aerosol plume was present over northeastern India, with AOD at 443 nm of 1.0~2.0 and SSA at 443 nm of 0.85~0.90. From Rana *et al.* (2019), metropolitan cities and industrial cluster in India are heavy emitters of black carbon, and high concentrations of black carbon are distributed over the Indo-Gangetic Plain (IGP). Therefore, the aerosol plume with high AOD and low SSA (high absorbing) was a result that actually exists, and it was not a result with high uncertainty due to edge of GEMS observation field. Except for the inland parts of India, AEH in high AOD pixels ranged from 1.5 to 3.5 km.

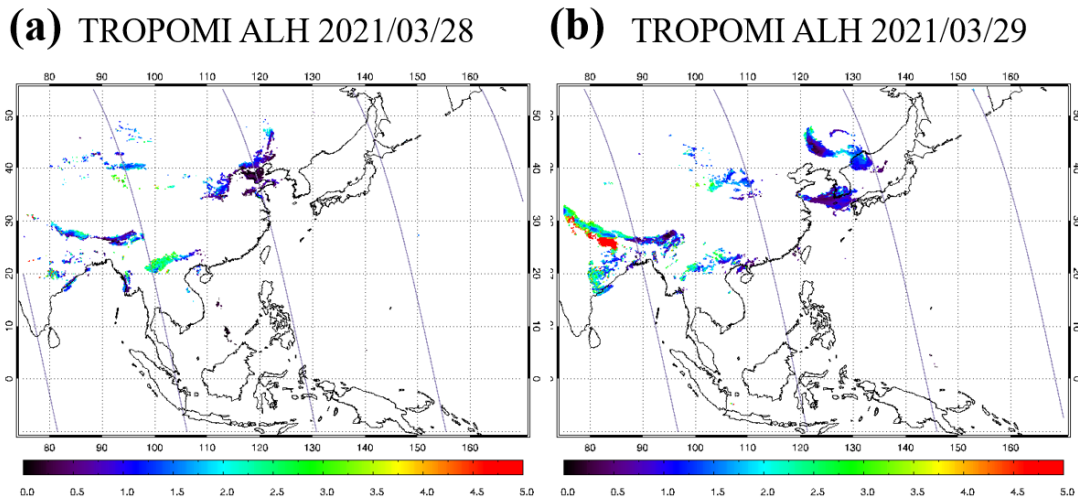

Figure 4. ALH retrieved from TROPOMI and orbit path of CALIOP on (a) March 28 and (b) March 29, 2021 (Unit: km).

For comparison of the retrieval, Figure 4 shows the ALH retrieved from TROPOMI on March 28 and 29, 2021 over East Asia. A dust plume was transported from China to South Korea during this period, then split into two distinct plumes over northeastern China and the coastal area of South Korea. The ALH retrieved from TROPOMI for both plumes were 0.5~1.5 km. Given the difference in definition for the aerosol height

parameters between ALH and AEH, relatively high height values were retrieved from GEMS compared to TROPOMI. In an ideal case under symmetric gaussian distribution with a width of 1 km, the AEH from GEMS was around 0.5 km higher than the peak height of aerosol layer. The ALH expresses the center (or peak) height, thus, the AEH from GEMS was overestimated by around 0.5 km relative to the ALH from TROPOMI. Although AEH had higher values than ALH from TROPOMI, the GEMS AEH retrievals for the dust transport case study were successfully retrieved and mostly shown the expected uncertainty of 1 km.

Furthermore, the AEH retrieved pixels covered by GEMS is larger than by TROPOMI, as demonstrated by a comparison of Figures 3 and 4. In East Asia, AEH from GEMS estimated a continuous dust plume from China to South Korea. In addition, the GEMS retrieval more widely estimated aerosol height information in coastal India compared to TROPOMI. Although high AEH values were retrieved for low AOD regions over low latitude ocean surface, the AEH from GEMS was successfully retrieved over the area of interest for the case study.

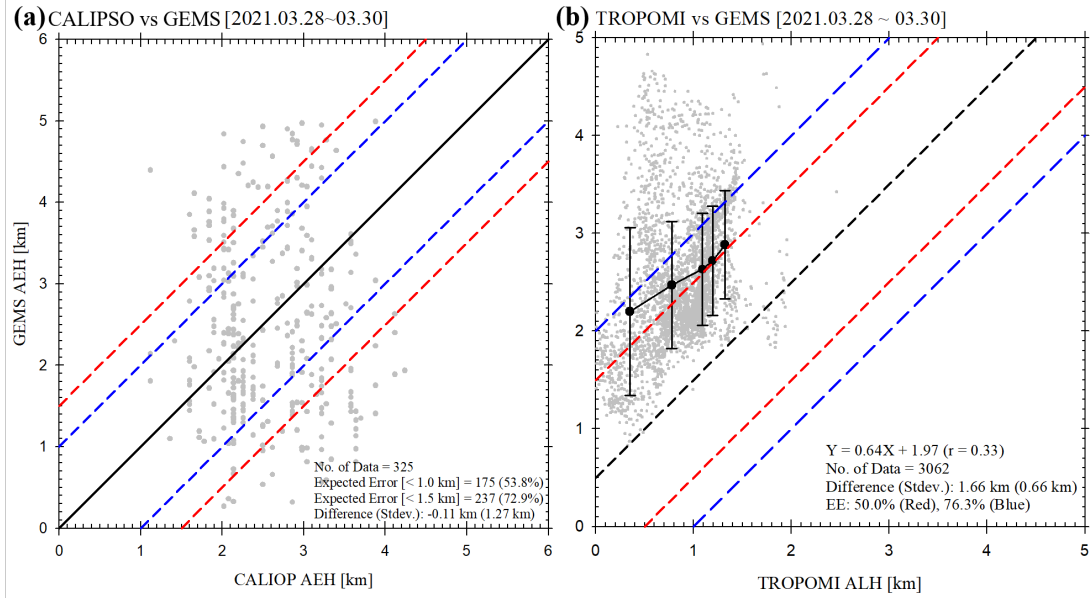

Figure 5. Intercomparison of (a) AEH between CALIOP and GEMS and (b) ALH from TROPOMI and AEH from GEMS (black dot and error bar is mean and standard deviation in 20% interval of each TROPOMI ALH) over the period from March 28 to 30, 2021.

Figure 5 shows intercomparison results for aerosol plume height among GEMS, CALIOP, and TROPOMI during the case study of Yellow dust transport in East Asia from March 28 to 30, 2021. For spatial collocation, we selected pixels for which distance between GEMS and CALIOP observations was less than 50 km. In addition, only the closest 10% of pixels were used. Given the different orbital characteristics of CALIOP and GEMS, temporal collocation was also considered. During the period of image scanning from east to west over Asia by GEMS, CALIOP passes through the GEMS observation area from south to north every 98.3 minutes. On average, CALIOP passes three to four orbits through the GEMS scan area during a single day of daytime observation. To consider these different orbital characteristics, temporal collocation was

limited to a 1-hour difference between CALIOP and GEMS scans. As GEMS observes hourly, colocated pixels between the two satellites shift from east to west over time. Ultimately, the number of colocated pixels with AOD at 443 nm > 0.3 was 534 for this case study.

For the direct comparison shown in Figure 5a, the difference in AEH between GEMS and CALIOP was -0.11 ± 1.27 km. Nanda *et al.* (2020) reported that the difference in ALH between TROPOMI and CALIOP was 0.53 km for 4 cases of thick Saharan dust plumes. In addition, 53.8% and 72.9% of the total pixels showed differences less than 1.0 and 1.5 km, respectively. Large AEH uncertainty occurred mostly over the inland area of China. Because AEH from GEMS uses only the O₂-O₂ absorption band, the accuracy of AEH is sensitive to uncertainty in surface reflectance and AOD. Recently, GEMS accurately estimated surface reflectance in near real time in operation. However, this study used the minimum reflectance under the Lambertian assumption to retrieve AOD and AEH to coincide with the use of surface information on L2AERAOD and AEH retrieval.

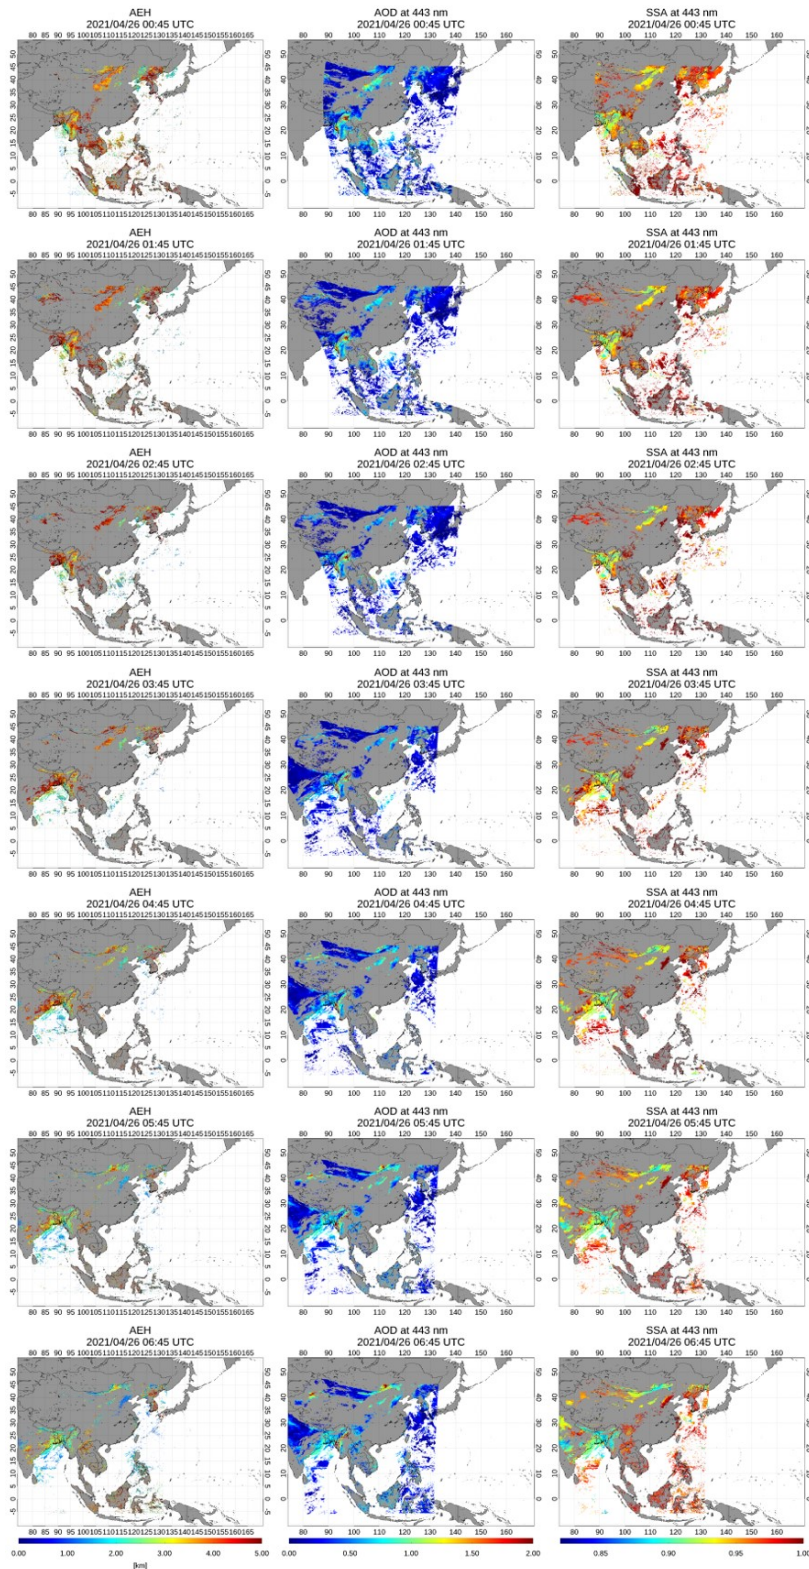

Figure 6. Case study results for AEH, AOD, and SSA based on GEMS observations on April 26, 2021.

Figure 5b shows a comparison of GEMS and TROPOMI for the period of March 28 ~ 30, 2021 in East Asia. To ensure the accuracy of ALH from TROPOMI, only pixels with quality assurance (QA) values greater than 0.5 were used. The difference between GEMS AEH and TROPOMI ALH was 1.66 ± 0.66 km in this case, and 49.9% of all pixels had differences less than 1.5 km. This proportion value was lower than the corresponding result from the comparison of GEMS and CALIOP. However, the ALH from TROPOMI is generally lower than the AEH from GEMS because of the discrepancy in definitions. To correct the inconsistency of definition between ALH and AEH, the difference between two retrieval results decreased to 0.5 km bias. After correction, 50.0% and 76.3% of pixels are within the expected error ranges of 1.0 and 1.5 km, respectively.

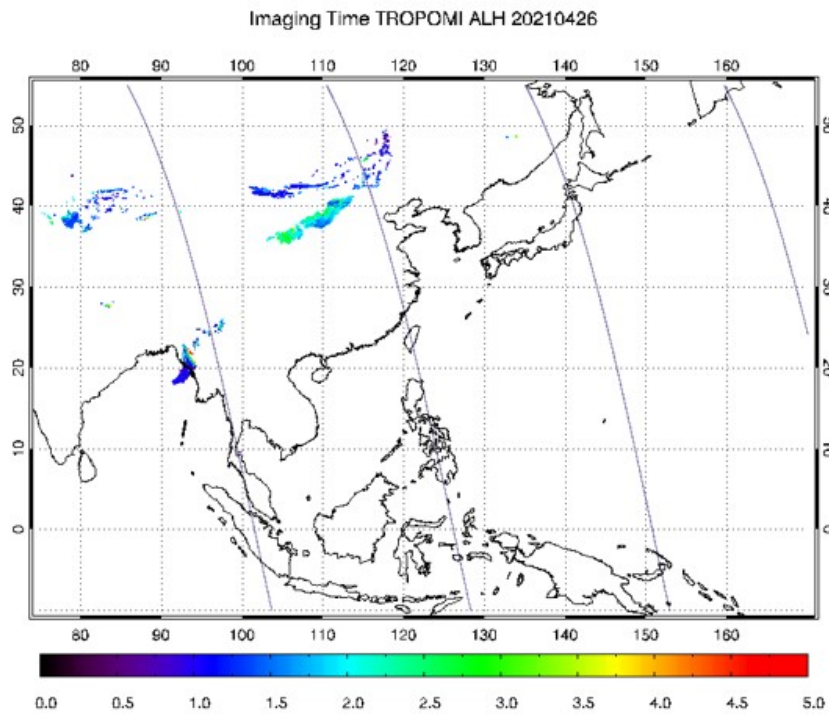

Figure 7. ALH retrieved from TROPOMI and orbit path of CALIOP on April 26, 2021 (Unit: km).

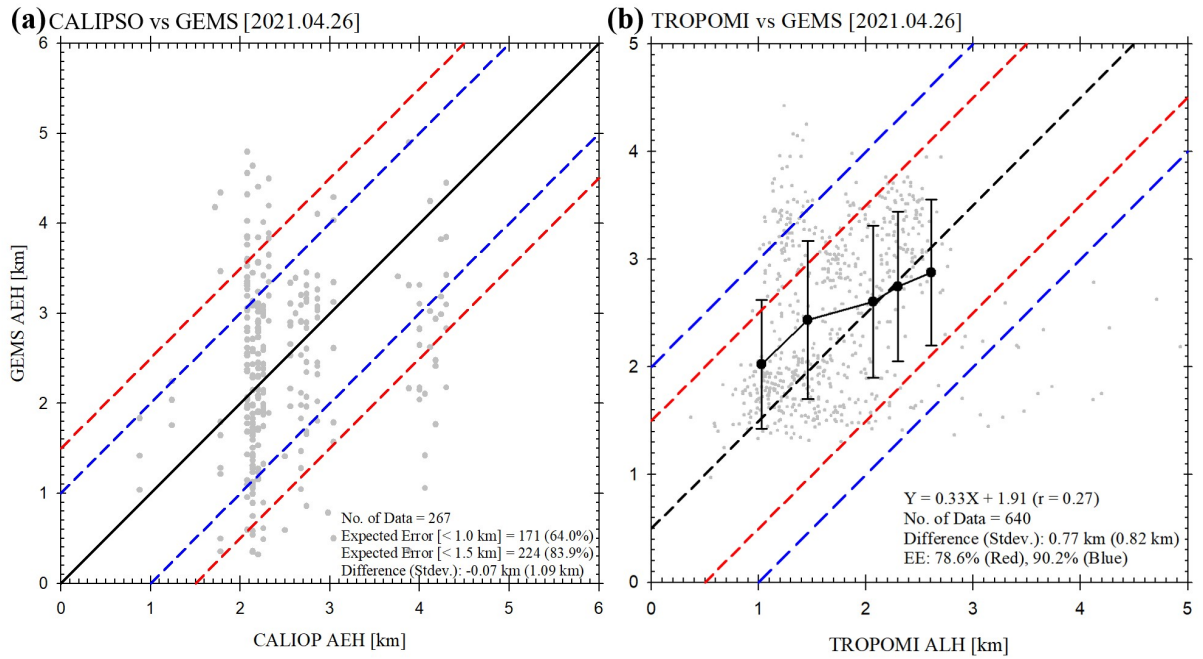

Figure 8. Intercomparison of (a) AEH between CALIOP and GEMS, and (b) ALH from TROPOMI and AEH from GEMS (black dot and error bar is mean and standard deviation in 20% interval of each TROPOMI ALH) on April 26, 2021.

An additional intercomparison case of April 26, 2021 is shown in Figures 6 (GEMS) and 7 (TROPOMI). During the transport of the Yellow dust plume from inland China to the coastal area, AEH changed from 4.0 km at 02:00 UTC to 2.0 km at 06:00 UTC. By contrast, ALH from TROPOMI only observed the 1.5~2.5 km layer height over East Asia around 04:00 UTC. Although the AEH from GEMS had spatio-temporal uncertainty, this case demonstrates the advantage of AEH retrieval from GEMS for continuous monitoring of changes in plume height, in particular during dust transport. As shown in Figure 8, AEH from GEMS showed differences in height of -0.07 ± 1.09 km (compared to CALIOP) and 0.77 ± 0.82 km (compared to TROPOMI).

5. Long-term validation

For long-term validation, we used the AEH retrieval results from January to June, 2021. Similar to the case studies, intercomparison datasets from CALIOP and TROPOMI were selected containing mean layer height values in the closest 10% of pixels within a 50 km range for spatial colocation. In addition, only observations taken within ± 1 hour of the GEMS observation time were selected for temporal colocation. As the CALIOP and TROPOMI satellites passed over the study area around 13:30 local time, which is around 04:30 UTC for East Asia and around 06:30 UTC for India. Most temporal colocation pixels aligned with observation times of 04:00~06:00 UTC, respectively. To check the dependence of several retrieval variables, the AI value for UV (UVAI), AOD, SSA, and dominant aerosol type in each pixel (TYPE) were obtained from the L2AERAOD. Although the GEMS algorithm retrieved AEH in the range of 0~10 km, the sensitivity of O₂-O₂ SCD was weak in cases of high AEH because of the vertical distribution of air molecules. To ensure sufficient quality of retrieved data, therefore, the AEHs from GEMS and CALIOP, and the ALH from TROPOMI were used only in pixels where the AEH from GEMS were lower than 5 km.

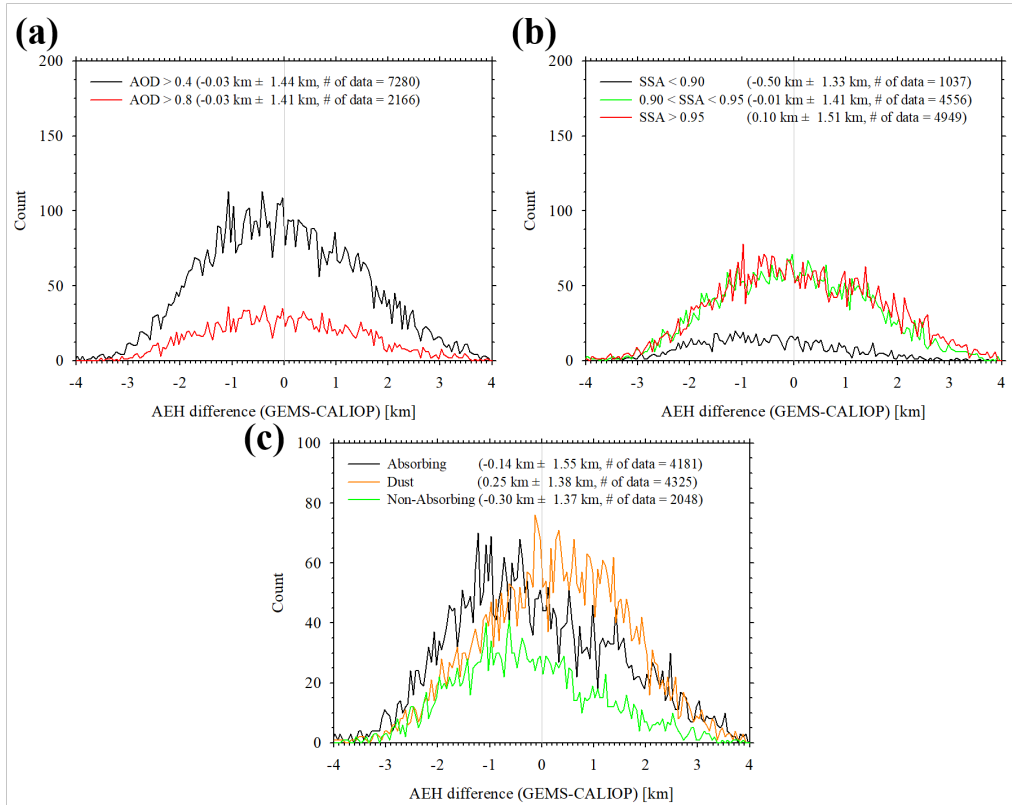

Figure 9. Histogram of AEH difference between CALIOP and GEMS with respect to (a) AOD, (b) SSA, and (c) TYPE from GEMS over the period from January 1 to June 30, 2021.

Figure 9 shows histograms of difference in AEH between GEMS and CALIOP according to AOD at 443 nm, SSA at 443 nm, and TYPE from GEMS. From Figure 9a, the dependence on AOD threshold was insignificant; the average estimated AEH difference was -0.03 km, but the variation in AEH difference was around 1.4 km based on the standard deviation for AOD > 0.4. Because of uncertainty in GEMS operational products, AEH from GEMS exhibits large variability. Although L2AERAOD from GEMS retrieved the AOD, SSA, and aerosol types, the retrieved results from L2AERAOD include significant uncertainty. Go *et al.* (2020) noted that the UV aerosol

retrieval algorithm, which is the basic method to the L2AERAOD algorithm, has significant discrepancies for both AOD and SSA compared to ground-based data. In addition, significant fitting error perturbs the fitting signals and tends to result in the underestimation of SCD. Although the fitting error of O₂-O₂ SCD from GEMS radiance was minimized, the fitting error is still remained around 6%, as indicated in Table 2. The discrepancy in fitting condition between the simulated and observed radiance biased the SCD estimation, which in turn led to bias and variation in the AEH retrieval. Combined with the high sensitivity of AEH errors to aerosol optical properties, uncertainty arising from L2AERAOD causes significant variability in AEH.

The variation in AEH difference between observation platforms is shown in Figure 9b as a histogram according to SSA threshold. Across the entire SSA threshold range, the standard deviation of the AEH difference was 1.33~1.51 km. In particular, this standard deviation decreased slightly with decreasing SSA. Aerosol height information is significantly more sensitive to absorbing-dominant aerosols than scattering-dominant aerosols (e.g., Park *et al.*, 2016; Nanda *et al.*, 2020). Even if the uncertainty due to aerosol properties is fixed, the variability of AEH is affected by the sensitivity of AEH error to aerosol absorptivity.

Figure 9c shows the dependence of AEH difference on TYPE. Changing the Type significantly changed the mean value of AEH difference. The TYPE product included dependence on the aerosol size and optical absorptivity. For this reason, the AEH difference graphs for the “Dust” and “Absorbing” types differ, despite both types being absorbing-dominant aerosols. The AEH difference for the “Absorbing” type showed a negative bias with a large standard deviation, whereas a positive bias with a small standard deviation was obtained for the “Dust” type. The AEH difference for the “Non-

Absorbing” aerosol type showed the largest negative bias in this comparison. These results suggest that the aerosol size distribution of fine particles affects the negative bias of AEH. Combined with the AEH difference bias illustrated in Figure 8b, these findings indicate that the bias in AEH difference for “Absorbing” aerosols is weakened by their absorbing-dominant property.

Figure 10 shows means and standard deviations for AEH difference between CALIOP and GEMS according to AOD and AI values from GEMS. For AOD, the mean AEH difference ranged from -0.13 to 0.03 km with a standard deviation of approximately 1.45 km. Similar to Figure 9a, the variation in AEH difference with AOD change was insignificant. For AI, the smallest AEH difference was -0.19 km, obtained for the AI range of 1.5~2.0. The largest AEH difference was 0.24 km for the AI range of 4.0~4.5. Although the AEH difference varied slightly, no consistent tendency in AEH variation with AI was observed Overall, the standard deviation of AEH difference ranged from 1.49 km ($0.0 < AI < 0.5$) to 1.18 km ($4.5 < AI < 5.0$), and a consistent tendency of decreasing variance in AEH difference was found with increasing AI.

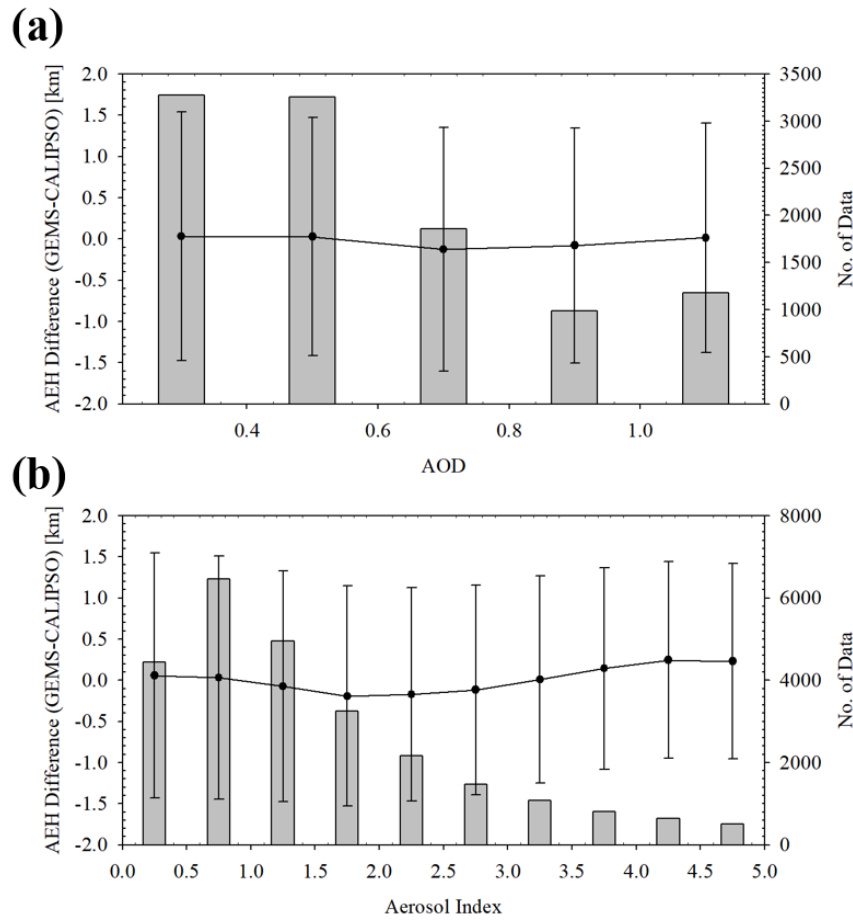

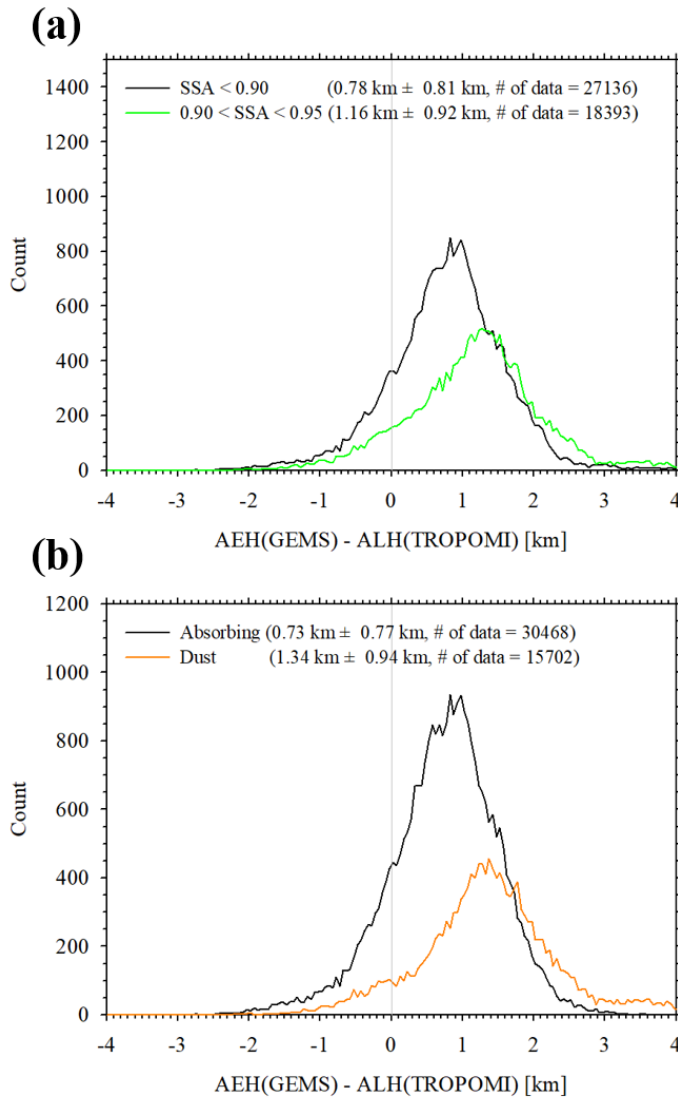

Figure 10. AEH difference between CALIOP and GEMS with respect to ranges of (a) AOD and (b) AI obtained from GEMS from January 1 to June 30, 2021 (line and error bar is the mean and standard deviation of AEH difference, and the box is number of data).

Figure 11 shows histograms of differences between ALH from TROPOMI and AEH from GEMS [(AEH from GEMS) – (ALH from TROPOMI)] according to the SSA and TYPE obtained from GEMS. As TROPOMI retrieved only ALH data with high QA values over pixels containing strong aerosol plumes, the AOD dependence of aerosol height difference is not shown in this comparison. In addition, the number of pixels

462 corresponding to non-absorbing aerosols (i.e., pixels with $SSA > 0.95$ or “Non-
 463 Absorbing” type) was insufficient. Nanda *et al.* (2020) showed that the operational
 464 algorithm of TROPOMI is only retrieved the ALH over absorbing dominant aerosol
 465 pixels. In addition, Griffin *et al.* (2020) reported that the pixels with small positive
 466 UVAI (weak absorbing cases) pixels are identified with small QA values in the offline
 467 product of ALH.

468

469 **Figure 11.** Histograms of differences between ALH from TROPOMI and AEH from
 470 GEMS [(AEH from GEMS) – (ALH from TROPOMI)] with respect to (a) SSA, and (b)

TYPE from GEMS in the period from January 1 to June 30, 2021.

As shown in Figure 11, (AEH from GEMS) – (ALH from TROPOMI) was significantly dependent on both SSA and TYPE. The mean value of (AEH from GEMS) – (ALH from TROPOMI) decreased as the aerosol absorptivity increased. This difference was 0.78 ± 0.81 and 1.16 ± 0.92 km for pixels of $SSA < 0.90$ and $0.90 < SSA < 0.95$, respectively. Comparing these results to Figure 8b, we find that the standard deviation of the comparison with TROPOMI was approximately 60% of the corresponding value for CALIOP. It is because both TROPOMI and GEMS are passive sensors that use similar retrieval methods for oxygen absorption bands.

In addition, (AEH from GEMS) – (ALH from TROPOMI) was significantly dependent on TYPE, as shown in Figure 10b. The difference was 0.73 ± 0.77 and 1.34 ± 0.94 km for “Absorbing” and “Dust” type aerosols, respectively. Similar to Figure 8c, the TYPE dependence of aerosol height information was influenced by both absorptivity and size information. In addition, the difference in the definition of ALH from TROPOMI and AEH from GEMS impacted the comparison. “Dust” types of aerosol are mainly transported in the free troposphere, and the associated plume thickness is highly variable. By contrast, “Absorbing” aerosols mainly originate from anthropogenic emissions in East Asia (e.g., Gao *et al.*, 2014; Wang *et al.*, 2012; Peng *et al.*, 2016). In addition, the vertical distribution of aerosols is unstable for “Dust” case. For these reasons, the standard deviation of aerosol height was larger for the “Dust” type.

Figure 12. Histogram of the difference between ALH from TROPOMI and AEH from GEMS [(AEH from GEMS) – (ALH from TROPOMI)] over land and ocean pixels, respectively, from January 1 to June 30, 2021.

The non-Lambertian effect on the land surface impacted surface albedo uncertainty during AEH retrieval, and this effect led to bias and variance in AEH. In this study, the minimum Lambertian equivalent reflectance was used as the reference reflectance value. However, surface reflectivity has geometric dependence due to non-Lambertian effects, which leads to a bias of 0.01-0.02 for surface reflectance over the land surface (e.g., Qin *et al.*, 2019). To identify the sensitivity of surface property, a histogram was constructed of (AEH from GEMS) – (ALH from TROPOMI) after classification into land and ocean surface types, as shown in Figure 12. From the statistical results, the mean differences

were estimated to be 1.09 and 0.91 km for ocean and land pixels, respectively, indicating insignificant difference in bias between these two surface covers. However, the standard deviation of the two surface types indicated a significant difference. Over the ocean surface, the histogram is very narrow. Although there are 6.5 times more data for land than those for the ocean surface, the land surface has a relatively wide histogram distribution. This discrepancy arises because the non-Lambertian effect causes bias in surface reflectance, while also influencing the variability in surface reflectance related to observation geometry. For this reason, land surface reflectance based on the non-Lambertian surface assumption is not fully representative of actual surface reflectance as a function of observation geometry. Therefore, the standard deviation of the layer height difference is larger over the land surface, and the significant difference between land and ocean pixels is mainly driven by the assumption of surface reflection properties.

Figure 13. Diurnal dependence of AEH difference between CALIOP and GEMS from January 1 to June 30, 2021 (line and error bar is the mean and standard deviation

of AEH difference, and the box is number of data).

The results of hourly statistical analyses are presented in Figure 13. Because they use a consistent definition of AEH, we show only a comparison of GEMS and CALIOP. The diurnal variation in AEH difference ranged from -0.23 ± 1.45 km (07:00 UTC, Number of Data = 867) to 1.01 ± 1.96 km (03:00 UTC, Number of Data = 23). However, the number of pixels observed at 03:00 UTC was insufficient for the identification of diurnal variation. The AEH difference of 0.66 ± 1.45 km was the next highest value obtained at 04:00 UTC (Number of Data = 395). The inhomogeneous number of data is mainly due to the lack of spatial homogeneity among retrieval pixels. Over India, very high AOD values were consistently observed during the comparison period. Otherwise, the AEH was only retrieved under conditions of severe anthropogenic emissions over East Asia. In addition, the diurnal variation in AEH difference was caused by spatial characteristics of AEH difference. From 03:00 to 05:00 UTC, CALIOP mainly passed over East Asia, which has numerous sources of aerosol emissions, including biomass burning, dust, and industrial activity. In addition, GEMS observed only the eastern part of India, which is dominated by anthropogenic aerosols. The spatial distribution of the dominant aerosol types may impact the diurnal variation in AEH difference.

6. Summary & Conclusions

Based on the possibility of retrieving AEH from environmental satellite sensors, an AEH retrieval algorithm for GEMS was developed that solely uses the O_2-O_2 absorption band with considering aerosol and surface properties. Because the sensitivity of AEH retrieval is strongly affected by optical amounts and properties of aerosols, as well as surface reflectivity, an AEH retrieval algorithm for GEMS was developed after retrieval

of the GEMS operational algorithms, L2AERAOD and L2SFC. With the newly developed retrieval algorithm, GEMS can be used to monitor aerosol vertical information with high temporal and spatial resolution. To ensure significant sensitivity of AEH retrieval, only AEH retrieval results are with AOD larger than 0.3 were shown.

For dust plumes over East Asia, AEH indicated significant aerosol vertical information and insignificant diurnal variation in regions with severe dust plumes. After spatial and temporal collocation, the AEH from GEMS aligned well with the AEH information obtained from CALIOP. The differences in AEH between GEMS and CALIOP for dust plume cases were -0.07 ± 1.09 and -0.11 ± 1.27 km, with 53.8% and 72.9% of all pixels showing differences less than 1.0 and 1.5 km, respectively. Large AEH uncertainty was found mostly over inland China due to uncertainty in surface reflectance and AOD over the land surface. In addition, AEH from GEMS was overestimated compared to the TROPOMI ALH results due to different definitions of ALH from TROPOMI and AEH from GEMS.

In long-term intercomparison with CALIOP, the average AEH difference was estimated to be -0.03 km, with variation of around 1.4 km based on the standard deviation for $\text{AOD} > 0.4$. In terms of sensitivity to surface albedo, the mean differences were estimated to be 1.09 and 0.91 km over the ocean and land, respectively, which is an insignificant difference of the biases between these two surface types. The large variation in AEH difference between GEMS and CALIOP was caused by uncertainty in the input parameters estimated from L2AERAOD and L2SFC. In the long-term intercomparison with TROPOMI, this difference was significantly dependent on both SSA and TYPE. The difference was 0.78 ± 0.81 km and 1.16 ± 0.92 km for pixels with $\text{SSA} < 0.90$ and $0.90 < \text{SSA} < 0.95$, respectively. In addition, differences of 0.73 ± 0.77

and 1.34 ± 0.94 km were obtained for the “Absorbing” and the “Dust” types of aerosol, respectively. The AEH difference ranged from -0.23 ± 1.45 km (07:00 UTC, Number of Data = 867) to 1.01 ± 1.96 km (03:00 UTC, Number of Data = 23), showing diurnal dependence. The spatial difference in dominant aerosol type may impact the diurnal variation in AEH difference.

The case studies and results of the long-term validation show that AEH retrieved from GEMS can provide information on aerosol vertical distribution, with applications in diverse research fields. In particular, AEH information can be applied to AMF calculation for trace gases to consider the change in scattering weight change due to the presence of an aerosol layer. In addition, AEH considerably affects the surface particulate matter (PM) concentration obtained from satellite-based AOD because PM estimation is significantly affected by the mixing layer height of aerosols.

Although several fields of study may apply the AEH retrieval results, retrieval uncertainty in AEH remains due to the uncertainty of retrieved AOD and SSA. In addition, the uncertainty in surface reflectance and the discrepancy in O_2-O_2 SCD values between the simulation results and observations can be affected to the potential error sources of AEH from GEMS. Moreover, AEH provides representative layer height information as only one variable because of its sole reliance on O_2-O_2 SCD for direct estimation of aerosol height information. This method is limited to the consideration of aerosol vertical structures (i.e., Gaussian or exponential vertical distribution structures). Rather than using the GEMS sensor alone, using another absorption band for oxygen-based materials would provide additional scattering information about aerosols.
