10 **Abstract.** In this study, high-resolution radiosondes from the MAGIC field campaign and ERA5  
11 global reanalysis data are used to assess the elevated ducting layer characteristics along the  
12 transect over the northeastern Pacific Ocean from Los Angeles, California to Honolulu, Hawaii.  
13 The planetary boundary layer height (PBLH) increases as the strength of the refractivity gradient  
14 decreases westward along the transect. The thickness of the prevailing ducting layer remains  
15 remarkably consistent (~110 m) in the radiosonde data. On the other hand, the ERA5 generally  
16 resolves the ducting features well but underestimates the ducting height and strength especially  
17 over the trade cumulus region near Hawaii. A simple two-step end-to-end simulation is used to  
18 evaluate the impact of the elevated ducting layer on RO refractivity retrievals. A systematic  
19 negative refractivity bias (*N*-bias) below the ducting layer is observed throughout the transect,  
20 peaking (−5.42%) approximately 80 meters below the PBL height, and gradually decreasing  
21 towards the surface (−0.5%). The *N*-bias shows strong positive correlation with the ducting  
22 strength. The ERA5 data underestimate the *N*-bias with the magnitude of the underestimation  
23 increasing westward along the transect.

## 30 **1 Introduction**

31 The troposphere, where most weather occurs, consists of two main layers: the planetary  
32 boundary layer (PBL) and the free atmosphere (FA) (Garratt, 1994). The PBL characteristics  
33 change frequently on both spatial and temporal scales and the PBL height (PBLH) can impact  
34 the exchange of heat, momentum, and particulate matter with the FA, making it a critical factor  
35 in global energy balances and water cycling (Stull 1988; Ramanathan et al. 1989; Klein and  
36 Hartmann 1993). Regular PBL observations are mainly limited to in situ measurements from  
37 surface stations and radiosondes. However, spatially and temporally dense in situ PBL  
38 observations are only available from field campaigns such as the Boundary Layer Experiment  
39 1996 (BLX96, Stull et al. 1997), the Variability of the American Monsoon Systems (VAMOS)  
40 Ocean-Cloud-Atmosphere-Land Study Regional Experiment (VOCALS-REx, Wood et al. 2011),  
41 and the Marine Atmospheric Radiation Measurement (ARM) Global Energy and Water  
42 Experiment (GEWEX) Cloud System Studies (GCSS) Pacific Cross Section Intercomparison  
43 (GPCI) Investigation of Clouds (MAGIC, Zhou et al. 2015). Satellite observations of the PBL  
44 are also limited due to signal attenuation of the conventional infrared sounder in the lower  
45 troposphere and the low vertical resolution of microwave sounding instruments. Additionally,  
46 while the depth of the PBLH can vary from a couple hundred meters to a few kilometers (von  
47 Engeln and Teixeira 2013; Ao et al. 2012), the transition layer from the PBL to the FA is  
48 typically on the order of tens to hundreds of meters thick (Maddy and Barnet 2008), rendering  
49 ineffective PBL sensing from the low vertical resolution passive infrared and microwave  
50 sounders.

51 On the other hand, Global Navigation Satellite System (GNSS) radio occultation (RO) provides  
52 global atmospheric soundings with a vertical resolution of approximately 100 m in the lower  
53 troposphere under all weather conditions (Gorbunov et al., 2004; Kursinski et al., 2000, 1997).  
54 One of the major GNSS RO missions is the Formosat-3/Constellation Observing System for  
55 Meteorology, Ionosphere, and Climate (COSMIC), later referred to as COSMIC-1 (Anthes et al.  
56 2008), and its follow-on mission COSMIC-2 (Schreiner et al. 2020). Numerous studies have  
57 documented the high value of GNSS RO for profiling the PBL and determining the PBLH  
58 (Nelson et al. 2021; Winning et al. 2017; Ho et al. 2015; Ao et al. 2012; ; Guo et al. 2011; Basha  
59 and Ratnam 2009; Ao et al. 2008; Xie et al. 2008).

60 The advancement of the GNSS RO technique with open-loop tracking (Sokolovskiy et al., 2006;  
61 Beyerle et al., 2003; Ao et al., 2003) along with the implementation of the radio-holographic  
62 retrieval algorithm (Jensen et al., 2004; Jensen et al., 2003; Gorbunov, 2002) have led to much  
63 improved PBL sounding quality. However, probing the marine PBL remains challenging as  
64 systematic negative biases are frequently seen in RO refractivity retrievals (Feng et al. 2020; Xie  
65 et al. 2010). One major cause of the refractivity bias (hereafter *N*-bias) is the RO retrieval error  
66 due to elevated atmospheric ducting often seen near the PBLH (Ao et al., 2007; Xie et al., 2006;  
67 Ao et al. 2003; Sokolovskiy 2003). This elevated ducting prevails over the subtropical eastern  
68 oceans (Feng et al., 2020; Lopez, 2009; von Englen et al., 2003), and the horizontal extent of  
69 ducting in these regions can be on the order of thousands of kilometers (Winning et al. 2017; Xie  
70 et al. 2010). In the presence of ducting, the vertical refractivity gradient exceeds the critical  
71 refraction threshold for L-band frequencies (i.e.,  $dN/dz \leq -157$  N-units  $\text{km}^{-1}$ ). The steep negative  
72 refractivity gradient is often observed in the vicinity of the PBLH, which is typically caused by  
73 an atmospheric temperature inversion, a sharp decrease in moisture, or a combination of both.  
74 When ducting is present, the Abel inversion (e.g., Fjeldbo et al., 1971) in the standard retrieval  
75 process encounters a non-unique inversion problem due to a singularity in the bending angle,  
76 resulting in large, systematic underestimation of refractivity (*N*) below the ducting layer ( Xie et  
77 al. 2006; Ao et al., 2003; Sokolovskiy, 2003). The large uncertainty in RO refractivity coupled  
78 with the singularity in bending angle hinders assimilation of RO observations into numerical  
79 weather models, resulting in discarding of a significant percentage of RO measurements inside  
80 the PBL (Healy, 2001).

81 To comprehensively assess the potential impact of ducting on GNSS RO retrievals, we begin by  
82 constructing a detailed ground truth of PBL ducting statistics. This is derived from an extensive  
83 set of high-resolution radiosonde data over the northeastern Pacific Ocean, a region known for  
84 prevailing ducting conditions. Subsequently, we conduct a simulation study using the radiosonde  
85 data to evaluate the *N*-biases caused by varying ducting characteristics. Section 2 provides details  
86 of the two data sets used for this study: high-resolution radiosondes over the northeastern Pacific  
87 Ocean and the colocated ECMWF Reanalysis version 5 (ERA5, Hersbach et al. 2020) profiles.  
88 Additionally, we discuss the co-location criteria and the detection method for ducting layer and  
89 the corresponding PBLH. Section 3 presents the ducting statistics for key variables, such as  
90 ducting height, PBLH, minimum refractivity gradient, and sharpness parameter. The

91 characteristics of ducting including the thickness and strength along the cross-section are also  
92 shown. Furthermore, we evaluate the ducting-induced  $N$ -bias in GNSS RO refractivity retrievals  
93 by carrying out a two-step end-to-end simulation. Section 4 summarizes the findings and  
94 discusses the direction of future research.

## 95 **2 Data and methods**

### 96 **2.1 MAGIC radiosonde and colocated ERA5 data**

97 A collection of high-resolution radiosondes from the Marine Atmospheric Radiation  
98 Measurement (ARM) GCSS Pacific Cross Section Intercomparison (GPCI) Investigation of  
99 Clouds (MAGIC) are utilized as the primary data set in this analysis (Lewis 2016; Zhou et al.  
100 2015). The MAGIC field campaign took place from 26 September 2012 to 2 October 2013 as  
101 part of the U.S Department of Energy ARM Program Mobile Facility 2 (AMF2) aboard the  
102 Horizon Lines container ship, *Spirit*, which completed 20 round trip passes between Los  
103 Angeles, California and Honolulu, Hawaii during the yearlong data collection period (Painemal  
104 et al., 2015; Zhou, 2015). During each transit, radiosondes were launched at 6-hour intervals  
105 from the beginning of the program through the end of June 2013; the observation frequency  
106 increased to every 3 hours from July 2013 through the end of the campaign (Zhou et al., 2015).  
107 A total of 583 MAGIC radiosonde profiles were collected during the field campaign (Zhou et al.,  
108 2015), all with a vertical sampling frequency of 0.5 Hz (2 seconds), which provides an average  
109 vertical resolution of  $\sim 8$  m below 3 km, but varies due to local vertical motion.

110 Use of this data set serves multiple benefits. First, the northeast Pacific transitions from a  
111 shallow stratocumulus-topped PBL to a higher, trade-cumulus boundary layer regime along the  
112 GPCI transect (Garratt, 1994). Second, the large number of observations over a 12-month time  
113 frame provides high temporal (diurnal and seasonal) and spatial profiling of the PBL along the  
114 GPCI transect seen in Fig.1. Finally, ducting is prevalent throughout the domain which creates a  
115 natural cross-section of refractivity field in  $X$  (zonal) and  $Z$  (vertical) dimensions.

116  
117 **Figure 1: Location of radiosonde observations from the MAGIC field campaign October 2012–September 2013.**  
118

119 The radiosonde profiles are colocated with ERA5 model reanalysis profiles. The ERA5  
120 reanalysis data have a horizontal grid resolution of  $0.25^\circ \times 0.25^\circ$ , 1-hour temporal resolution, and  
121 137 uneven vertical model levels from the surface to 0.01 hPa. The model level density  
122 decreases with height: on average, there are 19 model levels below 1 km (10–100 m resolution),  
123 which reduces to 8 levels between 1 and 2 km (100–160 m resolution), and further reduces to 5  
124 levels between 2 and 3 km (160–200 m resolution). Each MAGIC radiosonde profile was  
125 colocated with the nearest ERA5 grid point that is within 1.5 hours of the closest 3-hourly model  
126 reanalysis profile.

## 127 **2.2 PBL height detection with the minimum gradient method**

128 At GNSS L-band frequencies, the atmospheric refractivity ( $N$  in N-units) is derived from the  
129 refractive index  $n$ , where  $N = (n - 1) \times 10^6$  and, in the neutral atmosphere (Kursinski et al.,  
130 1997), is a function of the atmospheric pressure ( $P$  in mb), temperature ( $T$  in K), and partial  
131 pressure of water vapor ( $P_w$  in mb) as seen in Eq. (1) from Smith and Weintraub (1953).

$$132 \quad N = 77.6 \frac{P}{T} + 3.73 \times 10^5 \frac{P_w}{T^2}, \quad (1)$$

133 Over the subtropical eastern oceans, a sharp decrease in moisture is often associated with a  
134 strong temperature inversion marking a clear transition from the PBL to the FA. Both the distinct  
135 decrease in moisture and the temperature inversion lead to a sharp negative refractivity gradient  
136 which can be precisely detected from GNSS RO. Numerous studies have implemented the

137 simple gradient method to detect the PBLH, i.e., the height of the minimum refractivity gradient  
138 (Ao et al., 2012; Seidal et al., 2010; Xie et al., 2006). To assess the robustness of PBLH  
139 detection with gradient method, Ao et al. (2012) introduced the sharpness parameter ( $\tilde{N}'$ ) to  
140 measure the relative magnitude of the minimum gradient from surface to 5 km as follows:

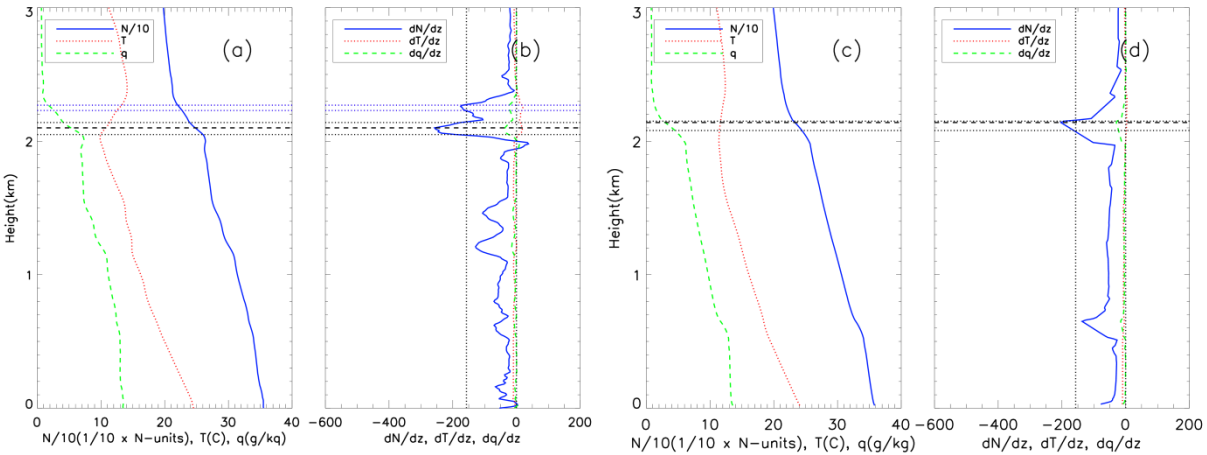

$$141 \quad \tilde{N}' \equiv -\frac{N'_{min}}{N'_{RMS}}, \quad (2)$$

142 Each refractivity gradient profile can then be filtered to identify the PBLH values with sharpness  
143 parameter exceeding a specific threshold, thus increasing the robustness of PBLH detection. In  
144 this study, the MAGIC radiosonde refractivity profiles were first interpolated to a uniform 10 m  
145 vertical grid and then smoothed by a 100 m boxcar window to reduce the noise in the gradient  
146 profile resulting from the high sampling rate. Moreover, the 100 m smoothed radiosonde will be  
147 more consistent with the vertical resolution of GNSS RO measurements (e.g. Gorbunov et al.,  
148 2004). Colocated ERA5 data were also vertically interpolated to the same 10 m grid but not  
149 smoothed as these data do not contain the inherent noise as the radiosonde observations. In  
150 addition, as the elevated ducting layer is the focus of this study, the lowest 0.3 km above mean-  
151 sea-level of the  $N$ -profile near surface are excluded (e.g., Xie et al., 2012). Subsequently, the  
152 height of the minimum refractivity gradient (within 0.3 km and 5 km) will be identified as the  
153 PBLH.

### 154 **2.3 Ducting layers**

155 When the vertical refractivity gradient is less than the critical refraction ( $dN/dz \approx -157.0$  N-units  
156  $\text{km}^{-1}$ ), ducting occurs (Sokolovskiy, 2003). A ducting layer is identified as any interval of  
157 continuous points with a vertical refractivity gradient equal to or less than  $-157$  N-units  $\text{km}^{-1}$ .  
158 Instances of multiple ducting layers occurring within a profile are present for both the MAGIC  
159 (31.5%) and ERA5 (6.7%) data sets. In this study, we only recognize one dominant “ducting  
160 layer” in each profile where the minimum vertical gradient is located. The ducting layer  
161 thickness ( $\Delta h$ ) is defined as the interval between the top and bottom of the ducting layer where  
162 the refractivity gradients reach critical refraction. Similarly, the strength of each ducting layer  
163 ( $\Delta N$ ) is defined as the refractivity difference between the bottom and top of the ducting layer.  
164 The ducting layer height is in reference to the top of the ducting layer (Ao, 2007), which is  
165 generally slightly above the PBLH.

166 Figure 2 shows vertical profiles of refractivity ( $N$ -units  $\times 1/10$ ,  $N/10$ ), temperature ( $T$ ), and  
 167 specific humidity ( $q$ ) along with their respective vertical gradients ( $dN/dz$ ,  $dT/dz$  and  $dq/dz$ ) from  
 168 a representative MAGIC radiosonde (Fig. 2a,b) case located at ( $23.69^\circ\text{N}$ ,  $-150.02^\circ\text{E}$ ), and its  
 169 colocated ERA5 (Fig. 2c,d) profile at ( $23.75^\circ\text{N}$ ,  $-150.00^\circ\text{E}$ ). The PBLH of the radiosonde (2.10  
 170 km) is almost identical to the colocated ERA5 (2.14 km) and the “dominant” ducting layer near  
 171 the PBLH demonstrates similar thickness. However, a second, weaker ducting layer seen in the  
 172 radiosonde above the PBLH was not captured by the ERA5.

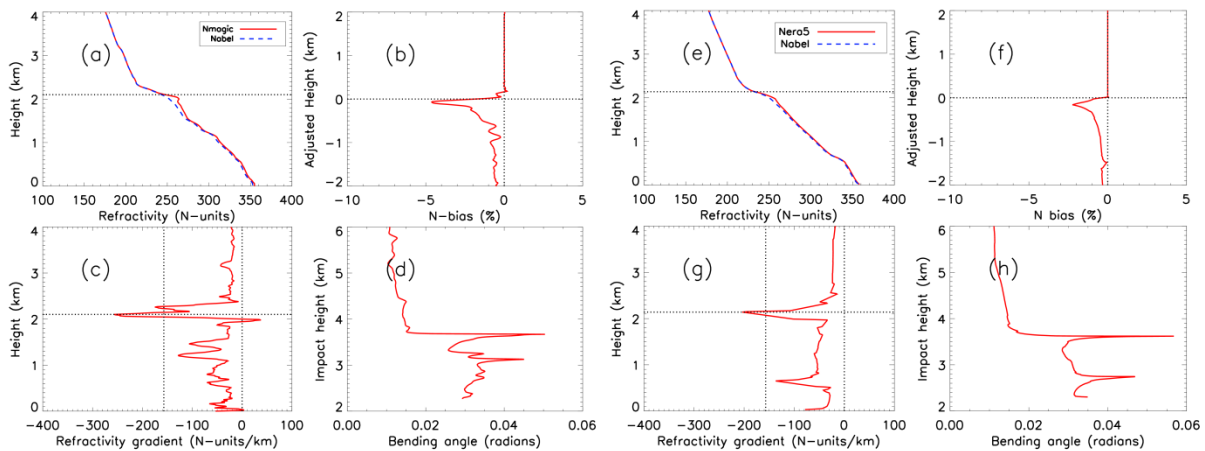

173  
 174 **Figure 2: Vertical profiles of refractivity ( $1/10 \times N$  in  $N$ -units,  $N/10$ , solid blue), temperature ( $T$  in  $^\circ\text{C}$ , dotted red) and**  
 175 **specific humidity ( $q$  in  $\text{g kg}^{-1}$ , dashed green) for (a) radiosonde at ( $23.69^\circ\text{N}$ ,  $-150.02^\circ\text{E}$ ) launched at 2012-10-02, 05:30**  
 176 **UTC, and (c) colocated ERA5 at ( $23.75^\circ\text{N}$ ,  $-150.00^\circ\text{E}$ ); and associated gradient profiles for radiosonde (b) and ERA5 (d).**  
 177 **The horizontal dashed line highlights the height of the minimum gradient, i.e., PBLH. The paired horizontal dotted lines**  
 178 **represent the bottom and top of the two ducting layers in the radiosonde profile (a and b) but only one in the ERA5**  
 179 **profile (c and d).**

## 180 2.4 Evaluation of GNSS RO $N$ -bias resulting from ducting

181 In order to estimate the systematic negative  $N$ -bias in GNSS RO observations in the presence of  
 182 ducting, we use an end-to-end simulation on the radiosonde and ERA5 refractivity profiles. The  
 183 simulation consists of a two-step process adapted from Xie et al. (2006). The first step is to  
 184 simulate the 1-dimensional GNSS RO bending angle as a function of impact parameter (i.e., the  
 185 product of refractive index and the radius of the Earth’s curvature) by forward Abel integration  
 186 of an input refractivity profile assuming a spherically symmetric atmosphere (Sokolovskiy, 2001;  
 187 Eshleman, 1973, Fjeldbo and Eshleman, 1968). The second step is to simulate the GNSS RO  
 188 refractivity retrieval by applying the Abel inversion on the simulated bending angle from step  
 189 one. In the absence of ducting, the impact parameter increases monotonically with height,  
 190 allowing a unique solution to the inverse Abel retrieval that is the same as the original

191 refractivity profile input. However, in the presence of an elevated ducting layer, the Abel  
 192 retrieval systematically underestimates the refractivity profile due to the non-unique Abel  
 193 inversion problem resulting from the singularity in bending angle across the ducting layer (Xie et  
 194 al., 2006; Sokolovskiy 2003). It should be noted that after the 100 m vertical smoothing on  
 195 radiosonde (no smoothing on ERA5) profiles as described in section 2.2, an additional 50 m  
 196 vertical smoothing has been applied to the simulated bending angle profiles of both radiosonde  
 197 and ERA5 data sets to alleviate the challenge of integration through the very sharp bending angle  
 198 resulting from ducting in the inverse Abel integration procedure (Feng et al., 2020).

199 Figure 3 shows the end-to-end simulation results for the same radiosonde (a–d) and the colocated  
 200 ERA5 (e–h) cases from Fig. 2. Figures 3a and 3e show refractivity profiles from the radiosonde  
 201 ( $N_{rds}$ ) and the colocated ERA5 ( $N_{ERA5}$ ) data as well as their corresponding Abel refractivity  
 202 retrievals ( $N_{Abel}$ ). The PBLH is marked by a horizontal dotted line. The peak bending angle is  
 203 consistent with the sharp refractivity gradient. Figure 3b shows the fractional  $N$ -bias between the  
 204 simulated Abel retrieved RO refractivity profile and the observation, i.e.,  $((N_{Abel} - N_{Obs})/N_{Obs})$ .  
 205 Considering the significant spatial and temporal variations of ducting height along the transect,  
 206 each  $N$ -bias profile is normalized to its PBLH for the purposes of comparison. For example, the  
 207 zero-adjusted height refers to the PBLH for each individual profile. The systematic negative  $N$ -  
 208 bias is clearly shown below the ducting layer marked by the PBLH in both cases, with the biases  
 209 decreasing at lower altitude, the largest magnitude bias ( $-5\%$  for radiosonde;  $-2.5\%$  for ERA5)  
 210 close to the ducting height and a minimum magnitude approaching zero near the surface.

211  
 212 **Figure 3: End-to-end simulation data for MAGIC radiosonde launched at 0530 UTC on 20121002 showing: (a)  $N_{Obs}$  (solid**  
 213 **red) and  $N_{Abel}$  (blue dashed) from surface to 4 km; (b) PBLH adjusted  $N$ -bias  $((N_{Abel} - N_{Obs})/N_{Obs})$ ; (c) refractivity gradient**  
 214 **and (d) bending angle vs. impact parameter. The same is shown in panels e-h for the colocated ERA5 profile.**

### 215 3 Analysis

216 Quality control for radiosonde (and colocated ERA5) profiles was based on five key criteria.  
217 First, a total of 19 radiosonde and 24 ERA5 profiles near the southern California coast were  
218 removed due to their positions east of  $-120^{\circ}\text{E}$  or anomalously high PBL ( $\text{PBLH} > 3.0 \text{ km}$ ) with  
219 no distinct minimum gradient. The remaining profiles in the easternmost portion of the domain  
220 were too few in number to calculate meaningful statistics. Second, any profile lacking critical  
221 refraction (i.e.  $dN/dz < -157 \text{ N-units km}^{-1}$ ) points was excluded from the analysis which resulted  
222 in the removal of 47 radiosonde and 176 ERA5 profiles. Third, the noisy bending angle could  
223 result in errors in Abel refractivity retrieval and cause positive  $N$ -bias. Therefore, the profiles  
224 with  $N$ -bias greater than  $+0.5\%$  are excluded resulting in the removal of 61 MAGIC profiles and  
225 16 ERA5 profiles. Fourth, the profiles with only surface ducting, i.e., below 300 m threshold, are  
226 discarded. Finally, 25 radiosonde profiles and 2 ERA5 profiles were removed due to the Abel  
227 retrieval failure. After implementing all quality control measures, the number of radiosonde and  
228 ERA5 profiles used for the  $N$ -bias analysis is reduced to 396 and 319 profiles, respectively.

#### 229 3.1 PBL analysis

230 To evaluate the ducting properties along the transect from the coast of southern California to  
231 Hawaii, we group the MAGIC radiosonde and the colocated ERA5 profiles into eight  $5^{\circ}$   
232 longitude bins between  $-160.0^{\circ}$  and  $-120.0^{\circ}$ , which allows for the spatial variation of the PBL,  
233 ducting layer and the associated properties along the transect to be easily illustrated. Figure 4  
234 shows the median value of PBLH (a), minimum gradient (b) and sharpness parameter (c) along  
235 the transect. The median-absolute-deviation (MAD) for each parameter is also shown.

236 In Fig. 4a, the MAGIC radiosondes clearly show the gradual increase of the PBLH along the  
237 transect from the shallow stratocumulus-topped PBL ( $\sim 800 \text{ m}$ ) near the southern California coast  
238 westward to the much deeper trade-cumulus regime ( $\sim 1.8 \text{ km}$ ) near Hawaii. A similar structure is  
239 seen in the colocated ERA5 data but with an average low bias of 165 m below the radiosonde.  
240 However, a nearly 800 m underestimation in PBLH over the two westernmost bins near Hawaii  
241 is also seen, this is consistent with what is found over the equivalent trade cumulus region of the  
242 subtropical southeast Pacific Ocean (Xie et al., 2012). Such a discrepancy could be due to the  
243 sensitivity of gradient method to the vertical resolution of the data. Over the western segment of

244 the transect (near Hawaii), two major gradient layers (one at ~1 km and the other at ~2 km) with  
 245 comparable refractivity gradients are often observed (e.g., Fig. 2). The gradient layer at around 2  
 246 km is well-known as the trade-wind inversion. While the lower-level gradient layer at ~1 km, is  
 247 generally called a mixing layer. Note the radiosonde data exhibit consistent vertical sampling (~8  
 248 m resolution) below 3 km, and resolve both layers well. However, the ERA5 data have an  
 249 uneven vertical sampling intervals increasing with height, with 10 – 100m resolution below 1  
 250 km, 100 – 160 m within 1-2 km, and 160 – 200 m within 2-3 km. Therefore, the ERA5 data are  
 251 more likely to resolve the sharp gradient structure below 1 km than the one at higher altitude.  
 252 This could result in resolving the mixing layer (below 1 km) with the sharpest refractivity  
 253 gradient, instead of the trade-wind inversion near 2 km in the ERA5 data. Note that the larger  
 254 median absolute deviation for the westernmost bins compared to the rest of the transect  
 255 illustrates the existence of greater PBLH variability closer to the trade-cumulus boundary layer  
 256 regime. The westward decreasing magnitude of the minimum refractivity gradient (Fig. 4b) and  
 257 sharpness parameter (Fig. 4c) indicates the westward weakening of moisture lapse rate and/or  
 258 temperature inversion across the PBL top, which is consistent with the decreasing synoptic-scale  
 259 subsidence from the California coast to Hawaii (Riehl, 1979).

260  
 261 **Figure 4: Zonal transect of 5° bin MAGIC and ERA5 PBLH (a), minimum refractivity gradient (b) and sharpness**  
 262 **parameter (c) for MAGIC (median in red circle and dashed line, MAD in red dotted error bars) and ERA5 (median in**  
 263 **blue diamond and dot-dashed line, MAD in blue dotted error bars).**  
 264

265 It is also notable that the ERA5 systematically underestimates not only the PBLH but also the  
266 magnitude of the minimum gradient across the entire transect. This can also be seen in the  
267 sharpness parameter west of  $-132.5^\circ$ . This discrepancy could be partially attributed to the  
268 decrease in vertical sampling in ERA5 profiles as compared to the radiosondes, the result of  
269 which leads to a weaker PBL refractivity gradient and coincides with an increasing PBLH.  
270 Therefore, the underestimation of the ERA5 minimum refractivity gradient increases in  
271 magnitude from east to west and becomes most prominent near Hawaii where the PBLH reaches  
272 the maximum height over the region.

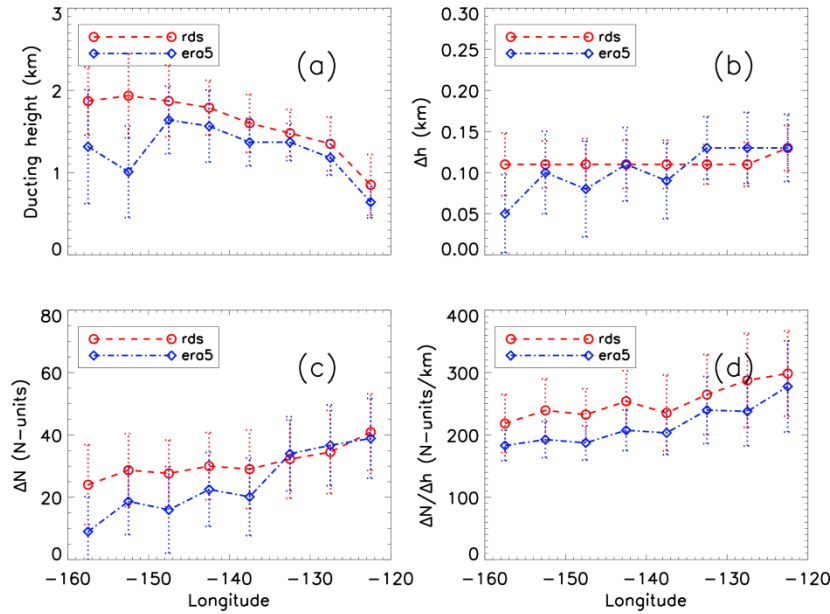

### 273 **3.2 Ducting characteristics**

274 As introduced in Sect. 2.3, the key characteristics of the ducting layer along the transect will be  
275 investigated, these include the ducting layer height, thickness ( $\Delta h$ ), and strength ( $\Delta N$ ), as well as  
276 the average refractivity gradient within the ducting layer ( $\Delta N/\Delta h$ ). All parameters are  
277 interpolated to a 10 m vertical grid.

278 The ducting layer heights from both radiosonde and ERA5 show a westward increase along the  
279 transect is seen in Fig. 5a. Note again that the ERA5 shows a systematic  $\sim 100$ – $200$  m low bias  
280 when compared to the radiosondes between  $-122.5^\circ$  and  $-147.5^\circ$ , with the difference increasing  
281 to more than 500 m near Hawaii. The ducting layer thickness is the median height from the  
282 bottom of the ducting layer to the top and is expressed in km (Fig. 5b). Ducting thickness ( $\Delta h$ )  
283 for MAGIC shows a near constant value of 110 m across the entire transect with only a slight  
284 increase to 130 m at  $-122.5^\circ$ , consistent with Ao et al. (2003). Conversely, the ERA5 shows a  
285 constant but slightly thicker ducting layer to the east of  $-137.5^\circ$  and then a decreasing thickness  
286 to the west of  $-137.5^\circ$  (Fig. 5b).

287 The ducting layer strength is the decrease in refractivity from the bottom of the ducting layer to  
288 the top (Fig. 5c) and the ratio  $\Delta N/\Delta h$  reflects the average gradient of the ducting layer (Fig. 5d).  
289 The ducting strength ( $\Delta N$ ) for the radiosondes generally ranges from 25 N-units near Hawaii to  
290 40 N-units near the coast of California. Both  $\Delta N$  and  $\Delta N/\Delta h$  show an overall westward  
291 decreasing trend along the transect which is consistent with the decrease in magnitude of the  
292 refractivity gradient (Fig. 4b). Note that MAGIC and ERA5 show similar ducting strength in the  
293 eastern part of the region but diverge near  $-137.5^\circ$  with ERA5 10 to 20 N-units weaker than the  
294 MAGIC profiles. On the other hand, ERA5 shows a systematic lower average refractivity

295 gradient ( $\Delta N/\Delta h$ ) than MAGIC throughout the transect, indicating the challenge in ERA5 to  
 296 consistently resolve the sharp vertical structure in refractivity, and likewise in temperature and  
 297 moisture profiles, across such a thin ducting layer. The problem becomes acutely clear near the  
 298 trade cumulus region.

299  
 300 **Figure 5: Zonal transect of 5° bin median (a) ducting height, (b) ducting layer thickness ( $\Delta h$ ), (c) ducting layer strength**  
 301 **( $\Delta N$ ), and (d) average ducting layer gradient  $\Delta N/\Delta h$  for MAGIC (median in red circle and red-dashed line, MAD in red-**  
 302 **dotted error bars) and ERA5 (median in blue diamond and dot-dashed line, MAD in blue-dotted error bar).**  
 303

304 Figure 6 shows ducting layer thickness as a function of ducting layer strength, with each data  
 305 point colored by its respective longitude bin. The relationship between  $\Delta h$  and  $\Delta N$  is not  
 306 longitude-dependent for either data set, but a linear trend is evident for thinner ducting layers ( $\Delta h$   
 307  $< 0.1$  km) with weaker ducting strength ( $\Delta N < \sim 25$  N-units). However, for the ducting layers  
 308 thicker than 0.1 km, such a trend becomes less identifiable, and the ducting strength  $\Delta N$  begins to  
 309 show more variability toward larger values.

310

311  
 312 **Figure 6: Comparison of individual profiles' ducting strength ( $\Delta N$ ) vs. ducting thickness ( $\Delta h$ ) for MAGIC (a) and ERA5**  
 313 **(b). The color of each circle represents the location of the  $5^\circ$  longitude bin of each observation.**

### 314 3.3 Ducting-induced GNSS RO $N$ -bias statistics

315 To estimate the systematic negative  $N$ -bias in GNSS RO observations due to ducting, we have  
 316 applied the end-to-end simulation described in sect. 2.4 to all radiosonde and ERA5 refractivity  
 317 profiles with at least one elevated ducting layer detected. The  $N$ -bias along the transect as well as  
 318 its relationship to the ducting properties are presented below.

#### 319 3.3.1 Assessing ducting-induced $N$ -bias

320 Figure 7 shows a composite of both MAGIC (396 profiles) and ERA5 (319 profiles)  $N$ -bias  
 321 profiles which have been normalized to their PBLH, with the median  $N$ -bias and MAD overlaid.  
 322 The systematic negative  $N$ -bias peaks at approximately 100 m below the PBLH and decreases at  
 323 lower altitude. The peak median value of the  $N$ -bias for radiosondes is  $-5.42\%$  (MAD, 2.92%),  
 324 nearly twice the ERA5 value of  $-2.96\%$  (MAD, 2.59%), indicating the significant  
 325 underestimation of ducting strength in ERA5 data. However, the variabilities (MAD) of the  
 326 radiosonde and ERA5 data are within 0.33% of each other, indicating that ERA5 data  
 327 successfully capture the variations of ducting features seen in the radiosondes. It is worth noting  
 328 that many radiosonde profiles show small negative  $N$ -biases above the PBLH (i.e., zero-adjusted  
 329 height), which is the result of a secondary ducting layer above the major ducting layer near the

330 PBLH. Conversely, few ERA5 profiles show the presence of the secondary ducting layer above  
 331 PBLH.

332

333

334 **Figure 7: Fractional refractivity difference ( $N$ -bias in %) between the simulated Abel-retrieved refractivity profile and the original observation profile ( $(N_{Abel} - N_{Obs})/N_{Obs}$ ), for all individual observations (dotted gray): (a) MAGIC radiosondes (396 total profiles) and (b) ERA5 (319 total profiles) with population median (solid red)  $\pm$  MAD (dashed red). Note the zero value in the adjusted height refers to the PBLH for each individual  $N$ -bias profile.**

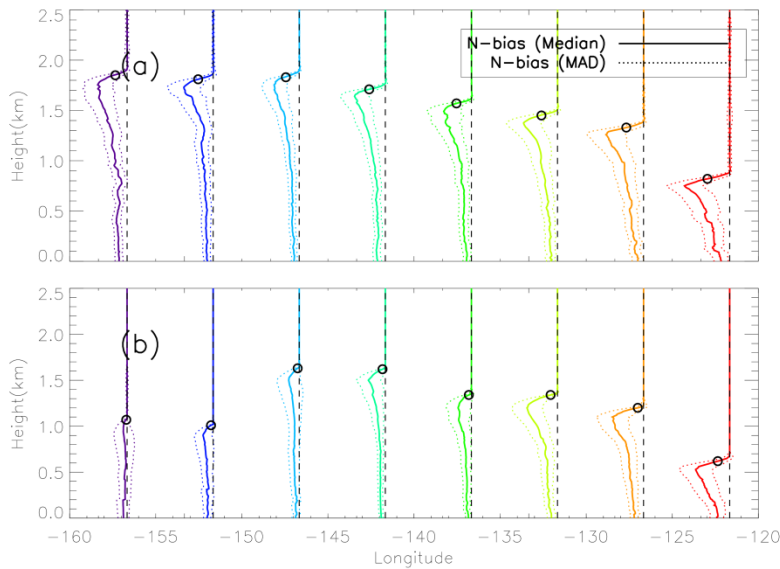

337

### 338 3.3.2 Zonal variation of the $N$ -bias along the transect

339 To illustrate the large variation in the  $N$ -bias vertical structure resulting from the spatial  
 340 variations of ducting height and strength, Fig. 8 presents the  $N$ -bias profiles (median  $\pm$  MAD) for  
 341 each  $5^\circ$  bin, replacing the zero adjusted height with the median PBLH for each bin. The  
 342 radiosonde composite (Fig. 8a) illustrates the westward transition of the median  $N$ -bias profiles  
 343 from the largest peak  $N$ -bias at  $\sim 0.8$  km near the coast of Los Angeles, California, to a much  
 344 reduced peak  $N$ -bias but higher altitude of  $\sim 1.8$  km at Honolulu, Hawaii. Table 1 lists detailed  
 345 statistics of the peak  $N$ -bias values at each bin for both radiosonde and ERA5 data. Although the  
 346 vertical structure of the  $N$ -bias profiles along the transect are consistent as seen in Fig. 7,  
 347 significant changes of the  $N$ -bias magnitude and its peak  $N$ -bias occurring height along the  
 348 transect are clearly seen.

349 The maximum peak  $N$ -bias ( $-7.86\%$ ) in the radiosonde data is located at the easternmost of the  
 350 transect near California ( $-122.5^\circ\text{E}$ ). Whereas the minimum peak  $N$ -bias ( $-4.37\%$ ) is located near  
 351 the center of the transect ( $-147.5^\circ\text{E}$ ). Similarly, the ERA5 also show the maximum peak  $N$ -bias

352 (-5.92%) near California (-122.5°E). However, the minimum peak *N*-bias (-0.77%) is found  
 353 near Hawaii (-157.5°E). Overall, the *N*-bias in ERA5 are smaller than radiosonde in all bins.  
 354 However, a noticeable difference exists between the ERA5 and radiosonde profiles for the two  
 355 westernmost longitude bins (-157.5°E and -152.5°E) where the ERA5 reveals a much lower and  
 356 weaker *N*-bias than the MAGIC data.  
 357 Note that the PBLH is above the height of the peak *N*-bias, with a maximum difference of 100 m  
 358 (-137.5°E) and a minimum difference of ~15 m (-152.5°E). Comparatively, the ERA5 PBL  
 359 height shows greater difference than the height of peak *N*-bias with a maximum difference of  
 360 230 m (-142.5°E) and a minimum of ~45 m (-157.5°E).  
 361

362  
 363 **Figure 8: Median *N*-bias (solid) ± MAD (dotted) along the north Pacific transect for MAGIC radiosondes (a) and ERA5**  
 364 **(b). Open circles represent the median PBLH for each 5° bin.**  
 365

366 **Table 1: Median and MAD peak *N*-bias values for MAGIC radiosondes (RDS) and ERA5 for each 5° bin.**

Peak <i>N</i> -bias				
Longitude	RDS median	RDS MAD	ERA5 median	ERA5 MAD
-157.5°	-5.12	±2.61	-0.77	±1.73
-152.5°	-5.10	±2.97	-1.76	±1.61
-147.5°	-4.37	±2.14	-1.83	±2.10
-142.5°	-5.36	±2.53	-2.95	±2.17
-137.5°	-4.82	±2.96	-2.31	±2.14
-132.5°	-5.90	±3.03	-5.31	±2.68
-127.5°	-6.55	±3.40	-5.45	±2.88
-122.5°	-7.86	±3.15	-5.92	±3.04

367  
 368

369 Figure 9 further illustrates the peak  $N$ -bias, median PBL  $N$ -bias (0.3 km to PBLH), and the near  
370 surface  $N$ -bias (at 0.3 km) at each bin along the transect. Note the median PBL  $N$ -bias refer to the  
371 median value from the near surface (0.3 km) to the PBLH. Contrary to the general trend of  
372 westward decrease in magnitude of the minimum refractivity gradient (Fig. 4b) and ducting  
373 strength (Fig. 5c), the radiosonde peak  $N$ -bias shows the maximum (median:  $-8.10\%$ , MAD:  
374  $3.26\%$ ) near California ( $-122.5^\circ\text{E}$ ) and the minimum (median:  $-4.85\%$ , MAD:  $2.18\%$ ) over the  
375 transition region ( $-147.5^\circ\text{E}$ ) as well as a slight increase to a secondary maximum (median:  
376  $-6.11\%$ , MAD:  $2.85\%$ ) near Hawaii ( $-157.5^\circ\text{E}$ ). The median PBL  $N$ -bias and the near surface  $N$ -  
377 bias also show a similar pattern. However, the median  $N$ -bias demonstrates a sharp decrease in  
378 the eastern half of the domain from  $-5.25\%$  (MAD:  $2.71\%$ ) at  $-122.5^\circ\text{E}$  to  $-1.71\%$  (MAD:  
379  $1.26\%$ ) at  $-137.5^\circ\text{E}$ , and then remains relatively constant over the western half of the domain.  
380 Similarly, the near surface  $N$ -bias reaches a maximum magnitude of  $-3.54\%$  (MAD:  $2.11\%$ ),  
381 sharply decreases to  $-1.06\%$  (MAD:  $0.85\%$ ) at  $-137.5^\circ\text{E}$ , and then remains relatively constant  
382 over the western half of the domain.

383 Note that normalizing each  $N$ -bias profile to the PBLH preserves the magnitude of the  $N$ -bias  
384 with various heights. Therefore, the relatively large normalized  $N$ -bias observed near Hawaii  
385 indicates more persistent ducting over the trade-cumulus boundary layer regime compared to the  
386 transition region in the middle of the transect at  $-147.5^\circ\text{E}$  (Fig. 8a).

387 On the other hand, the ERA5 data show a westward decrease of all three  $N$ -biases, systematically  
388 underestimating all three as compared to the radiosondes. This is expected as the decrease of  
389 ERA5 vertical resolution at higher altitude leads to a weaker PBL  $N$ -gradient observation (Fig.  
390 4b), and thus weaker ducting and a smaller ducting-induced  $N$ -bias. Such underestimation of the  
391  $N$ -bias in the ERA5 minimizes near California where the PBLH is lowest but becomes more  
392 severe westward with an increase in height, reaching a maximum magnitude  $N$ -bias difference  
393 near Hawaii. In this case, the peak  $N$ -bias is merely  $-0.71\%$  (MAD:  $1.80\%$ ) as compared to  
394  $-6.23\%$  (MAD:  $2.98\%$ ) at  $-122.5^\circ\text{E}$  (Fig. 9a and Table 1). The large difference seen in the  $N$ -  
395 bias along the transect strongly indicates the challenges of the ERA5 data to resolve the sharp  
396 gradient across the ducting layer, resulting in a large variation in PBLH of the ERA5 data in the  
397 western segment of the region. The increasing difference between the radiosonde and ERA5 data  
398 from east to west is most pronounced in the peak  $N$ -bias cross-section (Fig. 9a) but is also  
399 evident in both the median  $N$ -bias (Fig. 9b) as well as the near surface  $N$ -bias (Fig. 9c).

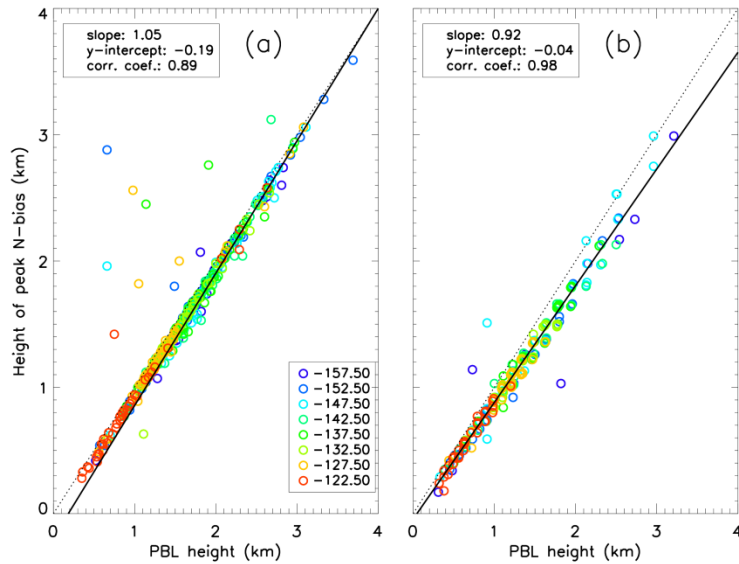

400  
 401 **Figure 9: Zonal transect of 5° bin (a) peak  $N$ -bias, (b) median PBL  $N$ -bias (0.3 km to PBLH), and (c) near surface  $N$ -bias**  
 402 **at 0.3 km for MAGIC (median in red circle and red-dashed line, MAD in red-dotted error bar) and ERA5 (median in**  
 403 **blue diamond and dot-dashed line, MAD in blue-dotted error bar)**

### 404 3.3.3 The relationship between $N$ -bias and key variables

405 Figure 10 shows a scatter plot of the PBLH vs. height of peak  $N$ -bias along the transect with each  
 406 data point colored by the center longitude of the bin to which it belongs. The PBLH and the  
 407 height of peak  $N$ -bias show a clear linear relationship with high correlation for both the MAGIC  
 408 (0.89) and ERA5 (0.98) data. The majority of the radiosonde data show the heights of peak  $N$ -  
 409 bias align well with the PBLH with a very small low bias (less than 80 m). The reason for the  
 410 lower correlation value in MAGIC data is attributed to outlier cases when the radiosonde  $N$ -bias  
 411 profiles with a double peak at which the larger magnitude bias is located (Fig. 7a). On the other  
 412 hand, the ERA5 maximum ducting heights show little difference from the PBLH near California  
 413 (e.g.,  $-122.5^\circ\text{E}$ ), but become lower moving westward, which is illustrated by the increasing  
 414 difference between the linear regression line and the 1:1 line.

415

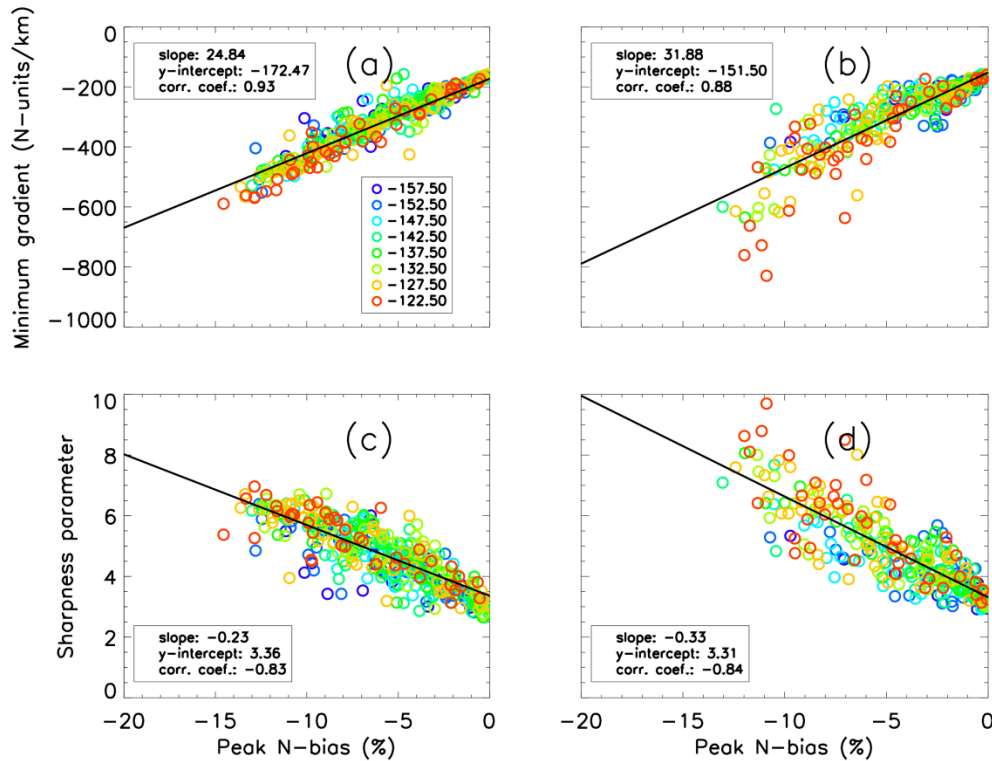

416

417 **Figure 10: PBLH vs. height of peak  $N$ -bias for individual profiles from MAGIC (a) and ERA5 (b) data. The color of each**  
 418 **open circle represents the center longitude of the  $5^\circ$  bin to which each profile belongs.**

419

420 Figure 11 shows a near-linear relationship between the minimum refractivity gradients and the  
 421 peak  $N$ -biases for both MAGIC radiosondes and ERA5 profiles, i.e., the sharper the refractivity  
 422 gradient, the larger the  $N$ -bias. The correlation coefficient for both MAGIC radiosondes (0.93)  
 423 and the ERA5 profiles (0.88) are also presented. The sharpness parameter (Fig. 11c, 11d) also  
 424 shows a linear relationship with the maximum  $N$ -bias which is a result of its dependence on the  
 425 minimum refractivity gradient. Interestingly, their relationship with the peak  $N$ -bias exhibits no  
 426 indication of zonal dependence.

427  
 428 **Figure 11:** (a, b) Minimum refractivity gradient ( $N\text{-units km}^{-1}$ ) and (c, d) sharpness parameter, as a function of the peak  
 429  $N$ -bias (%) for MAGIC (a, c) and ERA5 (b, d) data with the line of linear regression in solid black. Color of each open  
 430 circle represents the center longitude of the  $5^\circ$  bin to which each profile belongs.

431 **4 Summary and Conclusions**

432 In this study, radiosonde profiles from the MAGIC field campaign have been analyzed to  
 433 investigate ducting characteristics and the induced systematic refractivity biases in GNSS RO  
 434 retrievals over the Northeastern Pacific Ocean between Hawaii and California. Colocated ERA5  
 435 model reanalysis data were used as a secondary comparison to the radiosonde observations.

436 The nearly 1-year high-resolution MAGIC radiosonde dataset reveals the frequent presence of  
 437 ducting marked by a sharp refractivity gradient resulting from the large moisture lapse rate  
 438 across a strong temperature inversion layer. The PBLH increases by more than 1 km along the  
 439 transect from California to Hawaii while the magnitude of the refractivity gradient decreases by  
 440  $100 N\text{-units km}^{-1}$ . The zonal gradient of both variables illustrates the transition of the PBL from  
 441 shallow stratocumulus adjacent to the California coast to deeper trade-wind cumulus that are  
 442 prevalent near the Hawaiian Islands.

443 End-to-end simulation on all radiosonde and ERA5 refractivity profiles has been conducted to  
 444 estimate the systematic negative  $N$ -bias in GNSS RO observations. The ducting layer maintains

445 remarkably consistent thickness (110 m) along the transect with westward decreasing strength  
446 and increasing height. The ERA5 slightly underestimates both the height and strength of the  
447 ducting layer as well as the PBLH. A systematic negative refractivity bias ( $N$ -bias) below the  
448 ducting layer is observed throughout the transect, peaking ( $-5.42\%$ ) approximately 80 meters  
449 below the PBL height, and gradually decreasing towards the surface ( $-0.5\%$ ). The height of the  
450 peak  $N$ -bias and the PBLH show a highly positive correlation. The median difference between  
451 the two is about 80 meters in the radiosonde but increasing to about 120 meters in the colocated  
452 ERA5 data.

453 MAGIC radiosondes indicate larger values of both ducting strength ( $\Delta N$ ) and thickness ( $\Delta h$ ) than  
454 ERA5 in the western half of the transect. The opposite is true in the eastern portion of the  
455 domain, and is likely associated with the transition of the cloud layer from open-cell cumulus in  
456 the west to stratocumulus and stratus in the east (Bretherton et al., 2019; Wood et al., 2011). The  
457 ERA5 systematically underestimates the average ducting layer gradient ( $\Delta N/\Delta h$ ) comparing to  
458 the radiosondes. The largest  $N$ -bias is found over the region with strongest ducting and largest  
459 sharpness parameter. It is worth noting that the PBL over the western portion of the transect near  
460 Hawaii frequently shows two major gradient layers (a mixing layer at  $\sim 1$  km and the trade-  
461 inversion at  $\sim 2$  km), with comparable  $N$ -gradients (e.g., Fig. 2). The much lower PBLH seen in  
462 ERA5 in this region is likely due, in part, to the decreasing number of model levels in ERA5 at  
463 higher altitude, which could lead to higher possibility of identifying the lower gradient layer as  
464 the PBLH. However, the impact of the vertical resolution on the performance of gradient method  
465 for PBLH detection has not been performed in this study and warrants more comprehensive  
466 study in the future.

476 **5 Data availability**

477 Data for the Marine Atmospheric Radiation Measurement (ARM) GCSS Pacific Cross Section  
478 Intercomparison (GPCI) Investigation of Clouds (MAGIC, Zhou et al., 2015) can be accessed  
479 through the U.S. Department of Energy's Office of Science  
480 <https://www.arm.gov/research/campaigns/amf2012magic>.

481 Data for the ECMWF Reanalysis version 5 (ERA5, Hersbach et al., 2020) can be accessed at  
482 <https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-v5>.

483 **6 Author contribution**

484 Author Thomas Winning is responsible for all original text and, data analysis and production of  
485 graphics. Author Kevin Nelson contributed by providing updated data processing code,  
486 colocation of ERA5 data with MAGIC observations and first and second round edits. Author  
487 Feiqin Xie is the academic advisor for the primary author and also provided draft edits and paper  
488 organization and writing guidance.

489

490 **7 Competing interests**

491 The authors declare no competing interests, see Acknowledgements for current affiliation.

492 **8 Acknowledgements**

493 The authors acknowledge funding support of earlier work from NASA grant (NNX15AQ17G).  
494 Authors T. Winning and K. Nelson were also partially supported by research assistantship from  
495 Coastal Marine System Science Program at Texas A&M University – Corpus Christi. The high-  
496 resolution ERA5 reanalysis data were acquired from ECMWF and the Climate Data Service  
497 (CDS). The MAGIC radiosonde data were provided by the Atmospheric Radiation Measurement  
498 program (ARM) Climate Research Facility sponsored by the U.S. Department of Energy (DOE).
