9
10 **Abstract.** In this study, high-resolution radiosondes from the MAGIC field campaign and ERA5
11 global reanalysis data are used to assess characteristics of the elevated ducting layer along a
12 transect over the northeastern Pacific Ocean from Los Angeles, California to Honolulu, Hawaii.
13 The planetary boundary layer (PBL) height (PBLH) increases as the strength of the refractivity
14 gradient decreases westward along the transect. The thickness of the prevailing ducting layer
15 remains remarkably consistent (~110 m) in the radiosonde data. On the other hand, the ERA5
16 reanalysis generally resolves the ducting features well, but underestimates the ducting height and
17 strength, especially over the trade cumulus region near Hawaii. A simple two-step end-to-end
18 simulation is used to evaluate the impact of the elevated ducting layer on RO refractivity retrievals.
19 A systematic negative refractivity bias (*N*-bias) below the ducting layer is observed throughout the
20 transect, peaking (−5.42%) slightly below the PBLH, and gradually decreasing towards the surface
21 (−0.5%). The *N*-bias shows strong positive correlation with the ducting strength. The ERA5 data
22 underestimate the *N*-bias with the magnitude of the underestimation increasing westward along
23 the transect.

30 **1 Introduction**

31 The troposphere, where most weather occurs, consists of two main layers: the planetary boundary
32 layer (PBL) and the free atmosphere (FA) (Garratt, 1994). The PBL characteristics change
33 frequently on both spatial and temporal scales and the PBL height (PBLH) can impact the
34 exchange of heat, momentum, and particulate matter with the FA, making it a critical factor in
35 global energy balances and water cycling (Stull 1988; Ramanathan et al. 1989; Klein and
36 Hartmann 1993). Regular PBL observations are mainly limited to in-situ measurements from
37 surface stations and radiosondes. However, spatially and temporally dense in-situ PBL
38 observations are typically only available from field campaigns such as the Boundary Layer
39 Experiment 1996 (BLX96, Stull et al. 1997), the Variability of the American Monsoon Systems
40 (VAMOS) Ocean-Cloud-Atmosphere-Land Study Regional Experiment (VOCALS-REx, Wood
41 et al. 2011), and the Marine Atmospheric Radiation Measurement (ARM) Global Energy and
42 Water Experiment (GEWEX) Cloud System Studies (GCSS) Pacific Cross Section
43 Intercomparison (GPCI) Investigation of Clouds (MAGIC, Zhou et al. 2015). Satellite
44 observations of the PBL are also limited due to signal attenuation of the conventional infrared
45 sounder in the lower troposphere and the low vertical resolution of microwave sounding
46 instruments. Additionally, while the depth of the PBLH can vary from a couple hundred meters to
47 a few kilometers (Ao et al. 2012; von Engeln and Teixeira 2013), the transition layer from the PBL
48 to the FA is typically on the order of tens to hundreds of meters thick (Maddy and Barnet 2008),
49 rendering PBL sensing from the low vertical resolution passive infrared and microwave sounders
50 ineffective.

51 On the other hand, Global Navigation Satellite System (GNSS) radio occultation (RO) provides
52 global atmospheric soundings with a vertical resolution of approximately 100 m in the lower
53 troposphere under all weather conditions (Kursinski et al., 1997, 2000; Gorbunov et al., 2004).
54 Some of the recent major GNSS RO missions are the Formosat-3/Constellation Observing System
55 for Meteorology, Ionosphere, and Climate (COSMIC), later referred to as COSMIC-1 (Anthes et
56 al. 2008), and its follow-on mission COSMIC-2 (Schreiner et al. 2020). Numerous studies have
57 documented the high value of GNSS RO for profiling the PBL and determining the PBLH (Ao et
58 al. 2008; Xie et al. 2008; Basha and Ratnam 2009; Guo et al. 2011; Ao et al. 2012; Ho et al. 2015;
59 Winning et al. 2017; Nelson et al. 2021).

60 The advancement of the GNSS RO technique with open-loop tracking (Ao et al., 2003; Beyerle et
61 al., 2003; Sokolovskiy et al., 2006) along with the implementation of radio-holographic retrieval
62 algorithms (Gorbunov, 2002; Jensen et al., 2003; Jensen et al., 2004) have led to much-improved
63 PBL sounding quality. However, probing the marine PBL remains challenging, as systematic
64 negative biases are frequently seen in RO refractivity retrievals (Xie et al. 2010; Feng et al. 2020).
65 One major cause of refractivity bias (hereafter *N*-bias) is the RO retrieval error due to elevated
66 atmospheric ducting often seen near the PBLH (Sokolovskiy 2003; Ao et al. 2003; Xie et al., 2006;
67 Ao et al., 2007). This elevated ducting is found primarily over the subtropical eastern oceans (von
68 Englen et al., 2003; Lopez, 2009; Feng et al., 2020), and the horizontal extent of ducting in these
69 regions can be on the order of thousands of kilometers (Xie et al. 2010; Winning et al. 2017). In
70 the presence of ducting, the vertical refractivity gradient exceeds the critical refraction threshold
71 for L-band frequencies (i.e., $dN/dz \leq -157$ N-units km^{-1}). The steep negative refractivity gradient
72 is often observed in the vicinity of the PBLH, which is typically caused by an atmospheric
73 temperature inversion, a sharp decrease in moisture, or a combination of both. When ducting is
74 present, the Abel inversion (e.g., Fjeldbo et al., 1971) in the standard RO retrieval process
75 encounters a non-unique inversion problem due to a singularity in the bending angle, resulting in
76 large, systematic underestimation of refractivity (*N*) below the ducting layer (Ao et al., 2003;
77 Sokolovskiy, 2003; Xie et al. 2006). The large uncertainty in RO refractivity coupled with the
78 singularity in bending angle hinders assimilation of RO observations into numerical weather
79 models, resulting in the rejection of a significant percentage of RO measurements inside the PBL
80 (Healy, 2001).

81 To comprehensively assess the potential impact of ducting on GNSS RO retrievals, we begin by
82 constructing a detailed ground truth of PBL ducting statistics. This is derived from an extensive
83 set of high-resolution radiosonde data over the northeastern Pacific Ocean, a region known for
84 prevailing ducting conditions. Subsequently, we conduct a simulation study using the radiosonde
85 data to evaluate the *N*-biases caused by varying ducting characteristics. Section 2 provides details
86 of the two data sets used for this study: high-resolution radiosondes over the northeastern Pacific
87 Ocean and the colocated ECMWF Reanalysis version 5 (ERA5, Hersbach et al. 2020) profiles.
88 Additionally, we discuss the collocation criteria and the detection method for ducting layer and the
89 corresponding PBLH. Section 3 presents the ducting statistics for key variables, such as ducting
90 height, PBLH, minimum refractivity gradient, and sharpness parameter. The characteristics of

91 ducting including the thickness and strength along the cross-section are also shown. Furthermore,
92 we evaluate the ducting-induced N -bias in GNSS RO refractivity retrievals by carrying out a two-
93 step end-to-end simulation. Section 4 summarizes the findings and discusses the direction of future
94 research.

95 **2 Data and methods**

96 **2.1 MAGIC radiosonde and colocated ERA5 data**

97 A collection of high-resolution radiosondes from the Marine Atmospheric Radiation Measurement
98 (ARM) GCSS Pacific Cross Section Intercomparison (GPCI) Investigation of Clouds (MAGIC)
99 are utilized as the primary data set in this analysis (Zhou et al. 2015; Lewis 2016). The MAGIC
100 field campaign took place from 26 September 2012 to 2 October 2013 as part of the U.S
101 Department of Energy ARM Program Mobile Facility 2 (AMF2) aboard the Horizon Lines
102 container ship, *Spirit*, which completed 20 round trip passes between Los Angeles, California and
103 Honolulu, Hawaii during the yearlong data collection period (Painemal et al., 2015; Zhou, 2015).
104 During each transit, radiosondes were launched at 6-hour intervals from the beginning of the
105 program through the end of June 2013; the observation frequency increased to every 3 hours from
106 July 2013 through the end of the campaign (Zhou et al., 2015). A total of 583 MAGIC radiosonde
107 profiles were collected during the field campaign (Zhou et al., 2015), all with a vertical sampling
108 frequency of 0.5 Hz (2 seconds), which provides an average vertical resolution of ~ 8 m below 3
109 km, but varies due to local vertical motion.

110 Use of this data set serves multiple benefits. First, the northeast Pacific transitions from a shallow
111 stratocumulus-topped PBL to a deeper, trade-cumulus boundary layer regime along the GPCI
112 transect shown in Figure 1 (Garratt, 1994). Second, the large number of observations over a 12-
113 month time frame provides high temporal (diurnal- and seasonal-scale) and spatial profiling of the
114 PBL along the GPCI transect (Fig. 1). Finally, ducting is prevalent throughout the domain over
115 which the observations were captured creating an opportunity to perform an analysis over a natural
116 cross-section of X (zonal) and Z (vertical) dimensions.

117
118 **Figure 1: Location of radiosonde observations from the MAGIC field campaign October 2012–September 2013.**
119

120 The radiosonde profiles are colocated with ERA5 model profiles for this analysis. The ERA5 data
121 have a horizontal resolution of $0.25^\circ \times 0.25^\circ$, 137 non-equidistant vertical model levels from the
122 surface to 0.01 hPa, and 1-hour temporal resolution. The model level density decreases with height:
123 on average, there are 19 model levels below 1 km (10 –100 m resolution), which reduces to 8
124 levels between 1 and 2 km (100 – 160 m resolution), and further reduces to 5 levels between 2 and
125 3 km (160-200 m resolution). Each MAGIC radiosonde profile was colocated with the nearest
126 ERA5 grid point that is within 1.5 hours of the closest 3-hourly model profile.

127 **2.2 PBLH detection with the minimum gradient method**

128 At GNSS L-band frequencies, the atmospheric refractivity (N in N-units) is derived from the
129 refractive index n , where $N = (n - 1) \times 10^6$ and, in the neutral atmosphere (Kursinski et al., 1997),
130 is a function of the atmospheric pressure (P in mb), temperature (T in K), and partial pressure of
131 water vapor (P_w in mb) as seen in Eq. (1) from Smith and Weintraub (1953).

$$132 \quad N = 77.6 \frac{P}{T} + 3.73 \times 10^5 \frac{P_w}{T^2}, \quad (1)$$

133 Over the subtropical eastern oceans, a sharp decrease in moisture is often associated with a strong
134 temperature inversion marking a clear transition from the PBL to the FA. The distinct decrease in
135 moisture and the temperature inversion leads to a sharp negative refractivity gradient which can
136 be precisely detected from GNSS RO. Numerous studies have implemented the simple gradient
137 method to detect the PBLH, i.e., the height of the minimum refractivity gradient (Xie et al., 2006;

138 Seidel et al., 2010; Ao et al., 2012). To assess the robustness of the PBLH detection with the
139 gradient method, Ao et al. (2012) introduced the sharpness parameter (\tilde{N}') to measure the relative
140 magnitude of the minimum gradient, which is defined as the ratio of the minimum vertical
141 refractivity gradient (N'_{min}) to the root mean square (N'_{RMS}) of the refractivity gradient profile from
142 surface to 5 km as follows.

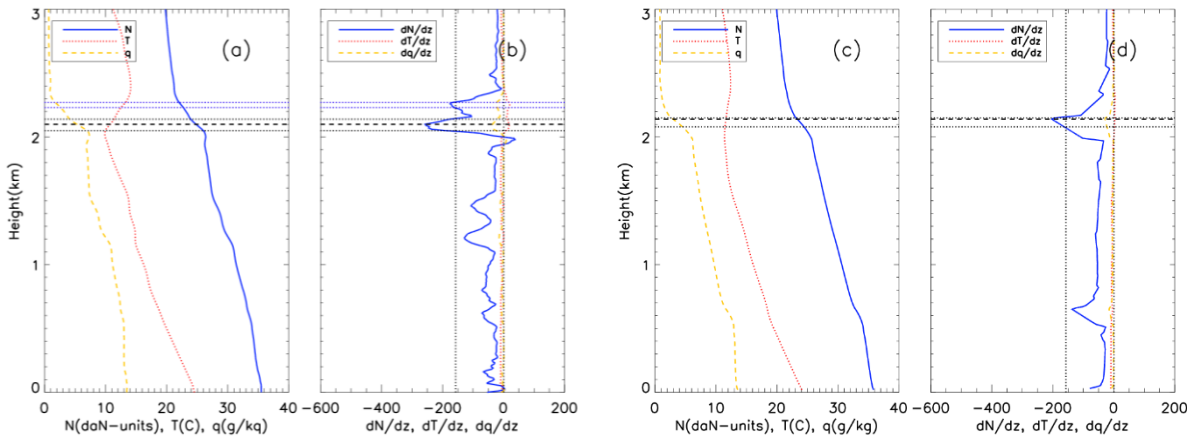

$$143 \quad \tilde{N}' \equiv - \frac{N'_{min}}{N'_{RMS}}, \quad (2)$$

144 In this study, the MAGIC radiosonde refractivity profiles were first interpolated to a uniform 10
145 m vertical grid and then smoothed by a 100 m boxcar window to reduce the noise in the gradient
146 profile resulting from the high sampling rate. Moreover, the 100 m smoothed radiosonde will be
147 more consistent with the vertical resolution of GNSS RO measurements (e.g., Gorbunov et al.,
148 2004). Colocated ERA5 data were also vertically interpolated to the same 10 m grid but not
149 smoothed as these data do not contain the inherent noise as the radiosonde observations. In the
150 case of both data sets, quadratic interpolation is used to translate the refractivity profiles from their
151 native height values to a uniform height. Finally, as the elevated ducting layer is the focus of this
152 study, the lowest 0.3 km above mean-sea-level of the N -profile are excluded (e.g., Xie et al., 2012).
153 Subsequently, the height of the minimum refractivity gradient (within 0.3 km and 5 km) will be
154 identified as the PBLH.

155 **2.3 Ducting layers**

156 The refractivity gradient profile is calculated by differentiating the 10 m interpolated refractivity
157 profile with respect to height. When the vertical refractivity gradient is less than the critical
158 refraction threshold for radio waves ($dN/dz < -157.0$ N -units km^{-1}), ducting occurs (Sokolovskiy,
159 2003). A ducting layer is identified as any interval of continuous points with a vertical refractivity
160 gradient equal to or less than the critical refraction threshold. Instances of multiple ducting layers
161 occurring within a profile are present for both the MAGIC (31.5%) and ERA5 (6.7%) data sets. In
162 this study, we only recognize one dominant “ducting layer” in each profile where the minimum
163 vertical gradient is located. The ducting layer thickness (Δh) is defined as the interval between the
164 top and bottom of the ducting layer where the refractivity gradients reach critical refraction.
165 Similarly, the strength of each ducting layer (ΔN) is defined as the refractivity difference between

166 the bottom and top of the ducting layer. The ducting layer height is defined as the height of the top
 167 of the ducting layer (Ao, 2007), which is generally slightly above the PBLH.
 168 Figure 2 shows vertical profiles of refractivity (N in daN-units), temperature (T in $^{\circ}\text{C}$), and specific
 169 humidity (q in g/kg) along with their respective vertical gradients (dN/dz , dT/dz , and dq/dz) from
 170 a representative MAGIC radiosonde (Fig. 2a,b) case located at $(23.69^{\circ}, -150.02^{\circ})$, and its
 171 colocated ERA5 (Fig. 2c,d) profile at $(23.75^{\circ}, -150.00^{\circ})$. The PBLH of the radiosonde (2.10 km)
 172 is almost identical to the colocated ERA5 (2.14 km) and the “dominant” ducting layer near the
 173 PBLH demonstrates similar thickness. However, a second, weaker ducting layer seen in the
 174 radiosonde above the PBLH was not captured by the ERA5. It should be noted that the weak “saw
 175 tooth-like” gradients seen above the minimum in the ERA5 refractivity gradient (Fig. 2d) are a
 176 result of the vertical derivative being calculated from the interpolated ERA5 refractivity profile.
 177 When interpolating the relatively coarse vertical resolution ERA5 profile (up to 200 m in the
 178 lowest 3 km) into 10 m vertical sampling, the higher-order interpolation could lead to fine structure
 179 in the first order derivative. However, these minor gradients only marginally affect the estimates
 180 of minimum gradient and associated heights from ERA5 and is most often overshadowed by the
 181 PBLH gradient.

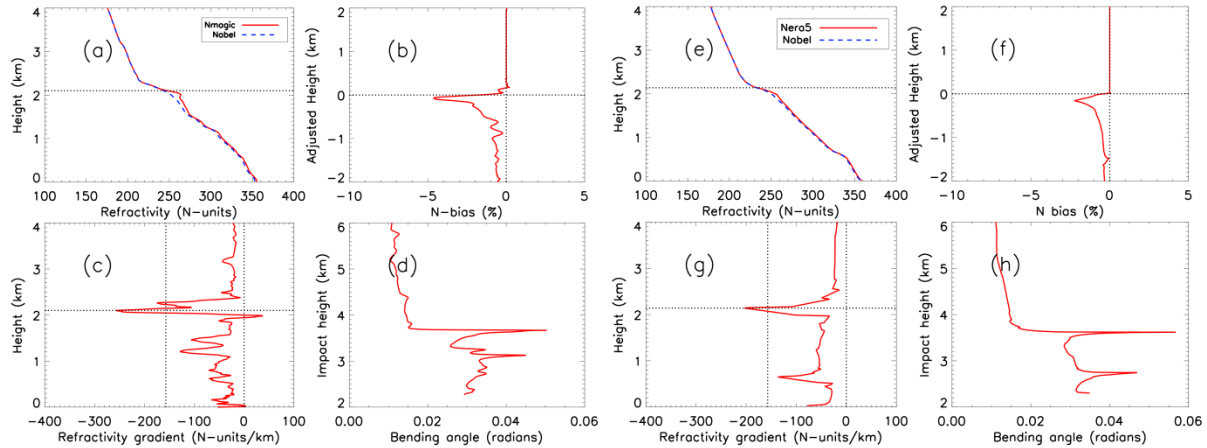

182
 183 **Figure 2: Vertical profiles of refractivity (N in daN-units, solid blue), temperature (T in $^{\circ}\text{C}$, dotted red) and specific humidity**
 184 **(q in g kg^{-1} , dashed gold) for (a) radiosonde at $(23.69^{\circ}, -150.02^{\circ})$ launched at 2013-10-02, 05:30 UTC, and (c) colocated ERA5**
 185 **at $(23.75^{\circ}, -150.00^{\circ})$; and associated gradient profiles for radiosonde (b) and ERA5 (d). The horizontal dashed line highlights**
 186 **the height of the minimum gradient, i.e., PBLH. The paired horizontal dotted lines represent the bottom and top of any**
 187 **ducting layers.**

188 2.4 Evaluation of GNSS RO N -bias resulting from ducting

189 In order to estimate the systematic negative N -bias in GNSS RO observations in the presence of
 190 ducting, we use an end-to-end simulation on the radiosonde and ERA5 refractivity profiles. The

191 simulation consists of a two-step process adapted from Xie et al. (2006). The first step is to
192 simulate the 1-dimensional GNSS RO bending angle as a function of impact parameter (i.e., the
193 product of refractive index and the radius of the Earth's curvature) by forward Abel integration of
194 an input refractivity profile assuming a spherically symmetric atmosphere (Fjeldbo and Eshleman,
195 1968; Eshleman, 1973; Sokolovskiy, 2001). The second step is to simulate the spaceborne GNSS
196 RO refractivity retrieval by applying the Abel inversion on the simulated bending angle from step
197 one. In the absence of ducting, the impact parameter increases monotonically with height, allowing
198 a unique solution to the inverse Abel retrieval that is the same as the original refractivity profile
199 input. However, in the presence of an elevated ducting layer, the Abel retrieval systematically
200 underestimates the refractivity profile due to the non-unique Abel inversion problem resulting
201 from the singularity in bending angle across the ducting layer (Sokolovskiy 2003; Xie et al., 2006).
202 It should be noted that after the 100 m vertical smoothing on radiosonde (no smoothing is
203 performed on ERA5) profiles as described in section 2.2, an additional 50 m vertical smoothing
204 has been applied to the simulated bending angle profiles of both radiosonde and ERA5 data sets
205 to alleviate the challenge of integration through the very sharp bending angle resulting from
206 ducting in the inverse Abel integration procedure (Feng et al., 2020).

207 Figure 3 shows the end-to-end simulation results for the same radiosonde (a–d) and the colocated
208 ERA5 (e–h) cases from Fig. 2. Figures 3a and 3e show refractivity profiles from the radiosonde
209 (N_{MAGIC}) and the colocated ERA5 (N_{ERA5}) data as well as their corresponding Abel refractivity
210 retrievals (N_{Abel}). The refractivity gradients are shown in Figures 3c and 3g. The derived PBLH is
211 marked by a horizontal dotted line in the refractivity/height space. The peak bending angles in
212 Figures 3d and 3h are consistent with the corresponding sharp refractivity gradient. Figure 3b
213 shows the fractional N -bias between the simulated Abel retrieved RO refractivity profile and the
214 radiosonde, whereas Figure 3f shows the same for the ERA5 profile. Considering the significant
215 spatial and temporal variations of ducting height along the transect, each N -bias profile is displayed
216 as a function of an adjusted height, which is the height minus the corresponding PBLH for the
217 purposes of profile intercomparison. For example, the zero-adjusted height refers to the PBLH for
218 each individual profile. The systematic negative N -bias is shown below the ducting layer marked
219 by the PBLH in both cases, with the biases decreasing at lower altitude, the largest magnitude bias
220 (-5% for radiosonde; -2.5% for ERA5) close to the ducting height and a minimum magnitude
221 approaching zero near the surface.

222
 223 **Figure 3: End-to-end simulation results for a MAGIC radiosonde launched at 0530 UTC on 20131002 showing: (a) N_{MAGIC}**
 224 **(solid red) and N_{Abel} (blue dashed) from surface to 4 km; (b) PBLH adjusted N -bias; (c) vertical refractivity gradient and**
 225 **(d) bending angle vs. impact parameter. Panels e-h show end-to-end simulation results for the collocated ERA5 profile.**

226 **3 Analysis**

227 Quality control for radiosonde (and collocated ERA5) profiles was based on five key criteria. First,
 228 a total of 19 radiosonde and 24 ERA5 profiles near the southern California coast were removed
 229 due to their positions east of -120° or anomalously high PBL (PBLH > 3.0 km) with no distinct
 230 minimum gradient. The remaining profiles in the easternmost portion of the domain were too few
 231 in number to calculate meaningful statistics. Second, any profile lacking critical refraction (i.e.
 232 $dN/dz < -157$ N-units km^{-1}) points was excluded from the analysis which resulted in the removal
 233 of 47 radiosonde and 176 ERA5 profiles. Third, an anomalously noisy bending angle profile could
 234 result in errors in Abel refractivity retrieval and cause positive N -bias. Therefore, the profiles with
 235 N -bias greater than $+0.5\%$ are excluded resulting in the removal of 61 MAGIC profiles and 16
 236 ERA5 profiles. Fourth, the profiles with only surface ducting, i.e., below 300 m threshold, are
 237 discarded. Finally, 25 radiosonde profiles and 2 ERA5 profiles were removed due to the Abel
 238 retrieval failure. After implementing all quality control measures, the number of radiosonde and
 239 ERA5 profiles used for the N -bias analysis is reduced to 396 and 319 profiles, respectively across
 240 the MAGIC transect.

241 **3.1 PBL analysis**

242 To evaluate the ducting properties along the transect from the coast of southern California to
 243 Hawaii, we group the MAGIC radiosonde and the collocated ERA5 profiles into eight 5° longitude

244 bins between -160.0° and -120.0° , which allows for the assessment of the spatial variation of the
245 PBL, ducting layer, and the associated properties along the transect to be easily illustrated. Figure
246 4 shows the median value of PBLH (a), minimum gradient (b) and sharpness parameter (c) along
247 the transect. The median-absolute-deviation (MAD) for each parameter is also shown.
248 In Figure 4a, the MAGIC radiosondes (rds) clearly show a gradual increase of the PBLH along the
249 transect from the shallow stratocumulus-topped PBL (~ 800 m) near the southern California coast
250 westward to the much deeper trade-cumulus regime (~ 1.8 km) near Hawaii. A similar structure is
251 seen in the colocated ERA5 data but with an average low bias of 165 m below the radiosonde.
252 Additionally, a nearly 800 m ERA5 underestimation in PBLH over the two westernmost bins near
253 Hawaii is also seen, this is consistent with what is found over the equivalent trade cumulus region
254 of the subtropical southeast Pacific Ocean (Xie et al., 2012). Such a discrepancy could be due to
255 the sensitivity of the gradient method to the vertical resolution of the data. Over the western
256 segment of the transect (near Hawaii), two major gradient layers (one at ~ 1 km and the other at ~ 2
257 km) with comparable refractivity gradients are often observed (e.g., Fig. 2) in the ERA5 data. The
258 gradient layer near 2 km is well-known as the trade-wind inversion (Riehl, 1979; Ao et al., 2012;
259 Xie et al., 2012), while the lower-level gradient layer at ~ 1 km, is generally called a mixing layer
260 (Xie et al., 2006). Due to the differences in vertical sampling noted in Section 2.1, the ERA5 data
261 are more likely to resolve the sharp gradient structure below 1 km than the one at higher altitude.
262 This could result in resolving the mixing layer (below 1 km) with the sharpest refractivity gradient,
263 instead of the trade-wind inversion near 2 km in the ERA5 data. Note that the larger median
264 absolute deviation for the westernmost bins compared to the rest of the transect illustrates the
265 existence of greater PBLH variability closer to the trade-cumulus boundary layer regime. The
266 westward decreasing magnitude of the minimum refractivity gradient (Fig. 4b) and sharpness
267 parameter (Fig. 4c) indicates the westward weakening of moisture lapse rate and/or temperature
268 inversion across the PBL top, which is consistent with the decreasing synoptic-scale subsidence
269 from the California coast to Hawaii (Riehl, 1979).

270
 271 **Figure 4: Zonal transect of 5° binned MAGIC and ERA5 PBLH (a), minimum refractivity gradient and**
 272 **sharpness parameter (c) for MAGIC (median in red circle and dashed line, MAD in red dotted error bars) and ERA5**
 273 **(median in blue diamond and dot-dashed line, MAD in blue dotted error bars).**
 274

275 It is also notable that the ERA5 systematically underestimates not only the PBLH but also the
 276 magnitude of the minimum gradient across the entire transect. This can also be seen in the
 277 sharpness parameter west of -132.5° . This discrepancy could be partially attributed to the decrease
 278 in vertical sampling in ERA5 profiles as compared to the radiosondes, the result of which leads to
 279 a weaker PBL refractivity gradient and coincides with an increasing PBLH. Therefore, the
 280 underestimation of the ERA5 minimum refractivity gradient increases in magnitude from east to
 281 west and becomes most prominent near Hawaii where the PBLH reaches the maximum over the
 282 region.

283 3.2 Ducting characteristics

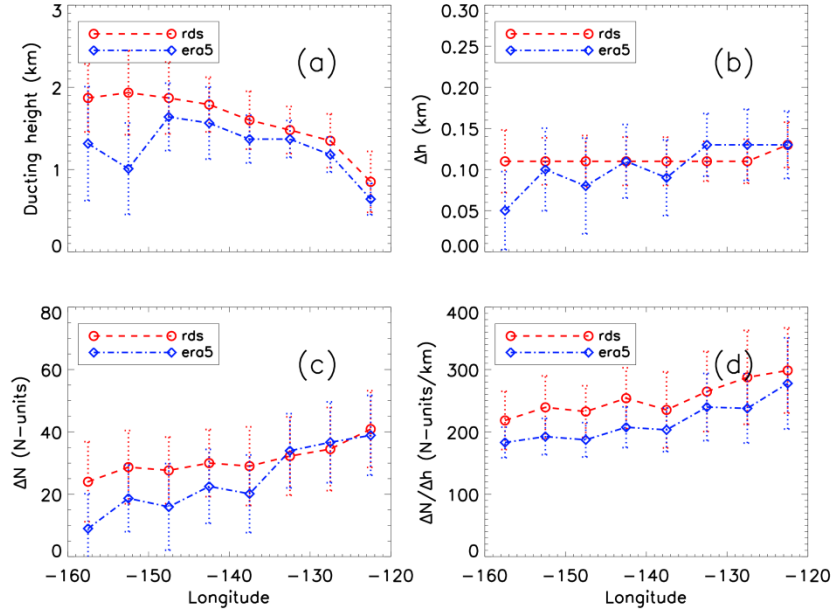

284 As introduced in Sect. 2.3, the key characteristics of the ducting layer along the transect will be
 285 investigated. These characteristics include the ducting layer height, ducting layer thickness (Δh),
 286 and ducting strength (ΔN), as well as the average refractivity gradient within the ducting layer
 287 ($\Delta N/\Delta h$). The ducting layer heights from both radiosondes and ERA5 show a westward increase
 288 along the transect, as seen in Figure 5a. Note again that the ERA5 shows a systematic $\sim 100\text{--}200$
 289 m low bias when compared to the radiosondes between -122.5° and -147.5° , with the difference

290 increasing to more than 500 m near Hawaii. The ducting layer thickness is the median height from
291 the bottom of the ducting layer to the top and is expressed in km (Fig. 5b). Ducting thickness (Δh)
292 for MAGIC shows a near constant value of 110 m across the entire transect with only a slight
293 increase to 130 m at -122.5° , consistent with Ao et al. (2003). Conversely, the ERA5 shows a
294 constant but slightly thicker ducting layer to the east of -137.5° and then a decreasing thickness to
295 the west of -137.5° (Fig. 5b). It should be noted that the estimated thicknesses of the ducting
296 layers, especially for ERA5, may be affected by the chosen interpolation method.

297 The ducting layer strength is the decrease in refractivity from the bottom of the ducting layer to
298 the top (Fig. 5c) and the ratio $\Delta N/\Delta h$ reflects the average gradient of the ducting layer (Fig. 5d).
299 The ducting strength (ΔN) for the radiosondes generally ranges from 25 N-units near Hawaii to 40
300 N-units near the coast of California. Both ΔN and $\Delta N/\Delta h$ show an overall westward decreasing
301 trend along the transect which is consistent with the decrease in magnitude of the refractivity
302 gradient (Fig. 4b). Note that MAGIC and ERA5 show similar ducting strength in the eastern part
303 of the region but diverge near -137.5° with ERA5 10 to 20 N-units weaker than the MAGIC
304 profiles. On the other hand, ERA5 shows a systematically lower average refractivity gradient
305 ($\Delta N/\Delta h$) than MAGIC throughout the transect, indicating the challenge in ERA5 to consistently
306 resolve the sharp vertical structure in refractivity, and likewise in temperature and moisture
307 profiles, across such a thin ducting layer. The problem becomes acutely clear near the trade
308 cumulus region.

309

310

311
 312 **Figure 5: Zonal transect of 5° binned median (a) ducting height, (b) ducting layer thickness (Δh), (c) ducting layer strength**
 313 **(ΔN), and (d) average ducting layer gradient $\Delta N/\Delta h$ for MAGIC (median in red circle and red-dashed line, MAD in red-**
 314 **dotted error bars) and ERA5 (median in blue diamond and dot-dashed line, MAD in blue-dotted error bars).**

315
 316 Figure 6 shows individual ducting layer thicknesses as a function of ducting layer strength. The
 317 shape and color of each data point is used to identify its respective longitude bin. The relationship
 318 between Δh and ΔN is not longitude-dependent for either data set, but a linear trend is evident for
 319 thinner ducting layers ($\Delta h < 0.1$ km) with weaker ducting strength ($\Delta N < \sim 25$ N-units). However,
 320 for the ducting layers thicker than 0.1 km, such a trend becomes less identifiable, and the ducting
 321 strength ΔN begins to show more variability toward larger values.

322

323
 324 **Figure 6: Comparison of individual profiles' ducting strength (ΔN) vs. ducting thickness (Δh) for MAGIC (a) and ERA5**
 325 **(b). The shape and color of each character represents the location of the 5° longitude bin of each observation.**

326 3.3 Ducting-induced GNSS RO N -bias statistics

327 To estimate the systematic negative N -bias in GNSS RO observations due to ducting, we have
 328 applied the end-to-end simulation described in Sect. 2.4 to all radiosonde and ERA5 refractivity
 329 profiles with at least one elevated ducting layer detected. The N -bias along the transect as well as
 330 its relationship to the ducting properties are presented below.

331 3.3.1 Assessing ducting-induced N -bias

332 Figure 7 shows a composite of both MAGIC (396 profiles) and ERA5 (319 profiles) N -bias profiles
 333 which have been displayed as a function of their zero-adjusted height. The median N -bias and
 334 MAD are also shown. The systematic negative N -bias peaks at approximately 100 m below the
 335 PBLH and decreases at lower relative altitudes. The peak median value of the N -bias for
 336 radiosondes is -5.42% (MAD, 2.92%), nearly twice the ERA5 value of -2.96% (MAD, 2.59%),
 337 indicating the significant underestimation of ducting strength in ERA5 data. However, the MAD
 338 of the radiosonde and ERA5 data are within 0.33% of each other, indicating that ERA5 data
 339 successfully capture the variations of ducting features seen in the radiosondes. It is worth noting
 340 that many radiosonde profiles show small negative N -biases above the PBLH (i.e., positive zero-

341 adjusted height), which is the result of a secondary ducting layer above the major ducting layer
 342 near the PBLH. Few ERA5 profiles show the presence of the secondary ducting layer above PBLH.
 343

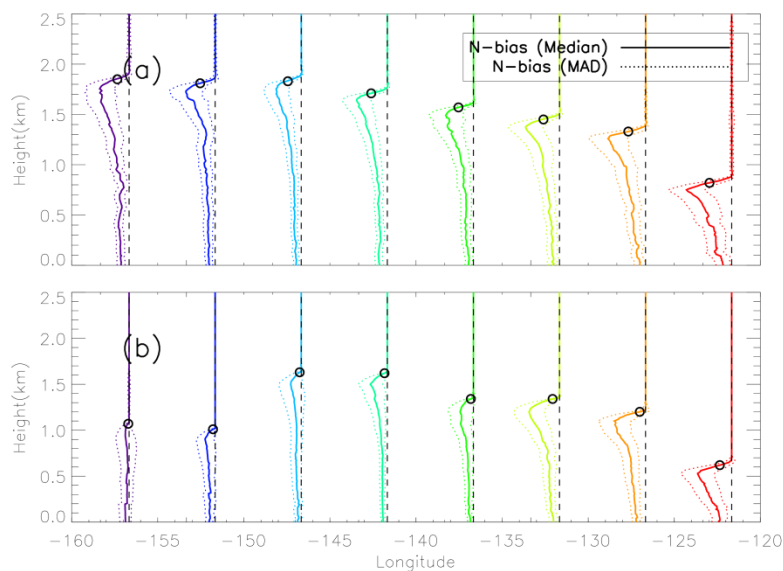

344
 345 **Figure 7: Fractional refractivity difference (N -bias) between the simulated Abel-retrieved refractivity profile and the**
 346 **original observed refractivity profile for all individual observations (dotted gray): (a) MAGIC radiosondes (396 total**
 347 **profiles) and (b) ERA5 (319 total profiles) with population median (solid red) \pm MAD (dashed red). Note the zero value in**
 348 **the adjusted height refers to the detected PBLH for each individual N -bias profile.**

349 3.3.2 Zonal variation of the N -bias along the transect

350 To illustrate the large variation in the N -bias vertical structure resulting from the spatial variations
 351 of ducting height and strength, Figure 8 shows the median N -bias profiles (\pm MAD) for each 5°
 352 bin, replacing the zero adjusted height with the median PBLH for each bin. The zonal radiosonde
 353 composite (Fig. 8a) illustrates the westward transition of the median N -bias profiles from the
 354 largest peak N -bias at ~ 0.8 km near the coast of Los Angeles, California, to a much-reduced peak
 355 N -bias but higher altitude of ~ 1.8 km at Honolulu, Hawaii. Table 1 lists detailed statistics of the
 356 peak N -bias values at each bin for both radiosonde and ERA5 data seen in Fig. 8. Although the
 357 vertical structure of the N -bias profiles along the transect are consistent as seen in Fig. 7, significant
 358 changes of the N -bias magnitude and its peak height along the transect are seen.

359 The maximum peak N -bias (-7.86%) in the radiosonde data is located at the easternmost of the
 360 transect near California (-122.5°), whereas the minimum peak N -bias (-4.37%) is located near the
 361 center of the transect (-147.5°). Similarly, the ERA5 also show the maximum peak N -bias
 362 (-5.92%) near California (-122.5°). However, the minimum peak N -bias (-0.77%) is found near

363 Hawaii (-157.5°). Overall, the N -bias values for the ERA5 data set are less than the N -bias values
 364 calculated from the radiosonde data set for each longitude bin. However, a noticeable difference
 365 exists between the ERA5 and radiosonde profiles for the two westernmost longitude bins (-157.5°
 366 and -152.5°) where the ERA5 reveals a much lower and weaker N -bias than the MAGIC data.
 367 The PBLH is above the height of the peak N -bias for both data sets. The MAGIC data show a
 368 maximum difference of 100 m (-157.5°) and a minimum difference of ~ 70 m (-142.5°) while the
 369 ERA5 PBLH shows greater values for maximum difference (140 m at -132.5°) and minimum
 370 difference (60 m at -157.5°).

371
 372 **Figure 8: Median N -bias (solid) \pm MAD (dotted) N -bias along the north Pacific transect for MAGIC radiosondes (a) and**
 373 **ERA5 (b). Open circles represent the median PBLH for each 5° bin. Vertical dashed line represents the location of each 5°**
 374 **grid bin. See Table 1 for corresponding values of median and M.A.D. peak N -bias.**
 375
 376

377 **Table 1: Peak values of median N -bias and corresponding MAD (%) values for MAGIC radiosondes (RDS) and ERA5 for**
 378 **each 5° bin seen in Figure 8.**

Longitude	Peak N -bias (%)			
	RDS median	RDS MAD	ERA5 median	ERA5 MAD
-157.5°	-5.12	± 2.61	-0.77	± 1.73
-152.5°	-5.10	± 2.97	-1.76	± 1.61
-147.5°	-4.37	± 2.14	-1.83	± 2.10
-142.5°	-5.36	± 2.53	-2.95	± 2.17
-137.5°	-4.82	± 2.96	-2.31	± 2.14
-132.5°	-5.90	± 3.03	-5.31	± 2.68
-127.5°	-6.55	± 3.40	-5.45	± 2.88
-122.5°	-7.86	± 3.15	-5.92	± 3.04

379
 380

381 Figure 9 further illustrates the peak N -bias, median PBL N -bias (0.3 km to PBLH), and the near
382 surface N -bias (at 0.3 km) at each bin along the transect. Note the median PBL N -bias refers to the
383 median value from the near-surface (0.3 km) to the PBLH. Contrary to the general trend of
384 westward decrease in magnitude of the minimum refractivity gradient (Fig. 4b) and ducting
385 strength (Fig. 5c), the radiosonde peak N -bias (median: -8.10% , MAD: 3.26%) occurs near
386 California (-122.5°) and the minimum (median: -4.85% , MAD: 2.18%) occurs over the transition
387 region (-147.5°). There is also a slight increase in peak N -bias to a secondary maximum (median:
388 -6.11% , MAD: 2.85%) near Hawaii (-157.5°). The median PBL N -bias and the near surface N -
389 bias also show a similar pattern. However, the median N -bias demonstrates a sharp decrease in the
390 eastern half of the domain from -5.25% (MAD: 2.71%) at -122.5° to -1.71% (MAD: 1.26%) at
391 -137.5° , and then remains relatively constant over the western half of the domain. Similarly, the
392 near surface N -bias reaches a maximum magnitude of -3.54% (MAD: 2.11%), sharply decreases
393 to -1.06% (MAD: 0.85%) at -137.5° , and then remains relatively constant over the western half
394 of the domain. Note that normalizing each N -bias profile to the PBLH preserves the magnitude of
395 the N -bias with various heights. Therefore, the relatively large, normalized N -biases observed near
396 Hawaii indicates more persistent ducting over the trade-cumulus boundary layer regime compared
397 to the transition region in the middle of the transect at -147.5° (Fig. 8a).

398 On the other hand, the ERA5 data show a westward decrease of all three N -biases, systematically
399 underestimating all three as compared to the radiosondes. This is expected as the decrease of ERA5
400 vertical resolution at higher altitude leads to a weaker PBL N -gradient observation (Fig. 4b), and
401 thus weaker ducting and a smaller ducting-induced N -bias. Such underestimation of the N -bias in
402 the ERA5 reanalysis minimizes near California where the PBLH is lowest but becomes more
403 severe westward with an increase in height, reaching a maximum magnitude N -bias difference
404 near Hawaii. In this case, the peak N -bias is merely -0.71% (MAD: 1.80%) as compared to -6.23%
405 (MAD: 2.98%) at -122.5° (Fig. 9a). The large difference seen in the N -bias along the transect
406 strongly indicates the challenges of the ERA5 data to resolve the sharp gradient across the ducting
407 layer, resulting in a large variation in PBLH of the ERA5 data in the western segment of the region.
408 The increasing difference between the radiosonde and ERA5 data from east to west is most
409 pronounced in the peak N -bias cross-section (Fig. 9a) but is also evident in both the median N -bias
410 (Fig. 9b) as well as the near surface N -bias (Fig. 9c).

411
 412 **Figure 9: Zonal transect of 5° binned (a) peak N -bias, (b) median PBL N -bias (0.3 km to PBLH), and (c) near surface N -**
 413 **bias at 0.3 km for MAGIC (median in red circle and red-dashed line, MAD in red-dotted error bar) and ERA5 (median in**
 414 **blue diamond and dot-dashed line, MAD in blue-dotted error bar)**

415 **4 Summary and Conclusions**

416 In this study, radiosonde profiles from the MAGIC field campaign have been analyzed to
 417 investigate ducting characteristics and the induced systematic refractivity biases in GNSS RO
 418 retrievals over the Northeastern Pacific Ocean between Hawaii and California. Colocated ERA5
 419 model reanalysis data were used as a secondary comparison to the radiosonde observations.

420 The nearly 1-year high-resolution MAGIC radiosonde data set reveals the frequent presence of
 421 ducting marked by a sharp refractivity gradient resulting from the large moisture lapse rate across
 422 a strong temperature inversion layer. The PBLH increases by more than 1 km along the transect
 423 from California to Hawaii, while the magnitude of the refractivity gradient decreases by 100 N-
 424 units km^{-1} . The zonal gradient of both variables illustrates the transition of the PBL from shallow
 425 stratocumulus adjacent to the California coast to deeper trade-wind cumulus that are prevalent near
 426 the Hawaiian Islands.

427 End-to-end simulations on all radiosonde and ERA5 refractivity profiles have been conducted to
 428 estimate the systematic negative N -bias in GNSS RO observations. The ducting layer maintains
 429 remarkably consistent thickness (~ 110 m) along the transect with westward decreasing strength
 430 and increasing height. The ERA5 slightly underestimates both the height and strength of the

ducting layer as well as the PBLH. A systematic negative N -bias below the ducting layer is observed throughout the transect, peaking (-5.42%) slightly below the PBLH, and gradually decreasing towards the surface (-0.5%).

MAGIC radiosondes indicate larger values of both ducting strength (ΔN) and thickness (Δh) than ERA5 in the western half of the transect. The opposite is true in the eastern portion of the domain and is likely associated with the transition of the cloud layer from open-cell cumulus in the west to stratocumulus and stratus in the east (Wood et al., 2011; Bretherton et al., 2019). ERA5 systematically underestimates the average ducting layer gradient ($\Delta N/\Delta h$) comparing to the radiosondes. The largest N -bias is found over the region with strongest ducting and largest sharpness parameter. It is worth noting that the PBL over the western portion of the transect near Hawaii frequently shows two major gradient layers (a mixing layer at ~ 1 km and the trade-inversion at ~ 2 km), with comparable N -gradients (e.g., Fig. 2). The much lower PBLH seen in ERA5 in this region is likely due, in part, to the decreasing number of model levels in ERA5 at higher altitude, which could lead to a higher possibility of identifying the lower gradient layer as the PBLH. However, the impact of the vertical resolution and on the performance of the gradient method for PBLH detection has not been performed in this study. Further, the ERA5 results may be affected by the interpolation resolution and gradient are calculation. Both warrant a more comprehensive study in the future.

5 Data availability

Data for the Marine Atmospheric Radiation Measurement (ARM) GCSS Pacific Cross Section Intercomparison (GPCI) Investigation of Clouds (MAGIC, Zhou et al., 2015) can be accessed through the U.S. Department of Energy's Office of Science <https://www.arm.gov/research/campaigns/amf2012magic>.

Data for the ECMWF Reanalysis version 5 (ERA5, Hersbach et al., 2020) can be accessed at <https://www.ecmwf.int/en/forecasts/dataset/ecmwf-reanalysis-v5>.

6 Author contribution

Author Thomas Winning is responsible for all original text data analysis, and production of graphics. Author Kevin Nelson contributed by providing updated data processing and end-to-end

459 simulation code, colocation of ERA5 data with MAGIC observations, and manuscript edits.
460 Author Feiqin Xie is the academic advisor for the primary author and also provided draft edits and
461 paper organization and writing guidance.

462

463 **7 Competing interests**

464 The authors declare no competing interests, see Acknowledgements for current affiliations.

465 **8 Acknowledgements**

466 The authors acknowledge funding support of earlier work from NASA grant (NNX15AQ17G).
467 Authors T. Winning and K. Nelson were also partially supported by research assistantships from
468 the Coastal Marine System Science Program at Texas A&M University – Corpus Christi. The
469 high-resolution ERA5 reanalysis data were acquired from ECMWF and the Climate Data Service
470 (CDS). The MAGIC radiosonde data were provided by the Atmospheric Radiation Measurement
471 program (ARM) Climate Research Facility sponsored by the U.S. Department of Energy (DOE).
