Abstract

To retrieve columnar intensive aerosol properties from sun-sky photometers both irradiance and radiance calibration factors are needed. For the irradiance the solar calibration constant, V_0, that is the instrument counts for a direct normal solar flux extrapolated to the top of the atmosphere, must be determined. The solid view angle, SVA, is a measure of the field of view of the instrument, and it is important for obtaining the Radiance from sky diffuse irradiance measurements. Each of the three sun-photometers networks considered in the present study (SKYNET, AERONET, WMO-GAW) adopts different protocols of calibration, and we evaluated the performance of the on-site calibration procedures, appliable to every kind of sun-sky photometers but tested in this analysis only to SKYNET Prede-POM01 instruments, during intercomparison campaigns and laboratory calibrations held in the framework of the Metrology for Aerosol Optical Properties (MAPP) EMPIR project. The on-site calibration, performed as frequently as possible (rather monthly) to monitor change of the devise condition, allow operators to track and evaluate the calibration status on a continuous basis considerably reducing the data gaps incurred by the periodical shipments for performing centralized calibrations. The performance of the on-site calibration procedures for V_0 was very good in sites with low turbidity, showing an agreement with a reference calibration between 0.5% and 1.5% depending on wavelengths. In the urban area, the agreement decreases between 1.7% and 2.5%. For the SVA the difference varied from a minimum of 0.03% to a maximum of 3.46%.

1. Introduction

The ground-based remote sensing measurements of the solar radiation are an important part of atmospheric physics aimed to determine the columnar aerosol optical properties. Sun-sky photometers and sun-photometers are instruments performing direct and diffuse solar radiation measurements in the wavelength regions where gases' absorption is low or negligible. Several networks have been established worldwide, such as AERONET (Holben et al., 1998), WMO-GAW (Kazadzis et al., 2018a) and SKYNET (Nakajima et al., 2020). These networks provide well tracked, but with different basic principles, calibration procedures, good quality standards and homogeneity on the retrievals. Traceability and data quality are essential requirements by the World Meteorological Organization (WMO) for monitoring atmospheric aerosol optical properties. In 2006, the Commission for Instruments and Methods of Observation (CIMO) of the WMO (WMO, 2007) recommended that the World optical depth research and calibration center (WORCC) at the PMOD-WRC is designated as the primary WMO Reference Centre for aerosol optical depth (AOD) measurements (WMO, 2005). Since 2000, reference instruments from different networks are intercompared in order to ensure worldwide aerosol optical depth homogeneity (e.g. Kazadzis et al., 2018b, Kim et al., 2008, WMO, 2023).

To obtain columnar aerosol properties from sun-photometers, both irradiance and radiance calibration factors are needed. For the irradiance, the solar calibration constant (V_0) must be determined whereas the solid view angle (SVA) is an intermediate step for the radiance calibration. V_0 is the instrument counts for a direct normal solar flux, F, (Irradiance, instrument units) extrapolated to the top of the atmosphere (Shaw, 1976), and it is an important issue for the estimation

of the AOD. An error of 10% in the estimation of V_0 induces an uncertainty in the retrieval of AOD of about 0.1 for airmass equal to 1, therefore a good accuracy is needed in its determination. SVA is a measure of the field of view of the radiance measurement, L, ($Wm^{-2}sr^{-1}$) obtained from sky diffuse irradiance measurements (E), being L the ratio between E and SVA.

Each of the three networks considered in the present study adopts different protocols of calibration. For the AERONET (Giles et al., 2019) CIMEL sun-sky photometers, V_0 is transferred from a value of reference instrument which is retrieved by Langley-plot based on measurements at a mountaintop calibration site (Shaw, 1976; Holben et al., 1998). The primary mountaintop calibration sites in AERONET are located at the Mauna Loa Observatory (latitude 19.536, longitude −155.576, 3402 m) on the island of Big Island (Hawaii) and the Izana Observatory (latitude 28.309, longitude −16.499, 2401 m) on the island of Tenerife in the Canary Islands (Toledano et al., 2018, Cuevas et al., 2022). These reference instruments are routinely monitored for stability and typically recalibrated every 3 to 8 months. Langley-calibrated instruments move to main calibration locations (such as Washington DC (USA), the Observatoire de Haute-Provence (OHP, France) or Valladolid (Spain)), and transfer their calibration to reference instrumentation. Then each of the CIMEL network instruments are visiting these locations and they are calibrated. Radiance L is directly obtained by a calibration with the integrating spheres at the AERONET calibration centers, providing an absolute calibration traceable to a NIST standard lamp hosted at the NASA GSFC calibration facility.

WMO-GAW uses PFR sun-photometers measuring only the direct solar Irradiance. V_0 is calculated by comparison against three Langley-calibrated instruments (triad) at the WORCC (Kazadzis et al., 2018a). The triad is also checked by comparisons of Langley calibrations with master instruments operating at Mauna Loa and Izana and visiting WORCC every six months. Within the ACTRIS European research infrastructure, reference PFRs are permanently located at the AERONET Europe calibration locations of OHP, Valladolid and Izana to ensure data homogeneity.

SKYNET adopts on-site calibration routines for the Prede-POMs sun-sky photometers to determine the V_0 and SVA, using the improved Langley plot method described in section 3.3 and the disk scan method (Nakajima et al., 1996; Boi et al., 1999; Uchiyama et al., 2018) described in section 4.3. The on-site calibration procedures are performed as frequently as possible (monthly) to monitor change of the device condition, since the deterioration of the optical filters or other parts of the optics is detectable in a change of the temporal behavior of the calibration constants. On-site calibration procedures allow operators to track and evaluate the calibration status on a continuous basis considerably reducing the data gaps incurred by the periodical shipments for performing centralized calibrations. Also, the likelihood of instrumental damages attributable to transport decreases.

In the present work we evaluate the performance of the on-site calibration procedures, applied in the past also to Cimel sun-sky photometers (Campanelli et al., 2007) but here tested only to Prede-POM 01 instruments, using intercomparison campaigns and laboratory calibrations held in the framework of the Metrology for Aerosol Optical Properties (MAPP) EMPIR project. The overall aim of MAPP is to enable the SI-traceable measurement of column-integrated aerosol optical properties retrieved from the passive remote sensing of the atmosphere using solar and lunar radiation measurements.

2. Instruments and Sites

The Prede-POM is a sun-sky photometer, standard instrument of the SKYNET network, developed by Prede ltd, operating (in the model 01) at seven wavelengths: 315 nm, 400 nm, 500 nm, 675 nm, 870 nm, 940 nm, 1020 nm. The field of view is 1° and the Full Width at Half Maximum (FWHM)is equal to 3 nm (UV) and 10 nm (visible, VIS and near-infrared). The optics are thermostated at 30°C. The on-site calibration procedures, valuated in this work, were applied to four Prede-POMs (listed in Table 1), and three of them have been modified by replacing the 315 nm filter with a filter at 340 nm.

The PFR instrument, manufactured by PMOD/WRC, is used in the GAW AOD network, and it is a classic sun photometer equipped with 3 to 5 nm bandwidth interference filters (368nm, 412 nm, 500 nm, 863 nm) and a field of view of 2.5∘. The detector unit is held at a constant temperature of 20 ∘C by an active Peltier system. Dielectric interference filters manufactured by the ion-assisted deposition technique are used to assure significantly larger stability in comparison to manufactured by classic soft coatings. The PFR was designed for long-term stable measurements; therefore, the instrument is hermetically sealed with an internal atmosphere that is slightly pressurized (2000 hPa) with dry nitrogen.

The Cimel CE 318 standard AERONET instrument is a multi-wavelength automatic sun-sky photometer developed by Cimel Electronique, measuring direct solar irradiance and sky radiance at nine bands (340 nm, 380 nm, 440 nm, 500 nm, 675 nm, 870 nm, 937 nm, 1020 nm, and 1640 nm) with 2-10 nm FWHM and a field of view of 1.3° (Torres et al., 2013). The detector is not thermostated and corrections are performed a-posteriori.

The datasets used in this work are from the campaigns held in two mountain sites, Davos (9.846W, 46.814N, 1588.4 m a.s.l), and Izana (16.499E, 28.309N, 2373.0 m a.s.l), and in two urban sites, Rome (12.516W, 41.902N, 83.0, m a.s.l) and Valencia (0.418E, 39.508N, 60.0m a.s.l). The periods of the campaigns are also listed in Table 1:

The QUALity and TRaceabiliy of Atmospheric aerosol Measurements (QUATRAM) campaigns (Campanelli et al., 2018; http://www.euroskyrad.net/quatram.html) are organized by the Institute of Atmospheric Science of CNR (Italy) and the Physikalisch-Meteorologische Observatorium Davos/World Radiation Center (PMOD/WRC). They are aimed to evaluate the homogeneity and comparability among measurements performed by equipment of different International Networks and/or manufactures, and to assess the accuracy of the new on-site calibration procedures. The instruments attending the campaigns and involved in this study are listed in Table 1. The approach of the campaigns consists of performing a

122 calibration transfer from a primary master PFR of the PMOD/WRC to the other instrumentation, of the evaluation of the
123 on-site calibration procedures, and of the comparison of AODs at the common wavelengths. They were held in both urban
124 (Rome) and mountain (Davos) sites to consider different atmospheric turbidity and aerosol optical characteristics. The
125 QUATRAM 3, held in Davos in 2021, was hosted by the Fifth WMO Filter Radiometer Comparison (FRC-V) (WMO,
126 2023). QUATRAM campaigns are used in this study to evaluate the long term differences between on-site calibrations
127 and PFR transfer, as described in section 3.7 b.
128 The Izana and Valencia campaigns were held in the framework of the Metrology for aerosol optical properties (MAPP)
129 project with the purpose of generating data to be used for a development of a comprehensive uncertainty budget for
130 aerosol optical properties from remote sensing techniques and to determine the Top-of-Atmosphere solar and lunar
131 spectra.

140 ## 3. Estimation of the Solar calibration constant
141 Six methods for the estimation of V_0 are analysed in the following sections: the in-lab calibration at PTB, the transfer of
142 calibration among instruments and the on-site procedures. The evaluation of the performance of the SKYNET on-site
143 calibration procedures was assessed by comparing the retrieved constants against:
144   a.   the laboratory calibrations performed by the Physikalisch-Technische Bundesanstalt (PTB), Germany, the Aalto
145   University, Finland, and the PMOD, Switzerland.
146   b.   the transfer of calibration from PFR and CIMEL to Prede -POM instruments operating simultaneously.
147
148 **3.1 The laboratory calibrations at PTB**
149 The two sun-sky radiometers, POM_VAL and POM_CNR, were calibrated at PTB with respect to their spectral irradiance
150 responsivities. The calibrations were accomplished using the tunable laser-based facility, TUnable Lasers In Photometry
151 (TULIP). The TULIP facility, shown in Figure 1, has recently been upgraded with a laser system based on an optical
152 parametric oscillator (OPO) operating in pulsed mode with a pulse length of 2.5 ps and a repetition rate of 80 MHz. The
153 laser wavelength is automatically tunable throughout the spectral range from 230 nm to 2300 nm. A high-accuracy laser
154 spectrum analyzer (LSA) is used to monitor the laser wavelength, which is stable within 10 pm during a typical
155 measurement sequence. The spectral bandwidth of the laser radiation is wavelength-dependent and varies between 0.2
156 nm and 0.7 nm in the visible spectral range. The centroid values of the measured laser spectrum are used as the
157 wavelengths of the corresponding spectral responsivity values.
158 A spatially homogeneous non-polarized field with temporally stabilized irradiance values is produced by a beam shaping
159 optics based on a micro lens array. The amplitude stabilization of the output radiation from the laser system is achieved
160 using two liquid crystal display (LCD)-based modulators inserted in the signal and idler beams of the OPO, before the
161 second and third harmonic (SHG and THG) modules of the laser system. The feedback signals for the control circuits of
162 the intensity modulators are taken from Si and InGaAs photodiodes irradiated by a fraction of the radiation field formed
163 by the micro lens array. In this way, the irradiance values at the measurement plane are stabilized to a level of a few parts
164 in 10^4. The homogeneity of the generated field is within a few parts in 10^3. Spectral irradiance responsivity calibrations
165 are made in such a field by comparing the signal of a device under test (DUT) to that of a reference detector (REF),
166 positioned sequentially at the same position in the measurement plane. The spectral irradiance responsivities of the
167 reference detectors built of Si and InGaAs photodiodes for the visible and near infrared wavelengths, respectively, are
168 obtained through a chain of calibrations from a primary cryogenic radiometer and from the calibrated areas of the precision
169 radiometric apertures used with the reference detectors.
170 The spectral irradiance responsivity calibrations of the sun photometers were made at ca. 1.5 m from the micro lens array.
171 At this distance, the illuminated area of the micro lens array seen by the radiometers subtends ca 0.3 degrees. The entrance
172 apertures of the sun photometers were aligned perpendicular to the optical axis of the TULIP setup. The angular
173 orientation of the POM instruments in the setup was optimised by tilting and rotating to maximize the signal. This ensured
174 that the central part of the field of view was illuminated by the laser-induced irradiation field. The digital signals (DN)

175 from the POM instruments were requested and read via a serial port of the TULIP control PC using respective software
176 commands. During the measurements it was not possible to select the internal gain settings of the POMs. These settings
177 are managed by the instrument firmware. It was therefore also not possible to verify the gain values during the laboratory
178 calibrations and their respective contributions to the measurement uncertainties.
179

186 system, variable neutral-density filter (NDF), reference (REF) and detector under test (DUT), current-to-voltage converter
187 (I/U), multiplexer (MUX), digital voltage meter (DVM) and laser spectrum analyzer (LSA); (b) a picture of the ps-OPO
188 system; (c) a picture of POM and reference detectors installed on the translation stage system; (d) a side view of the POM
189 facing the beam shaping optics inside the enclosure.
190
191
192 The results of the calibrations of all the channels of the two instruments are shown in Figure 2. The bandpass functions
193 of the spectral channels were found to match well the nominal filter function. Only the 940 nm channel of POM_VAL
194 showed a large deviation. Most of the spectral channels were confirmed to block the out-of-band radiation to the level of
195 1E-8 throughout the whole spectral range.
196
197
198
199
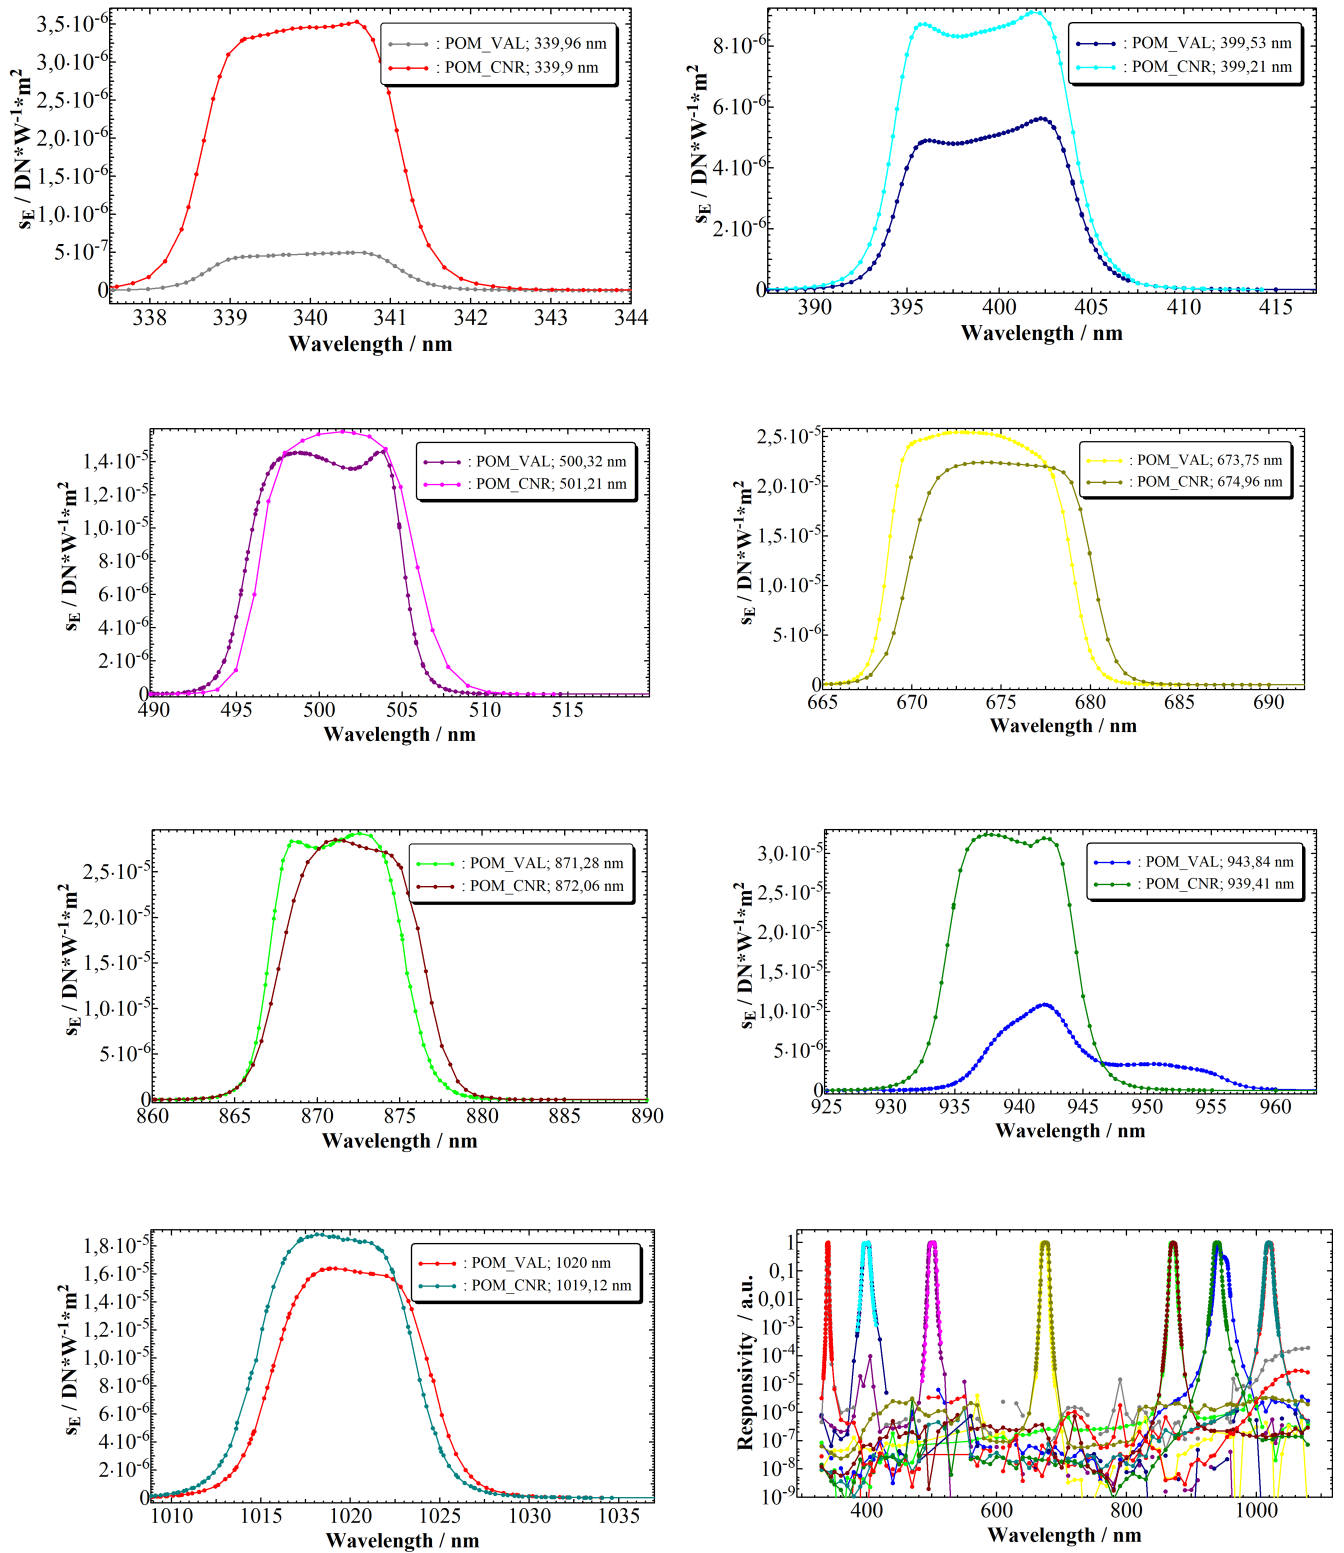

Figure 2. Measured spectral irradiance responsivities of all channels of the sun photometers and their normalized values displayed on a logarithmic scale.

The uncertainty analysis of the spectral irradiance measurements was accomplished by a Monte Carlo method according to Supplement 1 to the "Guide to the expression of uncertainty in measurement" using the measurement equation including all relevant uncertainty contributions. The known uncertainty components include the uncertainty of the reference detector responsivity, its aperture area, stability and LSA-based measurement of the laser wavelength, spatial homogeneity of the laser-generated field, the temporal stability of the irradiance values, laser bandwidth variation, and positioning of the detectors in the plane of measurements. For the latter uncertainty contribution, the position of the

209 effective radiometric aperture of the measured detectors along the optical axis must be known. In the case of the reference
210 detectors with well-defined mechanical apertures, their position can be determined with an accuracy of better than 0.1
211 mm. However, the position of radiometrically limiting apertures of sun photometers with lens optics cannot be measured
212 directly as they are behind the lens. In this case, they were determined through distance variation with much higher
213 resulting uncertainties. For the Prede POM sun photometers, the positions of the effective apertures could be determined
214 with estimated standard uncertainties of 3 mm. The respective uncertainty contribution was also dominating the
215 uncertainty of the spectral irradiance responsivity calibrations of the filter radiometers (Figure 3).
216 It should be noted that the uncertainty analysis only included the uncertainty components identified during the laboratory
217 calibrations under the respective measurement conditions. As mentioned above, uncertainty contributions from internal
218 gain values of the POMs could not be estimated due to the lack of functionality of the instruments for laboratory
219 calibrations. Also, the temperature stabilization of the POM_CNR did not work during the calibrations at PTB. The effect
220 of the instrument malfunction on the calibrated responsivity values was not included in the uncertainty analysis. In
221 addition, there may be some other differences between the operating conditions of the instruments during the laboratory
222 calibrations and their use in the field, which could lead to additional uncertainty contributions.
223
224
225 Figure 3. Example of spectrally dependent uncertainty components of spectral irradiance responsivity measurements of
226 the 500 nm channel of POM_CNR. The relative uncertainties on the left axis represent components due to reference
227 detector (u_{trap}), temporal irradiance stability (u_{stab}), detector positioning (u_{dist}), laser wavelength (u_{wl}), aperture area
228 ($u_{aperture}$), spatial homogeneity (u_{homog}) and the resulting standard uncertainty of the measurements (u_s).
229
230
231 The calibration factors V_0 were obtained a posteriori, by integration of the spectral response and the extra-terrestrial TSIS
232 spectrum (Coddington et al., 2023). The uncertainties were estimated by quadratic error propagation of the numerical
233 integral. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table
234 1A and 2A in the Appendix.
235
236 Within the EMPIR project 19ENV04 MAPP, sun photometers from GAW-PFR and AERONET networks were also
237 measured at PTB with respect to their spectral irradiance responsivities. The results of the laser-based calibrations of
238 several sun photometers were verified by additional methodologies for laboratory calibrations. The spectral irradiance
239 responsivities of a PFR and two CIMELs determined at the TULIP setup were verified by a calibration against reference
240 standard lamps with traceability to the primary spectral irradiance standard (a high-temperature blackbody). The results
241 agreed well within the uncertainties of the calibrations, i.e. in the range between 0,2% and 1%. One CIMEL was also
242 calibrated in radiance mode using an integrating sphere source calibrated at PTB for the spectral radiance. This calibration
243 data combined with the FOV values measured by PMOD yielded spectral irradiance responsivities of the CIMEL channels
244 that agreed within 1% to 2% to those determined at the TULIP setup in irradiance mode.
245 The spectral irradiance responsivities of the PRF were combined with the published spectral irradiance at the top of the
246 atmosphere (TOA) values (QASUMEFTS (λ<=500) & TSIS-1 HSRS (λ>500 nm)) to derive the signal values that would
247 be measured at the TOA. Those values were compared with those obtained by the Langley technique. The agreement
248 between the values was within 0,5%. Also, the AOD values derived using the laboratory-based calibration of the PFR
249 were well in agreement to those from the Langley-based calibration (Kouremeti et al, 2021; Gröbner et al., 2023).
250 For the three CIMEL instruments calibrated at PTB, the agreement between the calculated TOA values and those derived
251 by the Langley extrapolation technique was in the range of 1% to 5%, with the discrepancies systematically increasing
252 towards the short-wavelength channels. Thus, for all instruments, the results of the in-lab calibrations were consistent
253 within their respective uncertainties, regardless of the calibration methods used.

254
3.2 The standard Langley (SL) method for POM_CNR

The Standard Langley method (Shaw, 1976) is the most common procedure adopted to calculate the solar calibration constant. It is based on the Beer-Lambert law (Eq. 1)

$$V = V_0\ exp\ (-m_0\tau)$$
Or
$$ln\ V\ =\ ln\ V_0\ -\ m_0(\tau_{gas} + \tau_R) - m_0\tau_{ext}$$
Eq.1

Where V is the direct solar irradiance measured at ground, m_0 is the optical air mass as the inverse of the cosine of the solar zenith angle, τ_{ext} is the extinction AOD, τ_{gas} and τ_R are are respectively the gas absorption optical depth and the molecular (Rayleigh) scattering optical depth.

The Standard Langley method consists of the retrieval of V_0 by the fit of y vs x in Eq. 2, assuming that optical depth due to aerosol is constant, as it happens performing the measurements at high altitude (i.e. above the boundary layer, where AOD is low, and its absolute variability is also very low).

$$y = a_{SL} + b_{SL}x$$
$$where\ x = m_0$$
$$y = ln\ V + m_0 \cdot (\tau_{gas} + \tau_R)$$
Eq.2

The linear fitting provides intercept $a_{SL} = ln\ V_0$ and slope $b_{SL} = -\tau$.

This method is used for measurements taken at the Izaña observatory by the POM_CNR. The following criteria are used to filter the data: i) only data for $m_0 >= 2$ and $<= 5$ are considered; ii) using a and b parameters retrieved from the fit, y_{fit} is obtained from Eq.2 and the residuals are calculated for each point as y- y_{fit}; their RMSD is calculated and if it is > 0.006, the mean of residuals is calculated and points for which residual is greater than mean value are removed; a new fit is then performed and the process is repeated until RMSD < 0.006 is obtained; iii) special criterion is applied for 340 nm where data points were only selected for m < 2. The primary reason for choosing this airmass threshold is its sensitivity towards molecules (Rayleigh scattering). Selecting higher optical mass means light gets scattered more and can cause errors. A similar strategy is also used in Estelles, et al. (2004). The selected series were considered only if the number of data points are greater than 50. After a visual inspection, three days of the Izana campaign (7, 8 and 9 September 2022) were very stable and showed minor fluctuations. Calibration values were calculated for these three days, both in the morning (before 13 UTC) and afternoon for each wavelength with the air mass limit between 2 and 5.

Uncertainty was determined as the standard deviation of the calibration values calculated for three days in morning and evening (6 plots). The mean was taken as the final calibration value. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table 1A and 2A in the Appendix.

3.3 The improved Langley methods (IL-XIL) for POM_CNR and POM_VAL

Based on the above-described Langley method, the formula of Improved Langley method is expressed as follows:

$$y = a_{IL} + b_{IL}x\ \ where$$
$$x = m_0\omega\tau_{ext} = m_0\frac{\tau_{sca}}{\tau_{ext}}\tau_{ext} = m_0\tau_{sca}\ and$$
$$y = ln\ V + m_0 \cdot (\tau_{gas} + \tau_R)$$
Eq.3

where ω is the aerosol single scattering albedo (defined as $\frac{\tau_{sca}}{\tau_{ext}}$). The linear fitting provides intercept $a_{IL} = ln\ V_0$ and slope $b_{IL} = -\frac{1}{\omega}$.

The improved Langley plot method (Campanelli et al., 2004 and 2007, Nakajima et al., 2020) is the standard calibration method of the SKYNET network and it was used to calculate the solar calibration constants for both the Prede-POM sun-sky photometers.

The calibration value, V_0, is retrieved by fitting the natural logarithm of the direct solar irradiance versus the product of m_0 and the scattering optical depth, as retrieved by the SKYRAD 4.2 code (Nakajima et al., 2020), instead of only the air mass as occurs with the standard Langley plot.

As described in section 3.2, the standard Langley assumes that, in the selected time period, the AOD is constant, so data must be accurately chosen because the result is directly related to the variability of AOD. Shaw, 1979 and 1983, demonstrated that the linear dependence of AOD on m_0, which means a temporal change of the optical thickness because m_0 depends on time, corresponds to the second-order variation in terms of time. Limiting to the first order and following Eqs. 2 and 3 of Campanelli et al., (2004) AOD can be expressed as the sum of a stable term (AOD$_0$) and a term indicating the variability (AOD$_1$/m$_0$). Eq.1 can be therefore briefly expressed as $lnV = lnV_0 - AOD_1 - m_0\ AOD_0$. In the standard Langley plot the intercept value contains the variability (ln V_0 -AOD$_1$) and the retrieved V_0 value has a substantial dependence on the daily variability of AOD. Conversely in the Improved Langley plot V_0 is retrieved by the fit of lnV versus the product of m$_0$ and the scattering optical depth that includes the variability term. In contrast to the standard method, the intercept V_0 does not depend on the AOD in-day variation, if the product $\omega\tau_{ext}$ is correctly retrieved by the inversion process.

To understand now the main idea on which this method is based, we define the two observable quantities (for each wavelength λ) important for the Sun-sky photometer, the direct solar irradiance in Eq. 1 and the normalized radiance R in Eq. 4

$$R(\Theta) = \frac{E(\Theta)}{\Delta\Omega \cdot V \cdot m_0} \qquad \text{Eq. 4}$$

where Θ is the scattering angle at which the Prede-POM takes measurements of the sky diffuse irradiance E, V is direct irradiance and $\Delta\Omega$ is the solid-view angle of the instrument.

R is determined as the solution of the radiative transfer equation, as in Eq.5 in the Almucantar geometry for a one-layer plane-parallel atmosphere, where P is the phase function, and q indicates the multiple-scattering contribution

$$R(\Theta) = \omega\tau_{ext}P(\Theta) + q(\Theta) = \tau_{sca}P(\Theta) + q(\Theta) \qquad \text{Eq. 5}$$

Thus, normalized radiance R is approximately assumed as the product of τ_{sca} and P; τ_{sca} is derived via the inversion process (e.g., Skyrad 4.2) of volume size distribution from the normalized radiance in aureole region with scattering angles $3° < \Theta < 30°$ (Nakajima et al., 2020), keeping fixed the complex refractive index, and it is used in the improved Langley method for obtaining the intercept V_0. Note that the aerosol optical depth for scattering (in x in Eq. 3) is potentially retrieved more accurately than the optical depth for extinction τ_{ext}. To understand the reason, it must be considered that the volume size distribution is roughly obtained by only direct radiation information because of the limited information content of the extinction Kernel function (Tonna et al., 1995, Figure 4). On the other hand, for the sky radiance measurements in the range $3° < \Theta < 30°$, the scattering kernel functions (Tonna et al., 1995, Figure 4) have reliable information content (approximately within $1 < 2\pi r/\lambda < 60$, which means that $0.05 < r < 10$ μm for our wavelength set) that is sufficient for deriving volume size distribution and reliably reconstructing the connected quantities R, P, $\omega\tau_{ext}$. The radiance in the aureole region is also less sensitive to the refractive index (Tanaka et al., 1983), Therefore, the use of R in Eq.5 to obtain $\omega\tau_{ext}$, i.e. scattering optical thickness, is the best way to analyze data.

From R and V data collected each month, two V_0 values a day are calculated with data taken in the morning and in the afternoon, and the V_0 monthly means are quality checked according to Campanelli et al., 2007, and below summarized: i) the values of $\omega\tau_{ext}$ obtained from the SKYRAD4.2 code inversion with accuracy lower than 7% are rejected. The accuracy is estimated as the percent differences between the measured and retrieved radiance R, averaged over all the wavelengths and scattering angles; ii) only the measurements taken for $m_0 < 3.0$ and $1/\omega > 0$ and ≤ 2 are selected; iii) all the values of V_0 found for τ_{ext} (500 nm) ≥ 0.4 are rejected; iv) a minimum number of 10 points is used in each morning and afternoon fit.
The rejection of τ_{ext} (500 nm) values greater than 0.4, is not in contradiction with the AERONET strategy, where the retrieval of ω is performed only for $\tau_{ext} > 0.4$ (Aeronet web page, Holben et al., 2006) otherwise ω and other properties are not included in the AERONET L2 analysis, because the purpose of this selection for IL is different. In fact a potential problem in this procedure is that the refractive index is kept fixed. The aureole region has information for volume size distribution, but not for refractive index, as said before, and this allows to retrieve τ_{sca}. However, high τ_{ext} makes high multiple scattering contribution ($q(\Theta)$ in Eq. 5) and greater error in retrieving τ_{sca} with a fixed refractive index.

Once the filtered monthly V_0 series are obtained, the outliers and short-term variations related to the method itself are filtered using the Chauvenet criterion (H. D. Young, 1962), that rejects points out of 2 times the standard deviation (std), and a three-point moving average technique. Finally, if at least 3 values remain and the ratio between their std and mean (Coefficient of variation, CV) is <3%, the monthly mean V_0 value is calculated. The uncertainty related to this value is given for each wavelength by the CV coefficient. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table 1A and 2A in the Appendix.

In the real observations, it is difficult to separate natural variations and inversion errors of $\omega\tau_{ext}$ and thus undesired inversion errors can be included that lead the IL method to an underestimation of the fitting parameters in the case of large aerosol retrieval errors (Nakajima et al., 2020). A new solution to this problem is tested, named the cross IL method (XIL), which exchanges the role of x and y in the regression analysis as described in Eq. 6

$$x = a_{XIL} + b_{XIL}y \qquad \text{Eq. 6}$$

The linear fitting provides slope $b_{XIL} = \frac{1}{b_{IL}} = -\omega$ and intercept $a_{XIL} = -\frac{a_{IL}}{b_{IL}} = \omega ln\,V_0$

The selection of data for this method is performed using the threshold of 0.05 for the fitting error, assuming that retrieval errors on ω and τ from Skyrad are within 9% (Nakajima et al., 2020). Monthly V_0 and the corresponding %CV are then calculated. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table 1A and 2A in the Appendix. Some examples of XIL and IL Langley plots are shown for 340 nm in Figure 1A and 2A in the Appendix.

3.4 The standard Langley method Transfer from POM_CNR to POM_VAL

The calibration of the Prede POM_CNR by the Standard Langley Plot method at Izaña campaign in September 2022, was transferred to POM_VAL using data from the QUATRAM3 campaign, on September 2021, as it was the only campaign where both instruments were co-located.

After visual inspection of the signal ratios for the days of September 2021, the days in the intervals 4-9, 11-15, 17-19, are considered for the calibration transfer.

The transfer procedure consisted of the following steps: i) data were selected between 9 to 13 UTC to avoid the rapid change in airmass; ii) signals within 30 sec between POM_VAL and POM_CNR were considered; iii) V_0 for POM_VAL was calculated following Eq. 7:

$$\frac{V_0^{POM\_UV}}{V_0^{POM\_CNR}} = \frac{V^{POM\_UV}}{V^{POM\_CNR}}$$

Eq.7

iv) values that are more than three scaled median absolute deviations away from the median are assumed as outliers and deleted; v) daily $V_0^{POM\_UV}$ medians are calculated and 2std of the $V_0^{POM\_UV}$ series is calculated. If 2std is larger than 0.5% of the daily V_0 median, all data outside 2std are removed. The process is repeated until 2std becomes equal or smaller than 0.5% of the daily $V_0^{POM\_UV}$ median or standard deviation and median values becomes equal in continuous iteration; vi) after visual inspection only days were selected which are stable, resulting in the exclusion of the days stated before.

To calculate the uncertainty of the transferred calibration values, the equation below was used, where we account for uncertainties on the master instrument calibration, and the standard deviation of the signal ratios, that are sensitive to changes in AOD, etc.

$$u_{rel}(V_0^{POM\_UV}) = u(V_0^{POM\_UV})/V_0^{POM\_UV} = \sqrt{\left(\frac{u(V_0^{POM\_CNR})}{V_0^{POM\_CNR}}\right)^2 + \left(\frac{STD(SR)}{SR}\right)^2}$$

Eq.8

where: u_{rel} is the relative uncertainty, $V_0^{POM\_UV}$ is the mean of the calibration values series and $u(V_0^{POM\_UV})$ is the uncertainty associated; $V_0^{POM\_CNR}$ is the calibration factor, and $u(V_0^{POM\_CNR})$ is the uncertainty associated with it. This uncertainty was estimated as the standard deviation of the 6 calibration values obtained by the 6 plots used in section 3.2; SR is the ratio of signals ($\frac{V^{POM\_UV}}{V^{POM\_CNR}}$) and $STD(SR)$ is the standard deviation of the ratio of the signals available for the calibration. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table 1A and 2A in the Appendix.

3.5 The calibration transfer from PFR to POM_CNR and POM_VAL

The transfer of calibration from two reference PFR photometers of the PMOD one located in Davos and the other in Rome, has been carried out for both POM_CNR and POM_VAL, during the QUATRAM campaigns.

The transfer is based on the ratio of Eq. 9 for the two instruments, POM and PFR:

$$\frac{V_0^{POM,TR}}{V_0^{PFR}} = \frac{V^{PFR}}{V^{POM}}$$

Eq.9

where, V^{PFR} and V^{POM} are the solar direct irradiance measured by the two instruments, $V_0^{POM,TR}$ is the unknown solar calibration constant of the POM and V_0^{PFR} the known calibration constant of the PFR to be transferred. For QUATRAM 3 in Rome, days in the intervals (6-8; 11-14) of September 2021 were considered.

Signals ratios $\frac{V^{PFR}}{V^{POM}}$ were taken using measurements that are within 30 sec time difference, and cloudy conditions were removed, together with ratios outliers. Values outside of the interval time 9-13 UTC were rejected. From Eq.9 the time series of $V_0^{POM,TR}$ was limited to: i) choosing only those days for which at least 20 measurements in 1 hour are available; ii) Calculating the daily V_0 medians and compare each with 2std of the day's V_0 values; if 2std is larger than 0.5% of the daily V_0 median, remove all data outside 2std; repeat until 2std becomes equal or smaller than 0.5% of the daily V_0 median; when this is accomplished, if the day's measurements have dropped below 20 the day is excluded. Daily medians of the remaining values are calculated, and then a monthly mean $V_0^{POM,TR}$ is estimated. As uncertainty the std of the monthly mean values is assumed. The results are summarised in Table 2a and b, with only the percent differences, and more completely in Table 1A and 2A in the Appendix

406 For the transfer to POM_VAL during QUATRAM 3, the same procedure was applied but the selected days are in intervals
407 (6-9; 11-14) of September 2021.
408 The uncertainties were estimated as in other transfer cases, by assuming a nominal uncertainty of the PFR calibration of
409 1%. Results for both instruments are summarised in Table 2a and b, with only the percent differences, and more
410 completely in Table 1A and 2A in the Appendix.
411 The same procedure was applied for the QUATRAM 3 in Davos and QUATRAM 1 and 2 in both the sites for POM_CNR.
412
413 **3.6 Calibration transfer from CIMEL to POM_CNR and POM_VAL**
414 During QUATRAM 3, a calibration transfer from the Cimel #1270 was carried on, following the same selection criteria
415 of the transfer from PFR.
416 To calculate the total uncertainty of the transferred calibration values, Eq. 8 was used with V_0^{CIM} as the master instrument
417 and $u(V_0^{CIM})$ the associated uncertainty. As the estimated uncertainty is absent for the master instrument, it is assumed to
418 nominal 1% of V_0. The results are summarised in Table 2a and b, with only the percent differences, and more completely
419 in Table 1A and 2A in the Appendix.
420
421 Table 2a: Percent Coefficients of variation CV for all the methods and periods, for POM_CNR. When CV is 0, it means
422 that the monthly dataset is composed by only one point. In column three, there is the type of method used: IL (Improved
423 Langley), XIL (Cross Improved Langley), PFR (Transfer from PFR instrument), Cim_1270 (Transfer from Cimel), Lab
424 (laboratory calibration), SL (Standard Langley).

3.7 Comparisons

a) Differences between all methods against the reference one

The six calibration methods described in the above sections in the period September 2021- November 2022 for both the POMs are compared against a reference calibration. The time interval was chosen because the campaigns and laboratory calibrations were performed in this period in the framework of the MAPP project.

For the POM_CNR the reference calibration is the Standard Langley method performed at Izana in September 2022, whereas the transfer of this calibration to the POM_VAL is the reference value for the latter instrument. However, we need to consider that the frequent shipments of the equipment during this year for the project purpose and the usage can have affected the values of V_0 and probably can be the reason of discrepancies between the SL calibration and the calibrations performed about 1 year earlier. The aging of the instrument, without shipments, can also affect the V_0 but the order of magnitude and amount per year strongly depends on the instrument, and some wavelengths can be more affected than others. For the two instruments used in this work it is not possible to evaluate a degradation in one year and discern it from the shipment's effects, because the equipment was frequently travelling.

The percent difference was calculated with Eq.10:

11

$$451 \qquad Diff(\%) = \frac{(V_0^{ref} - V_0^x)}{V_0^{ref}} \cdot 100 \qquad\qquad\qquad \text{Eq. 10}$$

452 where V_0^{ref} is the reference value and V_0^x is the calibration obtained with each of the above-described methods. Results
453 are shown in Figure 4 and Table 3.
454 For the POM_CNR the agreement is very good with the reference SL and many of the points are within ±1%.
455 The transfer from Cimel and PFR in Rome and from PFR in Davos at 500 nm differ of -1.6%, -2.1% and -1.3%,
456 respectively. 340 nm is the wavelength with the most problematic results for the on-site procedures in Rome (differences
457 around 4%). Further studies, not yet published, showed that the 340 nm is also significantly affected by the assumed
458 surface Albedo, and improvements of the agreement were found if, for example, values from the POLarization and
459 Directionality of the Earth's Reflectances radiometer (POLDER) on ADEOS satellite, are considered. More tests are
460 needed to verify this dependence in for more sites. Moreover, according to Momoi (2022) the molecular polarization
461 potentially causes calibration errors from IL and XIL methods at the 340 nm, especially low aerosol loading atmosphere.
462 In fact the SKYRAD.pack 4.2 used for the on-site procedures has an un-polarized ("scalar") radiative transfer core forward
463 model, that can cause around 8% errors on the retrieval of radiance at 340 nm, so it might be one of the reasons for the
464 calibration constant of 340 nm to have errors.
465 The best agreement is for the IL in Davos with values < 0.5% at all the wl, and 1.5% at 1020 nm.
466 For the POM_VAL, many points are within ±1% but less respect to the POM_CNR. The agreement with the reference
467 method for the PTB laboratory calibration shows an improvement, remaining however between -1.3% and -8% except
468 for the 340 nm where it is 0.7%. The transfer from Cimel and PFR in Rome at 500 nm agrees within -1.9 %, a value
469 comparable with those of the POM_CNR. Also, in this case the 340 nm is the wavelength with the most problematic
470 results for the on-site procedures (differences up to 6%) as explained for the POM_CNR.
471 For both POMs, the comparison with PTB calibration shows very high underestimations (down to -10% except for
472 POM_CNR, and -8% for POM_VAL), but at this state of the art we are not able to provide a certain reason for the
473 discrepancy. It is noteworthy that the agreement between the laboratory calibration and the Langley measurements for
474 PFR was well consistent within the uncertainties. In the case of the CIMELs, however, discrepancies increasing towards
475 the short wavelengths and exceeding the uncertainties by a factor of 2-3 have been observed. The causes of the
476 discrepancies between the laboratory calibrations and the field measurements of the CIMEL and POM instruments are
477 not yet understood.
478 Focusing on the on-site methodologies, the IL works better in Davos with an agreement against SL always below 0.5%
479 except at 1020 nm where it increases up to about 1.5%. A very good accordance is also found in Valencia in November
480 2022, always within 0.8% except at 500 and 675 nm (within 1.5%). The similarity between the two cases is probably due
481 to the very low turbidity recorded in this month in Valencia, that makes the atmosphere optically more similar to the one
482 in Davos.
483 The XIL provides a consistent improvement, with values within 1%, only in Rome for all the wavelengths, but in very
484 clean atmosphere, as in Davos, it was not possible to retrieve values at 1020 nm, as conversely is done with the IL. This
485 is related to the differences in the data screening criteria between the two methods, set up for performing the linear fitting.
486

487

513
514
515
516
517   Figure 5. Percent differences between PFR transfer of calibration and the on-site calibration methods at the common
518   wavelengths (circles), and the uncertainty %CV of the IL and XIL as in Table 2a and b.
519
520   The difference between the on-site calibration methods and the PFR calibration transfer was analyzed in the period of the
521   3 QUATRAM campaigns held in Davos and Rome using Eq.10 with V_0^{ref} the transfer from PFR. V0s are shown in Table
522   1A in the Appendix and the percent difference is in Table 4 and Figure 5.
523   For the IL, the differences are always greater than the uncertainties (%CV) of the method, for both wavelengths, with the
524   exception of Davos in 2017. Values are around 1% in Davos and this is an important result for the validation of the IL
525   procedure, confirming the good performance of the Improved Langley on high mountain even if, as shown in Nakajima
526   et al. (2020), the IL accuracy is proportional to the optical thickness of the atmosphere of observation, generally low on
527   high mountains. The same result has been also obtained by Ningombam et al. (2014). The greater differences are observed
528   in Rome and at 500 nm. In this site the AOD is higher than in Davos, as shown in Figure 6, and we would have expected
529   a better performance of the on-site methodology. The reason of this result could be related to the fact that in the retrieval
530   of *x* for performing the fit in Eq.3, $\omega\tau_{ext}=\tau_{sca}$ and the refractive index must be assumed to not largely change during the
531   Langley plot (Campanelli et al., 2004), otherwise the retrieved optical thickness can include an error caused by the
532   inversion process and also by an improper assumption of the refractive index. In an urban site affected by traffic, as Rome,
533   we can expect this assumption not satisfied. Further studies are actually aimed to understand the possibility of defining
534   some selection criteria for the variability of τ_{sca} values particularly in urban sites. Moreover, the use of the Skyrad_MRI
535   (Kudo et al.,2021) instead of Skyrad 4.2 and possibility to use only the XIL method instead of the IL, is under evaluation.
536   For XIL many differences are within the uncertainties (%CV) of the method, and those higher are closer to the %CV
537   values than in the IL method. XIL improves the agreement particularly in Rome where the largest difference reduces from
538   3.5% to 2.5% at 500 nm and from 3% to 1.7% at 870 nm.

4. Estimation of the solid view angle (SVA)

The SVA is the measure of the field of view of the instrument that can be assumed from the geometry of the telescope. However, several factors contribute to this value: colour aberration of the lens and misalignment of the optical axis, that are wavelength dependent, surface nonuniformity of filters randomly function of wavelength, and diffraction at the edges of the lens and non-uniformity of the sensor that are wavelength independent.

This makes it necessary to develop laboratory and on-site methods for correctly estimating SVA values. The methods used in this work are described below.

4.1 Calibration at the laboratory of the AALTO University

The field of view of the Prede POM_CNR has been measured at the laboratory of Aalto University. The measurement setup consists of a two-axis gimbal and a light source. The light source is constructed from an integrating sphere (Gigahertz Optik type UMBB-300) and a 1 kW Xe-lamp. The diameter of the sphere is 300 mm, and the output aperture is limited to 10 mm in diameter. The distance D between the sphere aperture and the axis of rotation was ≈ 1060 mm (Figure 7). The purpose of the integrating sphere is to obtain a spatially uniform, well-defined light source. The aperture size and the distance D chosen provide the radiometer to see the light source at a solid angle corresponding to the same solid angle where it sees the Sun in the field measurements, angular diameter = 0.54˚.

Figure 7: Schematic of the measurement setup. From left to right: a switchable light source, an integrating sphere, and a two-axis gimbal.

The radiometer is mounted on the gimbal, tilted in the desired angle, and the signal amplitude is measured. The setup is built on an optical rail, which enables easy varying of the distance between the gimbal and the light source. The light source and gimbal are fixed in place. The point of rotation of the radiometer was chosen using an x-axis translator, and customized elevation blocks installed between the radiometer and the gimbal to set y-direction. The common optical axis of the light source and the radiometer is found by shifting the sphere aperture. The tilt angle range of measurements is [-0.7˚ 0.8˚] for all channels in both directions, and the step size is 0.1°. The measurement sequence and the data collection are automated using LabView. The integrating sphere and the Xe-lamp are shown in Figure 8.
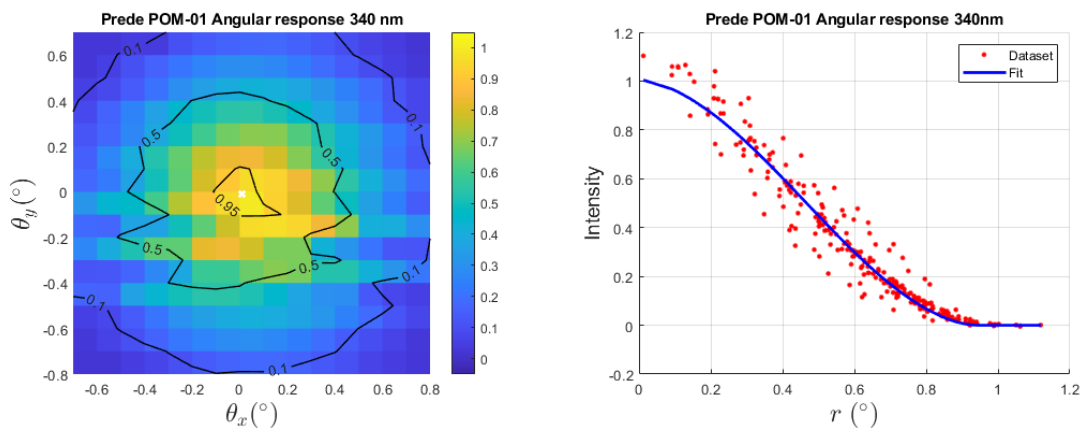

576 Figure 8. The integrating sphere with an interchangeable aperture and a monitor detector attached. The Xe-lamp housing
577 can be seen behind the sphere. Between the light source and the sphere there is a water cooled filter to remove the heat at
578 wavelengths above 1000 nm and a lens imaging the arc to the entrance of the sphere. The integrating sphere is of coaxial
579 type with a large screen between the entry and exit ports.
580
581 Collected data are used to derive the SVA of the POM following the method Boi et al. (1999). The solid viewing angle,
582 from the scanning centered at the origin of a local system of rectangular coordinates, is given by Eq. 11
583

$$\Delta \Omega = \iint_{\Delta A} \frac{E(x, y)}{E(0, 0)} \, \mathrm{d}x \mathrm{d}y \qquad \text{Eq. 11}$$
584 where E is the measured intensity (mA) and x and y (in radians) are the polar coordinates that determine the position of
585 the optical axis with respect to the position of the light source. The signals are registered as a function of the (x, y)
586 coordinates and a circular symmetry for the angular responsivity is assumed. Then a new system of coordinates centered
587 at the center of mass of the angular response is introduced and the needed parameters are obtained by fitting the
588 measurements.
589
590 The results are presented in Table 3A in the Appendix, and in Figure 9 example of measurements are shown. The left
591 figures display a 2D heat map of the relative signal amplitude as a function of the two tilt angles. The fluctuations of the
592 light source have been taken into account by using correction coefficients obtained from the monitor detector data. The
593 right figures present the signal intensity as a 1D function of distance (r) from the center of mass. Measurements are
594 particularly noisy, and it is probably due to the use of an integrating sphere as source of light for a photometer, providing
595 low radiation levels to which the instrument has low sensitivity. The measurements should form a plateau at small angles.
596 However, this plateau is disturbed by convolution, as the resolution of the measurement is of the same order of magnitude
597 as the plateau.

4.2 Calibration at the laboratory of PMOD

The field of view characterisation facility at PMOD/WRC consists of a 250-kW Xe-Lamp source and a 2-axis goniometer system with 0.2-mdeg resolution. The radiation from the Xe-Lamp shines on a Spectralon reflectance plate which produces a lambertian radiation distribution. An aperture with diameter 12 mm is placed in front of the reflectance plate, which is at a distance of 3600 mm from the goniometer system. Thus, the source has an apparent diameter of 0.19°. The field of view measurement consists rotating the radiometer head in both axes from -1.1° to + 1.1° in steps of 0.04°. At each position, the average of 10 measurements is stored, and every 100 positions, a reference measurement at the nominal center position (0°, 0°) is performed to monitor the stability of the source and of the radiometer. A whole measurement cycle for one channel of the radiometer takes 4.5 hours. The field of view (fov) of the instrument is obtained by normalising the measurements at every angle with the reference signal at (0°,0°), obtained by interpolating the reference measurements to the times of the individual measurements. For the measurements of this radiometer, the variability of the reference measurements varied by 0.38% during the whole measurement cycle.

Because the source apparent diameter of 0.19° is considerably smaller than the sun (apparent diameter 0.5°, which is the usual source that this instrument measures) the cross-section of the apparent source was not deconvolved from the measurements. Rather what has been done is to convolve the measurements with the apparent sun diameter to obtain the corresponding field of view. The slight error made by assuming an initial point source, instead of deconvolving the field of view, was assumed to be less than 0.5%, and added to the uncertainty budget.

The field of view measurement of the Prede-POM_VAL for the 500 nm channel is shown in Figure 10. As can be seen in the figure, the region with highest responsivity above 99% of the maximum is circular, with a diameter of approximately 0.5°.
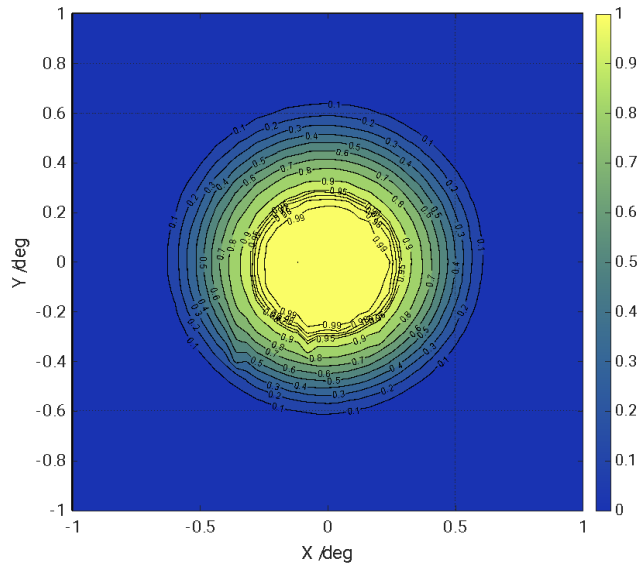

630

631 Figure 10: Field of view measurement at the 500 nm spectral channel of the Prede POM_VAL. The measurements
632 were normalised to the maximum signal.

633
634 From these measurements, the solid view angle Ω of the radiometer at this spectral channel is obtained by Eq. 11.
635 The standard uncertainty of the solid angle measurements is obtained from the variability of the individual measurements,
636 combined with the variability of the system obtained from the monitoring signals as described above. For the Prede
637 POM_VAL, the standard relative uncertainty of the solid angle determined from these measurements is 0.5%. Table 3A
638 in the Appendix summarises the solid angle measurements determined for all spectral channels.
639

640 **4.3 The solar disk methods**
641

642 A methodology based on the scanning of the Solar disk, described in Boi et al. (1999) is used to determine SVA directly
643 from optical data. It consists of the scanning of the irradiance field around the Sun, centered at the origin of a local
644 system of a rectangular domain 2° by 2°; the irradiance is measured for all the channels at 21 x 21 gridded points around
645 the solar disk with an angular resolution 0.1° (Figure 11 a, b). The instrument automatically follows the sun during the
646 scanning, lasting several minutes, and measurements are corrected for the movement of the solar disk. The solid viewing
647 angle, from the scanning centered at the origin of a local system of rectangular coordinates, is given by Eq 11. An
648 elliptical system of coordinates centered at (0,0) is introduced, to prevent the effect due to the difference between the
649 azimuth and zenith angle steps, and the needed parameters are obtained by fitting the measurements. This method is
650 called solid3m hereafter.
651

a)

Grid of the solar disk method;

b)
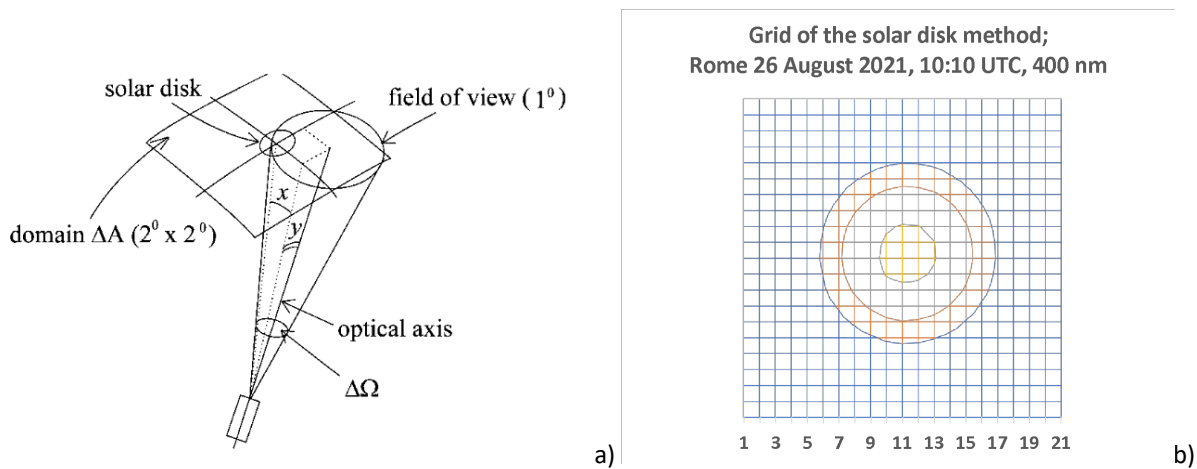

652
653 Figure 11. Geometry of the solar disk scanning measurements (a) and 2D image of the scanning.
654

655 The field of view of a Prede -POM is 1°, the size of the sun disk is about 0.5°, and the rectangular domain is 2°x2°,
656 therefore the data are taken from the sun for scattering angles up to 1.4° (= (1°) $\times\sqrt{2}$). As shown in Uchiyama et al.,
657 (2018) the influence of the direct solar irradiance as a light source extends up to 2.5°. To take this into consideration,

18

658 the integration of Eq 11 is performed by linear extrapolation for angles larger than 1.4°. Before starting the data
659 processing, the minimum measured value is subtracted from the measured values, then the values between 1.4 and 2.5°
660 are extrapolated. However, the subtraction of the minimum measured value largely affects the matrix of measurements
661 in the range of scattering angles [1.0° to 1.4°]. Uchiyama et al., (2018) extended the solid3m method, with a new version,
662 hereafter called solid3n, that does not perform this subtraction, and extrapolates the values between 1.4° and 2.5° using
663 the data from 1.0° to 1.4°.
664 SVA was calculated with the two solid3m and solid3n methods, using measurements taken in Rome and Valencia for
665 the POM_VAL and in Rome and Izana for the POM_CNR. The errors (ERR) for both 3m and 3n methods are estimated
666 as $((AM/ZM)-1)^2$ where AM is the measure and ZM is the calculated signals during the fitting phase. Only SVA having
667 ERR <0.2 is selected. The mean value over each campaign is assumed as the final SVA, and its std as the uncertainty
668 associated to the estimation. Results are in Table 3A in the Appendix.
669 The behavior of SVA values along the time, for the two methods (dashed lines is 3m and solid lines is 3n) and the two
670 instruments, was also analyzed in order to evaluate the stability of the method (Figure 12). The coefficient of variation
671 for the temporal variation (Std/mean) ranges from 1.1 to 1.3% for the POM_VAL and from 0.7 to 0.9% for the
672 POM_CNR with the exception of 340 nm (2.5%) and 870 (2.0%) due to the point of September 3 out of the general
673 patter for 340 and 870 nm.
674 Hashimoto et al, (2012) demonstrated that a SVA underestimation of 1.4 % to 3.7 % can cause an increase of SSA of
675 about 0.03 to 0.04. This estimation was done for Skyrad pack version 4.2. For the Skyrad_MRI_v2, actually used as
676 Skynet standard inversion model, it is expected to be similar because the same forward model, RSTAR, is used in the
677 retrieval and the relation between SSA and diffuse radiance is the same.

685 located in Rome.

686
687
688 **4.4 Comparisons**
689 SVA calculated with the two solid3m and solid3n methods, using measurements taken in Rome, Valencia, Davos and
690 Izana, are compared for both POM_VAL and POM_CNR instruments against the laboratory calibrations performed in
691 AALTO and PMOD (Table 5 and Figure 13).
692

$$Diff(\%) = \frac{(SVA - SVA^{lab})}{SVA^{lab}} \cdot 100$$ Eq.12

693 The solar disk scanning method uses the sun direct irradiance measurements as light source whereas the radiance from an
694 integrating sphere is the source at Aalto laboratory providing lower radiation levels and noisy measurements as already
695 mentioned in the paragraph 4.1. This is probably the reason why for the 340 nm channel of the POM_CNR, the
696 wavelength with the lowest intensity level, a large discrepancy is found ranging from 8.62% to 10.92% in Rome and
697 Izana.
698 The solar disk scanning matrixes, measured in Rome and Izana and analyzed with the solid3m method, provide SVA
699 values that generally agree better with the laboratory calibration than those obtained by the solid3n. The difference varies
700 from a minimum of 0.03% at 400 nm to a maximum of 3.46% at 870 nm in Rome and from 0.23% at 1020 nm to 2.07%
701 at 870 nm in Izana. Both the methods slightly overestimate the SVA values in Rome. The 870 nm shows the highest
702 discrepancy in both the sites and for both the solid3m and 3n methods. At this moment we are not able to provide a reason

703 for it, even if we expect it is due not to a physical cause, but to an instrumental one. A general overestimation by the
704 onsite procedures in the range [500-870] nm wavelengths is observed in both the sites. The overestimation is explained
705 considering that the field of view of a Prede -POM is 1° and the size of the sun disk is about 0.5°, therefore the scattered
706 light from aerosols and air molecules is included in the measurement of the direct solar irradiance. Moreover, the direct
707 solar light strikes the lens and results in "stray" light. The scattering contribution and stray light reaching the detector
708 increase the output, and the integrated value has a larger magnitude that can affect the estimation of the SVA. The
709 overestimation is lower in Izana due to a less important scattering effect.
710 For the POM_VAL, as for the other one, the 340 nm wavelength has a larger disagreement respect to the other
711 wavelengths reaching values of 4 and 5 % for both the sun disk methods, not explainable at this state of the art. Both in
712 Rome and Valencia a generally better accordance with the laboratory calibration is for the solid3m method when in the
713 range [400-870] nm the difference is below 1.5% and 2.15% in Valencia and Rome, respectively. For the 1020 nm the
714 comparison in Rome has a larger difference up to 2.63%. Also for this POM a general overestimation of SVA from onsite
715 calibration is visible in Rome, as explained in the above paragraph.
716 Finally, we compared the performance of the on-site calibration procedure, method 3m, in Rome for the two co-located
717 instruments calibrated at the two different laboratories (Figure 14). The SVA values for POM_CNR better agree with the
718 calibration performed in AALTO laboratory, with the exception of 340 nm and 870 nm.

5. Conclusions

The performance of the on-site calibration procedures applied to two Prede -POMs instruments, was evaluated using intercomparison campaigns and laboratory calibrations. Two periods were chosen for the validation: a) from September 2021 to November 2022, where 6 different calibration methodologies were compared against the SL method performed in Izana in September 2022; the reference SL calibration was done in September 2022 and there is no availability of a monthly reference calibration in the previous 12 months, to watch the stability of the instruments and check if their shipments or usage affected the calibrations; b) from August 2017 to September 2021, where the calibration transfer from a PFR during the QUATRAM campaigns was used to evaluate the on-site methodologies.

The comparison against the SL showed a very good agreement with many of the points within ±1%. The IL works better in Davos with an agreement below 0.5% except at 1020 nm where it increases up to about 1.5%. A very good accordance is also found in Valencia in November 2022, always within 0.8% except at 500 and 675 nm (within 1.5%). The similarity between the two cases is probably due to the very low turbidity recorded in this month in Valencia, that makes the atmosphere optically more similar to the one in Davos. These results are in accordance with Nakajima et al., (2020) where the estimation of the retrieval accuracy of V_0 from IL gives values of about 2.4% in Rome and around 0.3% - 0.5% at the mountain sites of Mt. Saraswati and Davos. These values are consistent with the RMSD in the aerosol optical depth comparisons with other networks, that is less than 0.02 for $\lambda \geq 500$ nm and about 0.03 for shorter wavelengths in city areas; smaller values of less than 0.01 are found in mountain comparisons.

The XIL provides a consistent improvement (with values within 1%) only in Rome for all the wavelengths, but in very clean atmosphere as in Davos it was not possible to retrieve values at 1020 nm.

The 340 nm is the wavelength with the most problematic results for the on-site procedures in Rome (differences around 4%) probably because of the molecular polarization that causes calibration errors from IL and XIL methods at the 340 nm. The polarisation effect becomes, indeed, significant when AOD is low, therefore they should be more evident in Davos, but they also depend on the surface pressure (in Davos lower than in Rome) and therefore potentially weaker than in Rome.

In Rome the calibrations transferred from PFR in September 2021 differ against the SL (performed in September 2022) in the range [-2.1%; -1.9%] at 500 nm for the two POMs, and the difference with the transfer from Cimel is about -1.6%. However simultaneous calculation of V_0 in September 2021 with IL and XIL at 500 nm provides values that differ from the SL of less then 0.5% for POM_CNR and 1.2% from POM_VAL. The reason of such discrepancy must be studied, because is not attributable to a change in the equipment due to shipping or usage, since it would have been visible also from the on-site methodologies.

For both the POMs the comparison with PTB laboratory calibration shows very high underestimations (down to -10% for POM_CNR, and -8% for POM_VAL). The discrepancies between the laboratory-based values and the field measurements are probably due to different operating conditions of the instruments (e.g., different alignment and measurement geometries, operating modes, polarization, etc.) and unknown POM settings (e.g., POM temperatures, signal readout procedures) under which the instruments were calibrated in the laboratory and used in the field.

The long term comparison of the on-site methods with the calibration transfer from PFR was performed in Davos and Rome, and showed for IL differences always greater than the uncertainties (%CV) of the method, for both wavelengths, with the exception of Davos in 2017. Values are around 1% in Davos whereas the largest differences are in Rome and at 500 nm, likely due to the unfulfilled assumption that the complex refractive index do not largely change during the Langley plot.

On the other hand, for XIL many differences are within the uncertainties (%CV) of the method, and those higher are closer to the %CV values than in the IL method. XIL improves the agreement particularly in Rome where the largest difference reduces from 3.5% to 2.5% at 500 nm and from 3% to 1.7% at 870 nm.

Future studies are planned to understand the effects of atmospheric scattering variability on the IL method and of the molecular polarization on 340 nm, switching from the use of the Skyrad 4.2 pack to the Skyrad_MRI (Kudo et al.,2021).

The solar disk scanning methods 3m and 3n performed in Rome and Izana were compared against the laboratory calibrations. The difference varied from a minimum of 0.03% at 400 nm to a maximum of 3.46% at 870 nm in Rome and from 0.23% at 1020 nm to 2.07% at 870 nm in Izana. Both the methods slightly overestimate the SVA values in Rome. The 870 nm shows the highest discrepancy in both the sites and for both the solid3m and 3n methods for the two POMs. A generally better accordance with the laboratory calibration was found for the solim3m method. An overestimation by the on-site procedures in the range [500-870] nm wavelengths is observed in both the sites due probably to an effect of the scattered light from aerosols and air molecules included in the measurement and to a contribution of the direct solar light striking the lens. The scattering contribution and stray light reaching the detector increase the output, and the integrated value has a larger magnitude that can affect the estimation of the SVA. The overestimation was lower in Izana due to a less important scattering effect.

Finally, a closer look at the effects of the on-site calibrations procedures uncertainties on the retrieval of aerosol optical depth, single scattering albedo and absorption aerosol optical depth is investigated in an upcoming paper.

Gröbner, J., Kouremeti, N., Hülsen, G., Zuber, R., Ribnitzky, M., Nevas, S., Sperfeld, P., Schwind, K., Schneider, P., Kazadzis, S., Barreto, Á., Gardiner, T., Mottungan, K., Medland, D., and Coleman, M.: Spectral aerosol optical depth from SI-traceable spectral solar irradiance measurements, Atmos. Meas. Tech., 16, 4667–4680, https://doi.org/10.5194/amt-16-4667-2023, 2023

Hashimoto et al, 2012 (https://doi.org/10.5194/amt-5-2723-2012) demonstrated that a SVA underestimation of 1.4 % to 3.7 % can cause an increase of SSA of about 0.03 to 0.04. This estimation was done for Skyrad pack version 4.2. For the Skyrad_MRI_v2, actually used as Skynet standard inversion model, it is expected to be similar because the same forward model, RSTAR, is used in the retrieval and the relation between SSA and diffuse radiance is the same.
