28 **Abstract:**

29 Cloud seeding experiments for modifying clouds and precipitation have been underway for nearly a
30 century; yet practically all the attempts to link precipitation enhancement or suppression to the
31 presence of seeding materials within clouds remain elusive. In 2019, the Cloud-Aerosol Interaction
32 and Precipitation Enhancement Experiment (CAIPEEX) investigated residuals of cloud
33 hydrometeors in seeded and non-seeded clouds with an airborne mini-Aerosol Mass Spectrometer
34 (mAMS). The mAMS was utilized in conjunction with a counterflow virtual impactor (CVI) inlet
35 with a cutoff diameter size of approximately 7 μm . The evaporated cloud droplets from the CVI inlet
36 as cloud residuals were evaluated through the mAMS. The Chlorine (Cl) associated with
37 hygroscopic materials, i.e., Calcium Chloride (CaCl_2) and potassium (K), which serve as the
38 oxidizing agents in the flares, is found in relatively higher concentrations in the seeded clouds
39 compared to the non-seeded clouds. In convective clouds, Cl and K as cloud residuals were found
40 even at an distance 2.25 km from the cloud base. Major findings from the seeding impact are: an
41 increase in the number concentration of small ($<20 \mu\text{m}$) droplets and an indication of raindrop
42 formation at 2.25 km above the cloud base. It is demonstrated that the seed particle signature can be
43 traced inside clouds along with the microphysical impacts.

51 **1. Introduction:**

52 E.G. Bowen first proposed in 1952 that hygroscopic particles can foster collision-coalescence
53 (CC) processes in a cloud (Bowen, 1952). Since then, cloud seeding experiments have been
54 conducted worldwide to mitigate and respond to the ever-increasing urban water demand during a
55 drought season or in drought-prone regions. More than 50 countries are involved in weather
56 modification projects (Flossmann, et al., 2019). Over the years, the interest in rain enhancement
57 projects has increased due to the accumulating evidence of a potentially positive effect (i.e.,
58 enhancement in rainfall) in several seeding experiments (Mather et al., 1996; Mather et al. 1997;
59 Bruintjes, 1999; WMO, 2000; Gayatri et al., 2023; Prabhakaran et al., 2023). However, skepticism
60 remains within the broader cloud physics community because the efficacy of many cloud seeding
61 experiments remains inconclusive (Ryan and King, 1997; Silverman, 2003; Flossmann et al., 2019).
62 In addition to the existing challenges of evaluating the effectiveness of cloud seeding experiments,
63 other pivotal longstanding issues revolve around accurately detecting the hygroscopic particles
64 released within a cloud, identifying the seeded cloud, and comprehending the impact of seeding on
65 the cloud microphysical properties.

66 Traditionally, in a cloud seeding experiment tracers such as the inert gas, sulfur hexafluoride
67 (SF_6) (Stith, et al., 1986; Stith et al., 1990; Bruintjes et al., 1995; Rosenfeld et al., 2010), or radar
68 chaff at cloud bases are released, and then efforts are made to measure these tracers higher in the
69 cloud. However, tracing of SF_6 in a seeded cloud is challenging and successful trials have been
70 reported only on a few occasions near the cloud base (Rosenfeld et al., 2010). The detection of SF_6
71 and chaff traces is hampered by detection limits, especially in the presence of high background
72 concentrations. Using these tracers as proxies for tracking air masses carrying seeding material is
73 limited by the challenge of unambiguously connecting their presence with the seeding material due

74 to their non-reactive nature with cloud particles. Consequently, several questions arise during these
75 experiments. For instance, does the dispersed seeding material effectively enter the targeted cloud
76 region? Up to what altitude do these materials reach? Are the in-situ measurements being conducted
77 within the intended cloud volume? How can transported flare particles be located within large
78 clouds? Due to these uncertainties the need to more quantitatively evaluate the direct link between
79 seeding materials and the formation of cloud hydrometeors, the development of a low-impact but
80 more effective tracer has been recommended, e.g. Tessororf et al., (2012).

81 A critical question in any cloud seeding experiment is whether the observed changes in the
82 cloud microphysical properties after seeding are due to the introduction of seeding material or to
83 natural cloud processes. There are two requirements necessary to address this question: (i) Can the
84 trajectory of seeding material be successfully traced in the cloud, and (ii) can changes in cloud
85 microphysical processing be linked to seeding materials? In this study, an instrumented aircraft was
86 deployed to acquire convincing evidence that addresses these questions. This work primarily
87 addresses how to trace seed particles' signatures in clouds and focuses on the question of changes in
88 cloud microphysical properties due to the introduction of seeding particles. This novel technique
89 uses a mini-Aerosol Mass Spectrometer (mAMS) (Jayne et al., 2000) behind a counterflow virtual
90 impactor (CVI) (Noone et al., 1988; Shingler et al., 2012) to identify seeding material in the cloud
91 droplets residuals i.e., the aerosols that remain after evaporation of the cloud droplets.

92 The hygroscopic cloud seeding hypothesis relies on a chain of microphysical processes.
93 Dispersal of giant cloud condensation nuclei (CCN), hygroscopic particles with diameter between 1-
94 10 μm , in the updraft region of cloud base adds larger drops to the tail of the natural cloud droplet
95 size distribution (DSD), known as the 'tail effect'. This effect further accelerates the formation of
96 raindrops through CC (Segal et al., 2004; Segal, et al., 2007; Kuba and Murakami, 2010; Konwar et

97 al, 2023). With the initial activation and growth of these larger CCN, the supersaturation over water
98 droplets (SS_w) decreases above the cloud base. As a result, the smaller, natural CCN do not activate.
99 This effect reduces the total droplet number concentration (N_t , cm^{-3}) and broadens the DSDs, a
100 phenomenon known as the ‘competition effect’. This broadening fosters the droplet growth rate by
101 intensifying the CC process, which accelerates the formation of precipitation (Cooper et al., 1997;
102 Rosenfeld et al., 2010). Past studies used in-situ measurements to evaluate well-formed seeded
103 clouds whose formation revealed a broadening of the DSDs by hygroscopic seeding in marine
104 stratocumulus clouds (Ghate et al., 2007). Researchers reported that an increased concentration of
105 small cloud droplets occurred at an earlier stage, while at a later stage, an increased concentration in
106 the large size range of 20-40 μm was noted. In another study, SF_6 was used to track air parcels in a
107 seeded cloud, where milled salt particles were used as the seeding agent. In this study a broadening
108 of the DSD was observed (Rosenfeld et al., 2010). Linking the evolution of cloud microphysical
109 processes to hygroscopic seeding remains elusive despite worldwide hygroscopic cloud seeding
110 experiments (Flossmann et al., 2019; Silverman 2003; Tessendorf et al., 2012). The major hurdle is
111 that the physical processes leading to precipitation formation are dynamic and complex and difficult
112 to directly and quantitatively track and link to the seeding (Tessendorf et al., 2012).

113 In the current study, using an mAMS, we demonstrate that the seeding signatures within
114 stratus and convective clouds are detectable with an evidence-based approach without using tracer
115 gasses. We further show that the seeding materials and the seeding-activated cloud droplets in
116 convective clouds can propagate to higher altitudes while also modulating the cloud’s microphysical
117 properties. The ultimate goal is to investigate the microphysical pathways that are modified in cloud
118 seeding operations. These experiments took place in the region near Solapur (17.66° N, 75.90° E),

119 India, during the Cloud-Aerosol Interaction and Precipitation Enhancement Experiment (CAIPEEX)
120 (Prabha et al., 2011; Kulkarni et al., 2012; Prabhakaran et al., 2023) in 2019 (phase-IV).

121 **2. Materials and Methods:**

122 **2.1 Measurements of cloud properties.**

123 Three cloud seeding events carried out on 21 August, 23 August and 24 August in 2019, are
124 selected here for evaluation of seeding signatures and plausible links to microphysical properties.
125 Instruments for the measurement of flare particles, aerosol, and cloud properties were operated on a
126 Beechcraft-B200 aircraft. This aircraft was equipped with flare racks located under both the wings
127 and the belly. The flare racks in the wings are used for warm cloud seeding operations (Mather et al.,
128 1997), while the belly is utilized for cold cloud seeding operations (French et al., 2018; Friedrich et
129 al., 2020). The temperature (T , °C), relative humidity (RH%), wind speed (ms^{-1}) and wind directions
130 were measured with the Airborne Integrated Meteorological Measurement System (AIMMS-20).
131 The DSD in the size range of 2-50 μm was measured with a Cloud Droplet Probe (CDP-2)
132 manufactured by Droplet Measurement Technologies LLC, USA. The bulk microphysical properties
133 are derived from the measured DSDs, e.g. the total number concentration (N_t , cm^{-3}) and liquid water
134 content (LWC, g m^{-3}). The effective radius (r_e , μm) was calculated from the ratio between the third
135 and second moments of the DSDs (Martin et al., 1994). The Precipitation Imaging Probe (PIP) was
136 used to document drizzle drops in the cloudcover the size range of 100-6200 μm . The technical
137 specifications of these instruments are shown in Table 1. The uncertainties associated with the CDP,
138 and single particle light scattering instruments like the CDP, have been well characterized and
139 documented (Baumgardner et al., 1983, 2001, 2016; Lance et al., 2010). In water droplets the sizing

140 uncertainty is $\pm 20\%$ and counting accuracy $\pm 16\%$, which propagates into a LWC uncertainty of
141 $\pm 38\%$.

142 Cloud properties are altered by the entrainment of cloud-free air masses at the edges of the
143 cloud; hence to minimize the influences of entrainment and mixing processes in the seeded and non-
144 seeded clouds, only clouds with near adiabatic or slightly diluted cloud parcels are considered to
145 evaluate cloud microphysical properties. Only cloud passes with LWC in the range of $0.75 <$
146 $LWC/LWC_{\max} < 1$ (Konwar et al., 2021) were selected for this study. Here, LWC_{\max} represents the
147 maximum measured value of LWC during a cloud pass. Note that this cloud regime may be
148 considered as the cloud core, typically located within the strongest updrafts zone. Our main aim is to
149 select the DSDs located within the cloud core regime. Note that in most naturally developing clouds
150 the LWC_{\max} values are less than the adiabatic LWC (LWC_{ad}) values because of the entrainment of
151 drier air, mixing, precipitation fallout and radiative heating/cooling (Korolev et al., 2007). The
152 maximum adiabatic fraction, $AF_{\text{mx}}=LWC_{\max}/LWC_{\text{ad}}$, indicates the extent of dilution that has
153 occurred in the cloud core regime. During their development and dissipation stages clouds undergo
154 significant changes; therefore, it is practically impossible to find two clouds identical in all states, let
155 alone their lifetimes. It is to be noted that the AF values may not accurately represent the mixing
156 state when CC is significant and drizzle particles form within the clouds. Additionally, studies of the
157 seeding effect using parcel model simulations without the inclusion of mixing processes indicates a
158 significant change in the LWC profile compared to the non-seeded cloud (Konwar et al., 2023). Such
159 changes in LWC values at different vertical distances from the cloud base of the seeded clouds do
160 not necessarily imply the true dilution rate in the observations. Since the cloud seeding flare
161 produces high concentrations of small-sized particles, they can be activated into cloud droplets in
162 strong updraft regimes with high supersaturation (Konwar et al., 2023; Prabhakaran et al., 2023). In

163 a parcel model simulation, small aerosols released from flares are found to be activated due to an
164 increase in supersaturation when the collision-coalescence process is active (Konwar et al., 2023).
165 For details on the nucleation process within the zone of intense collision, where rapid decrease in
166 drop concentration leads to an increase in supersaturation, readers are referred to Pinsky and Khain
167 (2002). At a given height, however, seeding does not change the adiabatic value, but activation of
168 new particles at a given level due to seeding can alter the AF. Another aspect is that near the cloud
169 base the LWC_{ad} values are quite small (e.g., $< 1 \text{ g m}^{-3}$), therefore any small change in the measured
170 LWC could indicate a large change in AF. With this background information in mind, the DSDs for
171 Seed Cloud (SCI) and No Seed Cloud (NSCI) conditions are compared at different vertical distances
172 above the cloud base (D^* , km). The lowest unbroken visible section of a convective cloud was
173 selected as the cloud base. The cloud top is defined as the maximum altitude attained by these clouds
174 at any given moment during their development.

182

183 2.2 Measurement of hygroscopic flare particles by mAMS and Correcting time trends of slow- 184 vaporizing species

185 We utilized a mAMS to analyze the chemical compositions of residual particles from cloud droplets,
186 specifically to trace flare particles within the seed clouds. The CVI is manufactured by Brechtel
187 Manufacturing Inc. (BMI, Model 1204, www.brechtel.com). The cloud droplets were passed through
188 the CVI to obtain the droplet residual that were sampled by the mAMS. Through the use of inertial
189 impaction, the CVI inlet allows cloud hydrometeors with aerodynamic diameters larger than a
190 certain size to pass through, depending on the velocity of the counterflow. A warm, particle-free dry
191 nitrogen gas is directed towards the inlet against the direction of the ambient air flow. This causes a
192 separation of in the incoming free stream air, with particles $>7 \mu\text{m}$ in the sampled air having enough
193 inertia to penetrate the counterflow and join the sample flow. The CVI adjusted flow rates with its
194 internal software based on true air speed (TAS) obtained from the AIMMS. The cut-size is a
195 function of various factors, e.g., air pressure, air speed, and the average angle of attack, is known to
196 have an uncertainty of approximately $\pm 1 \mu\text{m}$. The heated air evaporates cloud droplets and the
197 remaining dried residuals enter the mAMS where their chemical compositions are classified. Details
198 of the operational principles of the CVI can be found in Ogren et al., 1985; Ogren, 1987; Noone et
199 al., 1988; Shingler et al., 2012; Golderger et al. 2020; and references therein.

200 The mAMS measured the residual particles with vacuum aerodynamic diameters of less than $1 \mu\text{m}$,
201 sampling through an aerodynamic lens. The aerosol sample stream is intermittently blocked to
202 measure background signals. The aerosol signal is the difference between unblocked ("open")
203 measurements and those obtained during the blocked ("closed") period. The mAMS sampled 10
204 seconds of closed signal for every 110 seconds of open. The heater, operated at $600 \text{ }^\circ\text{C}$, vaporized
205 the sample, electron impact ionized the vapors, and the resultant ions were extracted into the mass

206 analyzer for measurement of chemical composition and mass distributions (Jayne et al., 2000;
207 DeCarlo et al., 2006; Canagaratna, et al, 2007; Drewnick et al., 2015; Giordano et al., 2018; Salcedo
208 et al., 2006).

209 Ice Crystal Engineering (ICE) Inc. (USA) manufactured the hygroscopic flares used in this
210 work. The flares were composed of an aggregated mixture of potassium perchlorate (KClO_4) and
211 calcium chloride (CaCl_2) (Hindman, 1978; Bruintjes et al., 2012).

212 For non-refractory ambient aerosol species (i.e., NH_4 , NO_3 , SO_4) aerosol concentrations are
213 obtained from the difference between the open and closed signals. The vaporization of non-
214 refractory aerosol species at 600°C typically completes on the timescale of hundreds of
215 microseconds, however, semi-refractory species such as metals and salts may take minutes to
216 completely vaporize (Canagaratna et al., 2007; Salcedo et al., 2006).

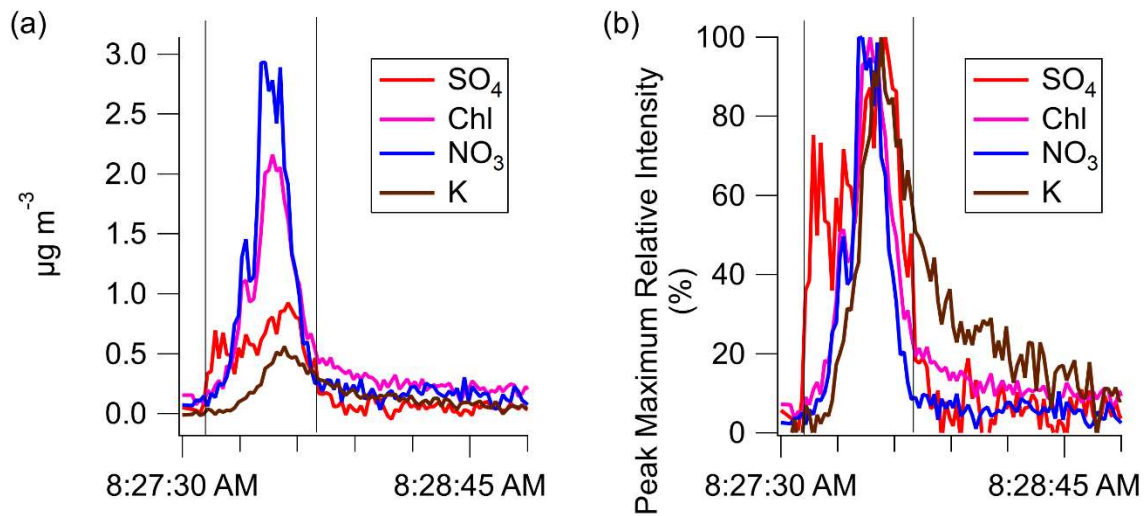

217 As discussed below, the Cl, HCl, and K from the KClO_4 and CaCl_2 in flares is a semi-
218 refractory species which exhibits slow vaporization. These slow vaporizing species were analyzed
219 using only the open signals. The background signal was calculated from measurements obtained
220 immediately before the cloud intercept of interest.

221
 222 **Figure 1.** Laboratory atomized CaCl₂ AMS measurements observing slow vaporization of semi-
 223 refractory Cl species on 2/12/2020. Atomization begins at 5:07 PM ending at 5:09 PM. Slow
 224 vaporization is evident after 5:10 PM. The presence of NO₃, NH₄, and SO₄ are from calibration
 225 species (NH₄NO₃, NH₄SO₄) contaminants in the atomizer.

226 CaCl₂, the seeding component in the flares, has a melting point of 774 °C. Laboratory
 227 measurements of atomized CaCl₂, primarily detected as Cl and HCl ions, exhibit the same slow
 228 vaporization seen in refractory salts (Drewnick et al., 2015). Fig. 1 shows a comparison of
 229 vaporization timescales of CaCl₂, NH₄NO₃, and (NH₄)₂SO₄ obtained with an AMS during laboratory
 230 measurements of CaCl₂ in solution with H₂O which had been atomized and passed through a drier
 231 before sampling. This behavior differs from that observed from non-refractory NH₄NO₃ and
 232 (NH₄)₂SO₄, which were present as tracers.

233

234

235 **Figure 2.** (a) shows the slowed time response of the species K and Cl for a seeded cloud pass on
 236 August 23rd (b) the relative intensity with respect to peak maximum of each species highlights the
 237 slowed decay of K and Chl compared to SO₄ or NO₃.

238 The seeded cloud pass shown in Fig. 2a illustrates a single seeded cloud pass. The K and Cl
 239 time series have a delayed decay to background compared to sulfate or nitrate. The relative intensity
 240 shown in Fig. 2b highlights the delayed response in the decay of the two flare associated species (K,
 241 Cl).

242 An exponential decay was fit to each cloud intercept, from the signal peak to 5 e-folding
 243 times. The average decay exponential (τ) for Cl, and K across all seeded cloud intercepts, is shown in
 244 Table 2.

245

246

247

248

Table 2

249 Average decay time constants from seeded cloud intercepts during CAIPEEX- IV, 23 August 2019.

T	K	HCl	Cl
Mean	6.7	3.4	3.3
Std Dev	2.3	0.5	0.8

250

251

252 **Figure 3.** The measured semi-refractory open K signal and corrected K* signal from the mAMS are
 253 depicted for a seeded cloud pass on 23 August 2019. The periods from the beginning to the end of
 254 the cloud passes are also shown.

255

256 For each slowly vaporizing species, a new corrected time series was created. The start, stop, and
 257 maximum total mass times were identified for each cloud pass (Fig. 3). For each species, a
 258 background signal was determined from measurements during the non-cloud period preceding each
 259 pass. This background was subtracted from the signal observed during each cloud intercept.

260 The cloud intercept time series peak at the same time as the uncorrected series. However, the tails
 261 were corrected to decay within 5 tau e-folding times, while preserving the total mass. The equations
 262 used in these calculations are shown below.

263 The measured mass from the start of the pass to the end of the slow vaporization regime was scaled
 264 by the ratio of the total area divided by the area of fast vaporization (equation 1)

$$265 \text{Conc.}_{\text{AreaCorrected}}(t) \Big|_{\text{End}+(5\tau)}^{\text{Start}} = (\text{Conc.}(t) - \text{Conc.}_{\text{Background}}) * \frac{\text{Area}_{\text{Peak+Tail}}}{\text{Area}_{\text{Peak}}} \quad (1)$$

266 The decay of this normalized mass is adjusted to the exponential decay fit (Table 2) to the slow
 267 vaporized mass (equation 2). This decay extends from the cloud pass peak to the end of the normal
 268 vaporization period plus five e-folding times (Giordano et al., 2018)

$$269 \text{Conc.}_{\text{TailCorrected}}(t) \Big|_{\text{End}+(5\tau)}^{\text{Peak}} = \text{Conc.}_{\text{AreaCorrected}}(t) * e^{-(\frac{1}{\tau})t} \quad (2)$$

270 This decay-corrected time-shifted time series is normalized to the unmodified slow vaporizing total
 271 mass (equation 3)

$$272 \text{Conc.}_{\text{Corrected}}(t) \Big|_{\text{End}}^{\text{Start}} = \text{Conc.}_{\text{TailCorrected}}(t) * \frac{\text{Area}_{\text{Peak}}}{\text{Area}_{\text{Peak+Area}_{\text{Peak+Tail}}}} \quad (3)$$

273

274 Finally, we applied an enhancement factor correction to the mAMS data resulting from the ambient
 275 aerosol concentration being concentrated in the CVI by following Shingler et al., (2012).

276 **3. RESULTS**

277 **3.1.1 Slow vaporization of semi-refractory seed aerosols**

278 Although many aerosol species readily vaporize at 600 °C, some semi-refractory materials in nature
279 do not. Submicron aerosol particles in the troposphere, that contain Cl, are rarely semi-refractory
280 and vaporize quickly in the mAMS. However, Cl in seeded clouds was found to vaporize slowly.

281 The Cl measured in clouds seeded using CaCl₂ and KClO₄ exhibited the same slow vaporization
282 (Fig. 2) as Atomized CaCl₂ in the laboratory (Fig 1). The majority of atmospheric Cl-containing
283 aerosols are non-refractory. In our study the slowly vaporizing Cl was only observed in seeded
284 clouds; thus, we assume that the source of the slow vaporizing Cl was from the flare material.

285 Aerosol K is uncommon except as super micron mineral dust. As shown in Fig.2b, slowly vaporizing
286 signals of Cl and K were observed in the campaign during seeded cloud intercepts.

287 The combination of the isolation of cloud residuals by the CVI and the presence of K and semi-
288 refractory Cl allow for discrimination of the particles containing the flare combustion products.

289 The element Ca, was also present in the flare. The boiling point of Ca of 1484 °C at ambient
290 pressure means that this species was not vaporized inside the AMS and is thus considered a
291 refractory species. Since Ca could not be observed in our study, the focus remained on the other
292 species present.

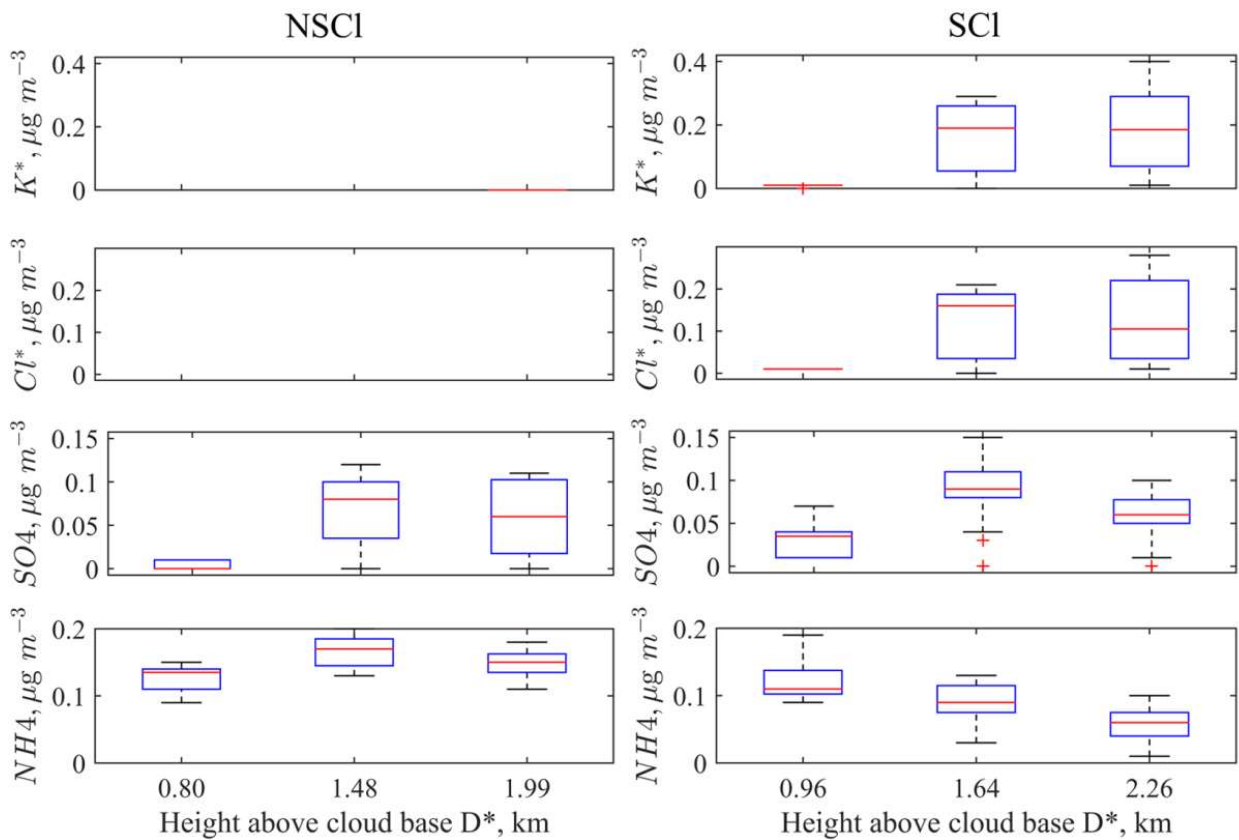

293 As previously discussed, the time series of semi-refractory Cl and K signals are corrected to account
294 for the difference in the decay response of slowly vaporizing species in the mAMS. Fig. 3 depicts
295 the corrected (K*) and uncorrected semi-refractory K signals in the mAMS measurements for a
296 seeded cloud pass, defining the periods for the start, peak, end, and tail of the pass.

297

298

299

300

301

302

303

304

305

306

307

Figure 4. mAMS measurements of the mass concentrations of Cl^* , K^* , NO_3 , and SO_4 versus D^* (km) for cloud particle residuals from six cloud passes through the same cloud on 23 August 2019. The vertical profile box plots of each mAMS species at different altitudes shows median concentration and range (25-75th percentiles). Three non-seeded clouds (NSCI) and three seeded clouds (SCI) are shown.

308 A vertical profile of cloud residual aerosols, within the same cloud, taken before and after
309 seeding, provides a platform for measuring and observing cloud physical and chemical changes. The
310 resultant mAMS measurements from one such experiment, on August 23, 2019, with three cloud
311 passes of the same cloud before and three passes after seeding are shown in Fig 4.

312 In the mid level, all chemical species were found in higher quantities in the seeded cloud than in the
313 non-seeded cloud. Cl and K concentrations were significantly increased for all seeded cloud passes
314 compared to non-seeded cloud passes. The measurement of the flare chemical species in the seeded
315 cloud indicates that the mAMS could successfully identify the cloud droplets that containing
316 seeding material.

317 An additional observation is the increased NO_3 and SO_4 concentration in the cloud drops of seeded
318 clouds at upper heights. We hypothesized that the increased concentrations of these two chemical
319 species could be linked with the activation of the flare particles and other organics while mixing with
320 the naturally available NO_3 and SO_4 aerosols. The increased concentration of NO_3 in the seeded
321 cloud may also be due to the presence of more LWC. The additional water drives nitric acid (HNO_3)
322 from gas to liquid NO_3 (Wang and Laskin, 2014).

323 This example highlights the ability of the mAMS to identify flare associated species, by both
324 increased concentration and time response, in order to confirm the presence of seeding material in
325 cloud droplet residual.

326

327 **3.2 Seeding experiment, Seeding Signature, and Cloud properties**

328 **3.2.1. Case i: 21 August 2019.** The flight pattern of the aircraft during the cloud seeding
329 experiment conducted on 21 August 2019 in a warm stratus layer is shown in Fig. 5a. The objective

330 was to identify the seeding materials and record the cloud microphysical properties. The wind
331 direction was north-westerly at an altitude of nearly 4.10 km with a mean wind speed of 7 ms^{-1} .
332 Cloud passes ($T=5.14 \text{ }^\circ\text{C}$, $H=4.39 \text{ km}$) were made through the stratus layer before the dispersal of
333 seeding materials. Four hygroscopic flares were burned, two at a time, inside the layer cloud, from
334 8:01-8:08 UTC at $H=4.10 \text{ km}$. Weak updrafts ($W=0.61\pm 1.53 \text{ m s}^{-1}$) prevailed indicate that the flare
335 material might have drifted horizontally. Increased mass concentrations of K^* and Cl^* are noted in
336 the downwind after the dispersal of the seeding agents, as shown in Fig. 5b and 5c. Repeated
337 crosswind cloud passes at a similar level ($T= 6.44 \text{ }^\circ\text{C}$, $H= 4.10 \text{ km}$) were made downwind of the
338 seeding. The aircraft could release non-volatile and fine aerosol particles through exhaust emission
339 (Anderson et al., 1998), which may also contaminate the cloud mass. Prabhakaran et al. (2023)
340 measured aerosol size distribution of background air mass, and then the background with aircraft
341 exhaust during CAIPEEX. They reported that the aircraft exhaust can impact mean radius, spectral
342 width and number concentrations of different modes of log-normal aerosol size distribution (see the
343 supplementary materials at <https://doi.org/10.1175/BAMS-D-21-0291.2>). Solution of simple
344 advection equations indicates dispersal of seeding plumes in the downwind region after nearly 3
345 minutes (not shown here) where the aircraft also recorded enhanced concentrations of K^* and Cl^* .
346 Gayatri et al., (2023) illustrated the seeding impact downwind of the seeded area through the high-
347 resolution numerical model in similar monsoon environment with the monsoon low-level jet (LLJ)
348 as detailed in the present study. The cloud bases are situated very close to the region with high wind
349 speeds in the monsoon low-level jet and the advection of seeding plume downwind of the seeded
350 location is noted. However, the fact that seeding was done specifically in the strong updraft zones
351 and the seed particles were also lifted inside the cloud and more cloud droplets were noted both in
352 the observations and simulations. Earlier, during the Seeded and Natural Orographic Wintertime

353 Clouds: The Idaho Experiment (SNOWIE) (Xue et al., 2022) noted seeding plumes dispersed within
354 orographic clouds in more than 1 hour along the slanted downwind direction.

355

356

357 **Figure 5.** (a) The flight path during the seeding experiment on 21 August 2019 color coded by LWC
358 at 1 Hz resolution. Periods during which cloud measurements were made for non-seeded clouds
359 (NSCI) and seeded clouds (SCI) are annotated. Mass concentrations of (b) K^* and (c) Cl^* during the
360 seeding experiment are shown along the flight track. The ambient wind fields shown as arrow
361 obtained from <https://cds.climate.copernicus.eu/> ($0.25^\circ \times 0.25^\circ$), which are resampled to $0.125^\circ \times$
362 0.125° . A small area of elevated K and Cl , prior to the flare burning is noted. This was measured
363 outside the cloudy region as suggested by the LWC values and it might be appeared probably due to
364 other unknown sources.

365
 366 **Figure 6:** Box plots of (a) total droplet concentrations, (b) Effective radius, (c) LWC are shown for
 367 NSCI and SCI. (d) Mean cloud DSDs with standard deviations (vertical bars) are depicted indicating
 368 the variability. The selected DSDs fall within the criteria of $0.75 < LWC/LWC_{max} < 1$.

369 Stratus cloud passes were selected for study based on two criteria: a cloud pass duration
 370 greater or equal to 5 seconds and $N_t > 10 \text{ cm}^{-3}$. Two NSCI cloud passes made during 7:53:00-7:53:31
 371 UTC and 7:55:17-7:55:41 UTC were chosen for the analysis. After the flares had dispersed, three
 372 passes during 08:08:37-08:08:45 UTC, 8:09:42-8:09:53 UTC, and 8:09:59-08:10:39 UTC were
 373 selected based on the elevated levels of detection of K and Cl (see Fig. 5b and 5c). Box plots of N_t ,
 374 r_e and LWC are displayed for NSCI and SCI in Figs. 6a, b and c, respectively. It is worth noting that
 375 the SCI cases exhibit greater median values for these three parameters. The properties of DSDs along

376 the cloud pass are shown in Supplementary Figs. S1 and S2. The DSD properties and mass
377 concentrations of K^* and Cl^* are provided in Table 3. Increased droplet concentrations in the
378 smallest size bin are noted after a few minutes from the seeding time while drizzle drops were not
379 observed in the SCl. Comparisons are made for mean SCl-DSD and NSCl-DSD in the range
380 $0.75 < LWC/LWC_{max} < 1$, as illustrated in Fig. 6d. An increase of $N(D)$ at $D \approx 3 \mu m$ and in the size
381 range $13 < D < 20 \mu m$ are noted in the SCl, while $N(D)$ decreased in the size range $4 < D < 13 \mu m$.
382 The increase in the smallest cloud droplets may be due to freshly nucleated aerosols, likely due to
383 the activation of seeding materials. The increase in the mid-size droplet concentrations could be due
384 to the activation of coarse mode aerosols and subsequent diffusional growth. Since drizzle drops
385 were not formed, it may suggest that hygroscopic seeding in stratus cloud with low LWC value e.g.
386 $< 0.5 g m^{-3}$ may not yield a significant positive seeding effect for the production of drizzle.

387

388 **3.2.2 Case ii: 23 August 2019.**

389 Fig. 7a depicts the flight patterns for the case on 23 August 2019. This seeding event is selected for
390 evaluation because (i) The SCl and NSCl convective clouds were isolated and in the growing and
391 non-precipitating stages, (ii) the cloud top was below freezing level (5 km) therefore ideal for
392 studying warm rain microphysics, (iii) The SCl and NSCl were formed within the same area (20 km
393 x 20 km) and lastly, (iv) both the SCl and NSCl grew to similar cloud top altitudes (≈ 4 km),
394 therefore roughly at similar growth stages. These conditions made this case suitable for evaluating
395 the seeding effect on warm rain. The cloud base height over the observational area was nearly 1.80
396 km. Northwesterly winds (mean wind speed of $12 ms^{-1}$) prevailed in the boundary layer at 1.30 km
397 (850 mb). Before the dispersal of flare materials at cloud base, the cloud microphysical properties of
398 NSCl were measured from 7:49 to 8:06 UTC by step-wise multiple cloud penetrations from the top

399 (≈ 3.90 km) to near the cloud base (≈ 1.80 km). A maximum updraft of 4.40 ms^{-1} was observed at
400 the cloud base. After completion of NSCI measurements, the aircraft then circled below the cloud
401 base and burned four hygroscopic flares (two on each wing) in the updrafts during 8:08-8:12 UTC,
402 followed by several step-wise cloud penetrations at nearly 1000 ft intervals, from near the cloud base
403 to cloud-top during the period 8:14-8:28 UTC.

404 The profiles of N_t and r_e *w.r.t.* the D^* s are shown in Fig. 7(b,c). The mass concentrations of
405 K^* and Cl^* corresponding to N_t and r_e , respectively, are also indicated. The statistical properties of
406 the DSD parameters are presented in Table 3. The variations of DSDs along the cloud transects,
407 values of r_e , drizzle concentration, LWC, and W are shown in the supplementary material's Figs. S3-
408 4. Note that the SCI and NSCI were not identical due to the natural variability discussed previously,
409 with this background the following observations are noted:

410

411

412
413

414 **Figure 7.** (a) Flight track during the seeding experiment on 23 August 2019. The flight track during
 415 the flare burning period is overlaid with black color. The areas of seeded cloud (SCI) and non-seeded
 416 cloud (NSCI) are indicated on the figure panels. The arrow indicates the wind direction near the
 417 cloud base height of 1.80 km. The color bar indicates the liquid water content (LWC, gm^{-3}) of
 418 clouds. Profiles of (b) N_t , (cm^{-3}) and (c) r_e , (μm) *w.r.t.* height above cloud base, D^* (km) are shown.
 419 The parameters are indicated in the color bars with the mass densities of K^* and Cl^* , ($\mu\text{g m}^{-3}$). The
 420 squares with black edges indicate NSCI, while filled circles indicate SCI. The sizes of the symbols
 421 increase with increasing mass of the chemical components. Mean cloud drop size distributions with
 422 standard deviations indicated by the error bars of slightly diluted clouds ($0.75 < \text{LWC}/\text{LWC}_{\text{max}} < 1$) at
 423 various D^* (km), for NSCI and SCI, (d), (e) and (f).

424

426 Cloud properties of Non-Seeded Cloud (NSCI) and Seeded Cloud (SCI) along the cloud transect are
 427 shown. Vertical distance above the cloud base (D^* , km), Mean values and standard deviation of total
 428 droplet concentration N_t , (cm^{-3}) in the diameter range 2-50 μm , maximum droplet concentration
 429 ($N_{t\text{max}}$, cm^{-3}), mean effective radius (r_e , μm), liquid water content (LWC, gm^{-3}), Maximum LWC
 430 (LWC_{max}), maximum adiabatic fraction ($\text{AF}_{\text{mx}} = \text{LWC}_{\text{max}}/\text{LWC}_{\text{ad}}$), where LWC_{ad} is the adiabatic
 431 LWC calculated from a parcel model. AF_{mx} for layer clouds on 21082019 is not calculated. The
 432 mean of small droplet concentration ($D < 11 \mu\text{m}$) and the maximum of small droplet concentration,
 433 and drizzle concentration (DrizzleCon, (cm^{-3}) are also shown. Concentrations of K^* and Cl^* in $\mu\text{g m}^{-3}$
 434 3 during NSCI and SCI observations are indicated. Due to limited field calibrations, the
 435 concentrations presented here are nitrate equivalent. Below Detection Limit (BDL) data are
 436 indicated.

Case	D^* (km)	$N_{t\text{mn}}$ $\pm\text{SD}$ (cm^{-3})	$N_{t\text{max}}$ (cm^{-3})	r_e $\pm\text{SD}$ (μm)	LWC $\pm\text{SD}$ (gm^{-3})	LWC _{max} (gm^{-3})	AF_{mx}	$N_{t\text{mn}}, [N_{t\text{mx}}]$ ($D < 11 \mu\text{m}$)	DrizCon $\pm\text{SD}$ (cm^{-3})	Mean K^* $\pm\text{SD}$ [K^*_{Max}] mg m^{-3}	Mean Cl^* $\pm\text{SD}$ [Cl^*_{max}] mg m^{-3}

438 (i) At nearly $D^* = 0.96$ km, smaller mean concentrations of N_t ($186 \pm 158 \text{ cm}^{-3}$) are noted for
439 SCl compared to the NSCl ($N_t = 208 \pm 198 \text{ cm}^{-3}$) cloud pass at $D^* = 0.80$ km. At these two nearly
440 similar levels, the mean r_e values for the SCl case ($r_e = 7.30 \pm 3.01 \text{ }\mu\text{m}$) were greater than those for the
441 NSCl case ($r_e = 6.57 \pm 2.60 \text{ }\mu\text{m}$). At greater D^* of 1.60 km ($r_e = 9.50 \pm 2.82 \text{ }\mu\text{m}$) and 2.26 km
442 ($r_e = 13.10 \pm 1.14 \text{ }\mu\text{m}$), drizzle drops (see Table 3) were noted in the SCl cases. This may indicate
443 active CC process in the SCl case. The mean DSDs are shown in Fig. 7(d,e) selected considering the
444 criteria $0.75 < \text{LWC}/\text{LWC}_{\text{max}} < 1$ of the cloud transects. The corresponding AF values indicated on
445 the panels suggest active entrainment and mixing processes in these clouds. The production of
446 drizzle in some of the clouds may also lower the AF values which means that the dilution rate is not
447 accurate in such clouds. The seeding effect may give rise to the initial production of drizzle particles,
448 which were seen within the tail of the DSDs. Hence, the tail effect of the seeding particles appears to
449 be active. Note that since the cloud passes were made in the developing stage of the cloud, these
450 drizzle drops were formed spontaneously, not falling from the cloud tops because their terminal
451 velocities are less than the updraft velocities. The broadening of the DSDs will serve to further
452 increase the efficiency of the CC process (Andreae, et al, 2004; Rosenfeld et al., 2008; Rosenfeld et
453 al., 1994; Freud et al., 2012; Konwar et al., 2012) leading to the production of drizzle drops at higher
454 D^* s. Also, stronger updrafts ($\approx 5 \text{ ms}^{-1}$) were observed in SCl (see Fig. S4n), which helped in the
455 growth of larger-sized droplets.

456 The formation of drizzle drops ($D > 100 \text{ }\mu\text{m}$) in the SCl was noted (Fig. 7(e,f) and Fig. S4) while no
457 significant drizzle concentrations were noticed for NSCl (Fig. S3). The difference in drizzle
458 concentration suggests that the flare particles modulate the mid-size cloud droplets ($D \approx 14 \text{ }\mu\text{m}$) that
459 grow further by diffusion process. As the drizzle drops fall under the influence of gravity, stronger
460 downdrafts are most likely due to the cooling by evaporation (see Fig. S4n). Moreover, small

461 droplets of $D \leq 11 \mu\text{m}$ were observed at high altitudes for both clouds (Table 3). The scatter plots
462 between $r_e\text{-K}^*$ and $r_e\text{-Cl}^*$ are shown in Fig. S5. The prevailing dynamical conditions e.g., vertical
463 velocity are also indicated. It is found that the larger sized droplets (greater r_e values) are associated
464 with the larger mass concentrations of K^* and Cl^* , in the SCl. In both the updrafts and downdrafts,
465 all these chemical species were present. Having found the seeding tracers Cl^* and K^* at different
466 altitudes, it may be emphasized that the modification of cloud properties occurs due to the dispersal
467 of seeding particles through the cloud base. Seeding particles were present at deeper D^* s as the
468 cloud droplets were transported through updrafts and re-circulated as the cloud developed (Khain et
469 al., 2013).

470 It is important to note that the differences in cloud microphysical properties observed between the
471 seeded and unseeded clouds could be a result of natural variability, and more data are needed to
472 arrive at a statistically significant result. However, given that these differences were accompanied
473 by statistically different concentrations of chemical composition in the cloud droplet residues in the
474 same environmental conditions, the evidence is compelling that seed material has a) transported to
475 altitudes above the cloud base where they were released and b) these aerosol particles have
476 influenced cloud microphysical processes.

477

478 3.2.3 Case iii: 24 August 2019.

479 The third cloud seeding case was carried out on an isolated convective cloud. The flight path is
480 shown in Fig. 8a. South-westerly winds with a mean speed of 9 m s^{-1} were noted near the cloud base
481 at 2.1 km with a maximum updraft of 8 m s^{-1} . One cloud pass before the flare dispersal was made
482 from 08:55-08:59 UTC above the cloud base at $\approx 2.3 \text{ km}$. Three downwind cloud passes during

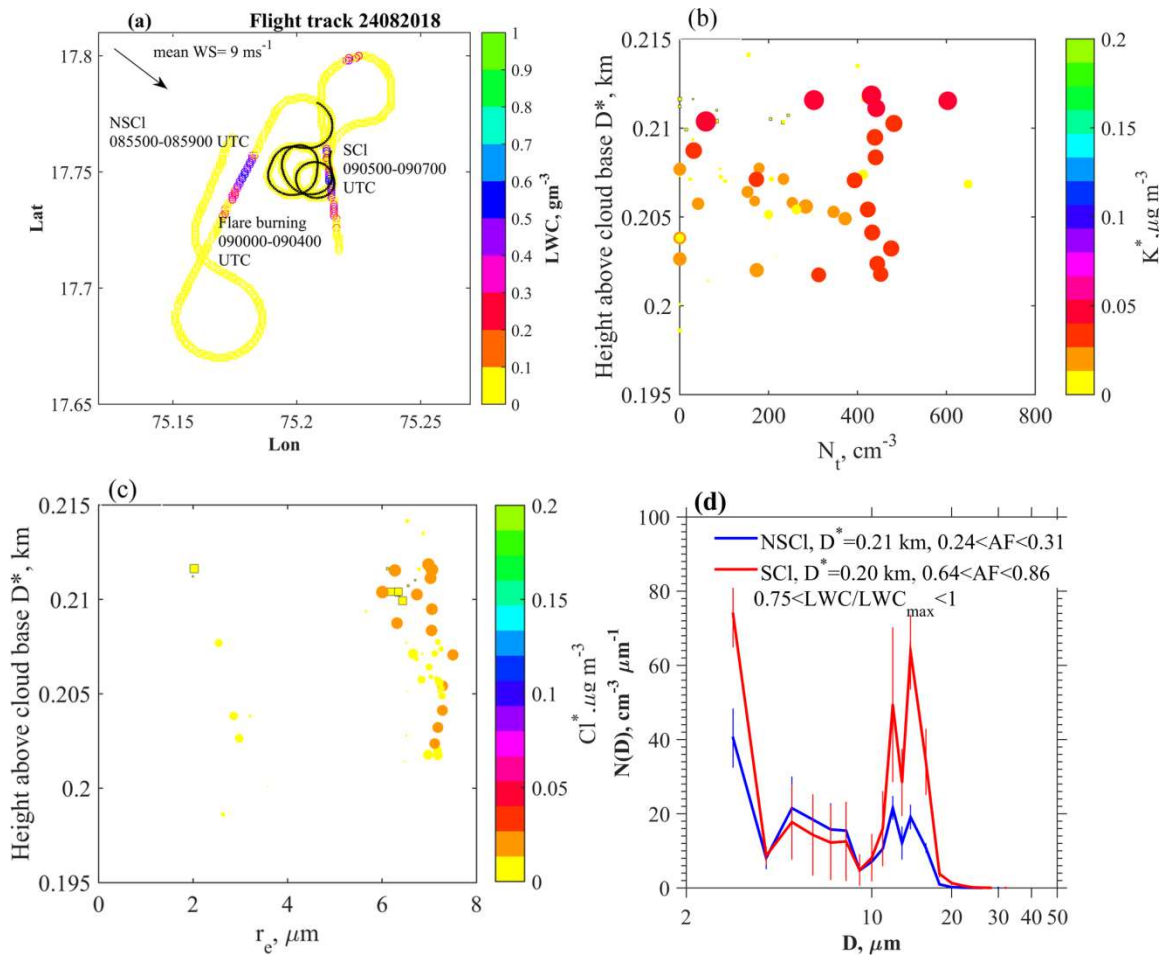

483 09:05-09:07 UTC were made at ≈ 2.3 km after the flares were burned. The variations of N_t , and r_e
484 *w.r.t.* D^* are shown in Figs. 8b,c. Increased mass concentrations of K^* and Cl^* are noted in SCl cases
485 that identify the seeded clouds. The DSD properties of the clouds are shown in supplementary Fig.
486 S6 & S7 and their parameters are indicated in Table 3. The mean DSDs (Fig. 8d) indicate increased
487 droplet concentration in the small and mid-drop diameter ranges. Note that the AF values indicated
488 strong dilution in the NSCl DSDs, which may also impact the observed differences in the droplet
489 number densities. No marginal increment in r_e values was observed in the SCl. Another aspect to
490 consider here is the effect of strong updraft of 8 m s^{-1} . Using the Twomey (1959) equation the
491 maximum droplet concentration formed in an updraft (W) can be expressed in terms of W and CCN-
492 SS spectra, i.e. $N_{CCN} = C SS^k$ i.e. (Roger and Yau, 1989),

$$493 \quad N \approx 0.88 C^{2/(k+2)} [7 \times 10^{-2} W^{3/2}]^{k/(k+2)} \quad (4)$$

494 Here, W is in cm s^{-1} , $N_{CCN} = 799 SS^{0.43}$, which is obtained from the CCN counter (Roberts and
495 Nenes, 2005; Nenes et al., 2001 and reference therein) operated in the research aircraft. During the
496 cloud passes, maximum updrafts of $W = 2.89 \text{ m s}^{-1}$, 1.00 m s^{-1} and 1.91 m s^{-1} were obtained. These
497 values suggest that droplets formed in these updrafts could be 593 cm^{-3} , 448 cm^{-3} and 531 cm^{-3} ,
498 respectively. If we use the maximum updraft speed of 8 m s^{-1} measured below cloud base, the droplet
499 concentrations formed in this updraft could be as high as 777 cm^{-3} . In this scenario, the
500 supersaturation could be greater than 1%, which can activate small-sized CCN. Therefore, the
501 presence of strong updrafts that yield high SS could be one reason for the increasing N_t in the seeded
502 clouds; while dry air mixing in the NSCl cases could be another reason for the smaller concentration
503 of N_t . These processes may be attributed for the change in LWC values in the SCl cases.

504

505

506

507 **Figure 8.** (a) Flight path during the seeding experiment on 24 August 2019. Periods during which
 508 cloud measurements were made for NSCI and SCl are indicated. The black line indicates the flare
 509 burning. Profiles of (b) N_t , and (c) r_e , *w.r.t.* D^* (km). The parameters are indicated with the mass
 510 concentrations of K^* , ($\mu\text{g m}^{-3}$), and Cl^* ($\mu\text{g m}^{-3}$). (d) Mean DSDs with standard deviations indicated
 511 by the vertical bars, of clouds ($0.75 < LWC/LWC_{\text{max}} < 1$) above the cloud base, for NSCI and SCl. The
 512 adiabatic LWC fractions corresponding to the DSDs are also indicated.

513

514

515

516 **4. Summary and conclusions:**

517 The successful identification of seeded cloud hydrometeors, and the tracing back to their
518 seeding origins in cloud seeding experiments has been an outstanding challenge for cloud seeding
519 operations. The unequivocal identification of seeding material within clouds was the primary
520 difficulty in such experiments. During the CAIPEEX 2019 seeding experiments conducted in India,
521 we measured cloud microphysical properties and traced the seeding material with an mAMS behind
522 a CVI in convective and stratus clouds.

523 In our experiments, the mAMS identified an enhancement of both K and Cl mass concentrations,
524 most likely from the oxidizing agent (KClO) and seed material (CaCl₂). In stratus and convective
525 clouds, such enhanced concentrations of refractory K and Cl should be considered as a seeding
526 signature.

527 Enhanced small-sized droplet concentrations that were measured near the cloud base of convective
528 clouds and in a warm stratus layer are noted. This result indicates that during the monsoon season
529 with an available moisture supply, even the small-sized CCN present in the seed material could be
530 activated into cloud droplets. The presence of strong updrafts near the cloud base of isolated
531 convective clouds could also play a major role in the activation of small-sized CCN to cloud
532 droplets. These strong updrafts would yield high supersaturation values, thus activating small-sized
533 CCN. The impact of strong updrafts on the activation of cloud droplets, especially when seeding
534 agents are dispersed below the cloud base, requires more focused attention and study.

535 In the case of a convective cloud, clear differences in the cloud microphysical properties of SCl
536 compared to NSCl are noted. The flare materials released below the cloud base were lifted to a
537 height of 2.25 km above the cloud base. In the lower part of the SCl larger droplet concentrations

538 were noted. The SCI also had a larger r_c than the NSCI at similar heights above the cloud base. The
539 seeded clouds contained more drizzle drops, suggesting that they reached the threshold for warm
540 rain initiation at a lower distance from the cloud base than the non-seeded clouds. These results from
541 the limited sample indicate the plausible tail effect of the largest particles in the flares, initiating
542 large cloud drops and drizzle. Though this case study indicate the importance tails effect; conclusive
543 evidence would require much more data.

544 Whether competition or the tail effect is important in a successful cloud experiment remains to be
545 examined, as the prevailing dynamical conditions can play a significant role in controlling the cloud
546 microphysical processes. These complexities need to be addressed with more experiments using
547 mAMS.

548 This study identifies a novel methodology to simultaneously track and measure the cloud seeding
549 signatures and to assess how the seeding alters the microphysical properties of clouds leading to
550 raindrop formation. The utilization of an mAMS in cloud seeding experiments together with a CVI
551 allows for identifying the seeded cloud parcels of interest, leading to a better understanding of the
552 effects on the microphysical properties of the cloud. Although these measurements of flare material
553 in seeded clouds are associated with changes in physical properties, the data set is too limited to
554 unequivocally assert that this methodology will always be successful. Future studies with a much
555 larger data set will provide more statistical evidence linking seed aerosol and increases in
556 precipitation.

557 **Acknowledgment:** Indian Institute of Tropical Meteorology, Pune and the CAIPEEX project are
558 funded by the Ministry of Earth Sciences, Govt. of India. We thank Director, IITM for continuous
559 supports. The authors are grateful to the team members, the ground staff, V. Ruge and S. Patil of

560 M/S Tesscorn AeroFluid, Inc., and the pilots for their dedicated efforts in conducting the project.
561 The authors are grateful to the Editor and two anonymous reviewers for their insightful suggestions
562 that helped improve the manuscript.

563 **Data availability**

564 mAMS and Cloud data are available at:
565 <https://iitmcloud.tropmet.res.in/index.php/apps/files/?dir=/&fileid=59847#>

566

567 **Author contributions**

568 TP and DW designed the mAMS experiment; MK, BW and ECF prepared the initial draft; KH,
569 MK, BW, ECF, SC, SB, NM, MV, SJ and TP participated in the aircraft experiment; DB, TP, DW,
570 DA, PM, MK, BW, ECF, MV, SC,SB and SAD reviewed the manuscript. All authors agree with the
571 final version of the manuscript.

572 **Competing interests**

573 The contact author has declared that none of the authors has any competing interests.

574 **References:**
