16 **Abstract:** In this work, an optimized protocol to generate an expansion-type liquid clouds with and without UV-
17 visible light irradiation conditions for simulation chamber studies is presented. Sensitivity of the process to key
18 parameters such as initial relative humidities, temperature inhomogeneities, droplets lifetime or seed particle
19 number is illustrated. The obtained clouds have shown that not all seeds particles were always activated and so an
20 iterative numerical method has been re-designed to separate cloud droplets from non-activated seed particles
21 during data analysis allowing the characterization of the cloud droplet formation properties without CCN counter
22 data.

23 Two types of experiments, clouds without irradiation (N-IC) and under UV-visible light irradiation conditions
24 (IC), have been conducted in the CESAM multiphase atmospheric chamber. Measured cloud droplet lifetimes
25 were in good agreement with atmospheric droplet lifetimes. The achieved supersaturation in the cloud was mostly
26 sensitive to the initial relative humidity in the chamber. The comparison between the cloud formation pattern of
27 N-IC and LC was also investigated. Under illumination conditions, the generated clouds clearly showed a gradual
28 activation of seed particles into droplets and thus of the microphysical properties like LWC and droplet
29 concentration, while under dark conditions, clouds faced a flash activation of seed particles. Because this
30 phenomenon may also impact the air/water partitioning of semi-volatile compounds, and it should be considered
31 for further studies, especially in further multiphase photochemical studies implying water-soluble volatile organic
32 compounds in the CESAM chamber.

33 1 Introduction

34 Atmospheric aerosol particles, acting as cloud condensation nuclei (CCN), affects the formation, as well as the
35 microphysical and radiative properties of clouds (Martinsson et al., 1999; Twomey, 1959; McFiggans et al., 2006),
36 still one of the major uncertainties in the attribution of climate forcing (Intergovernmental Panel on Climate
37 Change, 2023). The process of CCN (also named seed particles in chamber experiments) activation into cloud
38 droplet is often addressed as “cloud activation”. The cloud droplet size is controlled mainly by the local
39 meteorological parameters and physicochemical properties of CCN. CCN activation into droplet requires a
40 necessary amount of water (critical supersaturation) and depends in a complex way on cooling rate, aerosol particle
41 size, and chemical composition (Twomey, 1959).

42 Pruppacher (1986) reported that more than 90% of the atmospheric clouds on Earth re-evaporate without
43 precipitation, implying that a CCN particle is processed through several non-precipitating cloud life cycles before
44 being removed through precipitation. At the same time, a cloud droplet can absorb water-soluble gases, including
45 volatile organic compounds (VOCs), and oxidants. This reactive mixture can form less volatile compounds that
46 may remain as residues in a CCN after droplet evaporation. As a consequence turn, the cycles of formation-
47 evaporation of non-precipitating clouds have the potential of increasing the aerosol mass as well as of altering the
48 physicochemical properties of CCN (Brégonzio-Rozier et al., 2015; Ervens et al., 2011; Giorio et al., 2017; De
49 Haan et al., 2017; Hoyle et al., 2016a; Mertes et al., 2005a, 2005b).

50 In general, uncertainties still exist as these processes on or in cloud droplets are poorly understood under dark and
51 light conditions. Similarly, understanding of cloud microphysics in simulation chamber under both dark and light
52 conditions needs improved and controlled, which would be crucial to investigate the aqueous secondary organic
53 aerosol (aqSOA) formation (Lim et al., 2013) or the aging through cloud processing of already existing aerosol.
54 However, it is challenging to investigate the actual cloud droplets in the atmosphere because clouds are highly
55 complex and usually occur at inconvenient locations with sporadic and nonstationary occurrences (Stratmann et
56 al., 2004). Therefore, laboratory investigations using cloud and multiphase atmospheric chambers in conditions
57 relevant to the atmosphere are henceforth key to better understand and quantify cloud formation properties, as well
58 as the formation and aging of the organic aerosol (OA) during cloud-formation-evaporation cycles (Kreidenweis
59 et al., 2019; Stratmann et al., 2009). However, these experiments need to be reproducible and understood to provide
60 with meaningful results.

61 Over the last few decades, various cloud and multiphase simulation chambers, namely DRI chamber (Stehle et al.,
62 1981), CALSPAN (Hoppel et al., 1994), AIDA (Möhler et al., 2001), AIDAd (Alpert et al., 2023), LACIS
63 (Stratmann et al., 2004), CLOUD (Duplissy et al., 2010), CESAM (Wang et al., 2011), MRI (Tajiri et al., 2013),
64 MICC (Frey et al., 2018) and the Pi chamber (Chang et al., 2016), were used to investigate the cloud microphysical
65 process and cloud life cycles, chemical transformations inside and at the droplet interface. Among these,
66 expansion-type cloud chambers were used to generate clouds by performing a quasi-adiabatic expansion through
67 a decrement of chamber pressure with or without controlling the wall temperature. This method generates a few
68 minutes of long liquid clouds (nearly equal to atmospheric cloud droplet lifetime) and mixed-phase clouds (liquid
69 and ice) clouds. The cloud lifetime is defined by the time during which suspended droplets are observed in the
70 chamber. However, the cooling rate varies from high to low depending on the chamber type. Tajiri et al. (2013)
71 induced a dark liquid cloud on ammonium sulfate seed particles (80 nm mode diameter) by active pumping from

72 1000 to 850 mbar with an adiabatic ascent rate of 3 m s^{-1} . They reported that seed particles started activating into
73 cloud droplets after 4-min pumping, and nearly 70% activated at 1% supersaturation. Frey et al. (2018) generated
74 a dark expansion cloud on ammonium seed particles containing organic compounds and observed an unexplained
75 flash activation of seed particles into droplets just after a minute of pumping, subsequently decreasing the number
76 concentration of droplets. The seed particle activation ratio (for liquid cloud droplets) is defined as the fractional
77 activation of seed aerosol particles into cloud droplets. This seed particle activation ratio can depend on turbulence,
78 as turbulence induces a fluctuation in the supersaturation ratio (Shawon et al., 2021). Abade et al. (2018) suggested
79 that some “fortunate” CCN particles might get activated into droplets because of this fluctuation. These
80 supersaturation fluctuations lead to an increment in the seed particle activation ratio, and also broadens the cloud
81 droplet size distribution (Prabhakaran et al., 2020). Further, the cloud droplet formation is predominantly
82 controlled by the number concentration of CCN particles (Hoyle et al., 2016b). The droplet activation ratio
83 decreases monotonically as the concentration of CCN increases (Shawon et al., 2021).

84 All these studies mainly focused on chemical and microphysical transformations of aerosols and microphysical
85 properties of ice and mixed-phase clouds, turbulent clouds, and cloud processing of secondary organic aerosols
86 (SOA). None of the investigations listed above investigated the microphysical properties of a liquid cloud
87 generated by a quasi-adiabatic expansion under dark and simulated light conditions relevant to the atmosphere.
88 Although extremely challenging, the control of cloud formation under dark and light conditions is necessary for
89 further multiphase photochemical studies under realistic conditions. In this paper, we present a study aiming to
90 optimize a controlled protocol for generating quasi-adiabatic expansion clouds of realistic liquid droplets under
91 atmospheric relevant simulated dark and light conditions. Detailed microphysical characterizations of these clouds
92 using monodispersed ammonium sulfate seed particles were performed in the CESAM chamber. The experiments
93 were carried out under the PARAMOUNT project at the CESAM chamber as a basis for further inquiries on cloud
94 assisted SOA formation/evolution that will be described in future papers.

95 **2 Experimental Section**

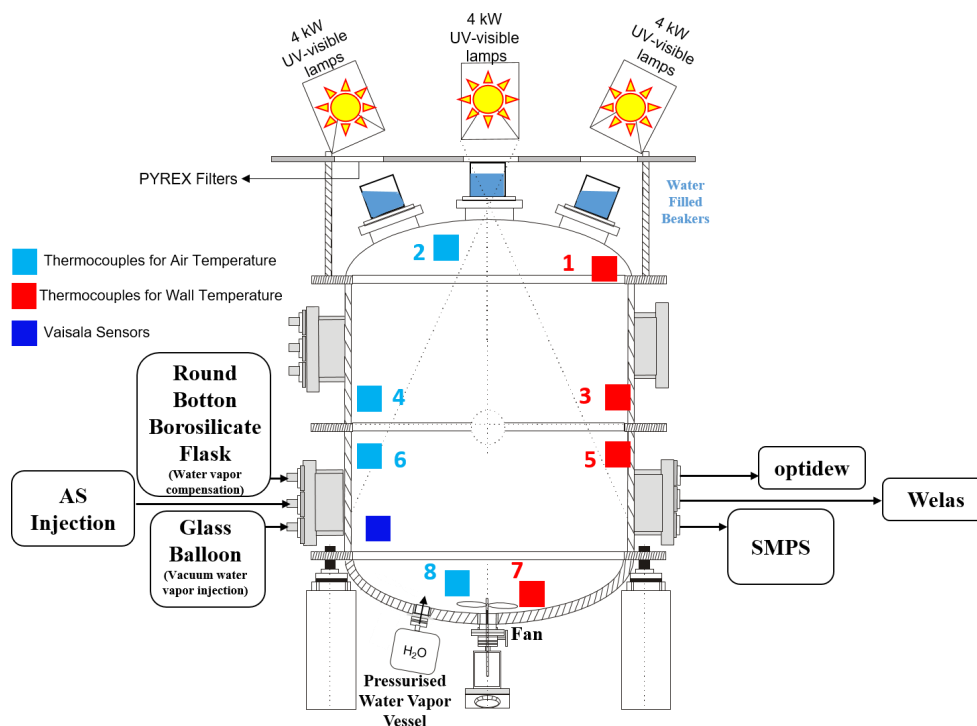

96 The CESAM atmospheric chamber, described in detail by Wang et al. (2011) and Brégonzio-Rozier et al. (2015);
97 is a vacuum-compatible 4.2 m^3 cylindrical stainless-steel reactor equipped with three Xenon arc lamps (3×6500
98 W) and Pyrex filters of 6.5 mm thickness. These lamps and filters produce an irradiation spectrum very similar to
99 the ground-level solar spectrum, both in terms of intensity and spectral distribution. CESAM is a double-walled
100 reactor, temperature-controlled thanks to a coolant circulating inside the walls.

101 Cloud generation under nearly atmospheric conditions is extremely challenging, and therefore, the experimental
102 protocols have been optimized to get close to realistic liquid droplet cumulus/liquid clouds for approximately 10
103 min, considered as 10 min pumping. The chamber was filled with a mixture of N_2/O_2 at 80/20% (generated using
104 N_2 from liquid nitrogen evaporation, purity $>99.995\%$, $\text{H}_2\text{O} < 5 \text{ ppm}$, Messer, and O_2 , quality N5.0, purity >99.995
105 %, $\text{H}_2\text{O} < 5 \text{ ppm}$, Air Liquide). The same N_2/O_2 mixture was also used to compensate from sampling by various
106 instruments and maintain a constant pressure in the reactor. Three large beakers (height: 40 cm; diameter: 25 cm)
107 were placed between the top of the chamber and the lamps, as shown in Fig. 1, to absorb infrared radiation from
108 the light and prevent from overheating while irradiating the sampling volume. These beakers were filled nearly
109 half (up to 20-25 cm) with water which was renewed before each experiment. CESAM is connected to a vacuum

110 system consisting of two pumping circuits. A first pumping line served to evacuate the air at 100 L min^{-1} during
111 each cloud run. It consisted in a dry, oil-free screw vacuum pump (Bush[®] CobraTM N0100–0300B) supported by
112 a root pump (Leybold[®] RUVACTM WAU 501) mounted on its forehead. The second pumping line served to clean
113 the chamber in between experiments by creating a vacuum in the 10^{-4} mbar range, and consisted in a
114 turbomolecular pump (Leybold[®] Turbovac 361[®]). For the cloud runs, the evacuation rate was precisely controlled,
115 by means of a high flow mass controller (ALICAT SCIENTIFIC).

116 A small, 5 l stainless steel vessel is installed below the chamber to generate pressurized water vapor. In addition,
117 a glass balloon and round bottom borosilicate flask were also connected to the chamber for vacuum water vapor
118 injection and water vapor compensation, as shown in Fig. 1, and kept at nearly 30–70 and 90 °C, respectively. The
119 balloon and flask were filled with ultra-pure water. The round bottom borosilicate flask was bubbled continuously
120 for compensation to limit the air drying due to continuous injection of N_2/O_2 . A stainless steel fan, mounted at
121 the bottom of the CESAM homogenized the aerosols and gas phase concentrations, temperature, and RH in the
122 chamber.

126

127 2.1 Experimental protocol of liquid droplet cloud generation

128 2.1.1 Cleaning Protocol

129 Previous studies have shown that cloud chamber experiments aiming at studying the aerosol-cloud processes are
130 extremely sensitive to chamber cleanliness (Brégonzio-Rozier et al., 2015; Duplissy et al., 2010; Frey et al., 2018).
131 To minimize contaminations, a cleaning protocol was established, which includes a manual cleaning with ethanol
132 and ultra-pure water after each experiment to remove the particles and semi-volatile compounds which may have
133 deposited on the chamber walls. Then, the walls were heated at 40 °C for several minutes and then CESAM was
134 vacuumed in the range of 6×10^{-4} hPa for a minimum of two hours (Brégonzio-Rozier et al., 2015). Finally, the
135 chamber was cooled and kept under vacuum overnight to perform controlled cloud experiments the next day.
136 Before starting each cloud experiments, the chamber was filled at atmospheric pressure, and aerosol number
137 concentration was measured using SMPS (scanning mobility particle sizer, TSI 3080) to ensure that the particle
138 number concentration was below 100 cm^{-3} , considering the chamber background level approximately 1-2% of the
139 maximum seed particle concentration injected in the chamber so that effect of background could be negligible. If
140 particle number concentration or mass were above the specified limit ($100 \text{ cm}^{-3}/10^{-2} \mu\text{g m}^{-3}$), the filling and flushing
141 cycle of the chamber was performed again until these limits were achieved. This limit ensures the cleanliness of
142 the chamber.

143 2.1.2 Cloud Generation Protocol

144 The cloud generation protocol was designed to investigate cloud microphysical properties under dark and light
145 conditions. Using the expansion technique, several clouds could be generated during a single experiment. The
146 optimized protocol was as follows: 1/ under vacuum (10^{-4} hPa) the temperature was adjusted to 15-16 °C by
147 regulating the coolant temperature, allowing the chamber temperature to be close to the surrounding laboratory
148 one to maximize temperature (T) homogeneity within the whole chamber. 2/ Water vapor (nearly 61-63 g) was
149 introduced under vacuum (10^{-4} hPa) using a heated bulb connected to the chamber in order to reach nearly 85-95%
150 relative humidity. Ultra-pure water from Fisher Scientific (LC-MS Grade) was used to limit impurities. 3/ The
151 chamber was then filled with N_2/O_2 at 10 hPa above the ambient pressure (to avoid any contamination from the
152 external air), analytical instruments were connected and started to sample, so water vapor “compensation” was
153 switched on to limit the air drying. It should be noted here that RH was extremely difficult to maintain at high
154 values (85-95%). As the chamber was filled, the temperature increased leading to a decrease of RH. So additional
155 water had to be injected to reach again the target high RH values needed for cloud generation. To do so, the
156 pressurized stainless-steel vessel was used as it allows increasing the RH by several % within a few seconds. 4/
157 Ammonium sulfate (AS) seed aerosol particle injection was started and stopped when desired seed concentration
158 was achieved. The fan was switched on during particle injection. 5/ Prior each cloud run, the pressure was set to
159 nearly 1090 mbar, and as soon as T reached stabilized values at $\text{RH} > 90\%$, the chamber was rapidly pumped down
160 to nearly 890 hPa (at 100 lpm). The pressure decrease leads to nearly adiabatic expansion, resulting in quasi-
161 adiabatic cooling and the development of sufficient supersaturation to form cloud droplets. Seed particles activated
162 and formed cloud droplets due to the achieved supersaturation, which is called the peak supersaturation. During
163 the entire experiment, i.e. before, during and after the cloud event, the chamber wall temperature was continuously
164 controlled and maintained above the dew point to avoid water condensation on the walls, which could occur
165 accidentally - in this case, no cloud was observed. Once the cloud event was over, the chamber was refilled with

166 N₂/O₂ for the next cloud generation. In a single experiment, between 1 to 4 clouds were generated using this
167 protocol.

168 All experiments were carried out with ammonium sulfate (AS) aerosol seed particles generated from a solution of
169 0.11 M ammonium sulfate solution with the highest possible purity (99.9999%, Merck) to avoid as much organic
170 contaminations (Wu et al., 2022). The solution was nebulized by atomization using a constant output atomizer
171 (TSI, model 3076) operated at a flow rate of 1.8 and 2.7 l m⁻³, respectively during light and dark experiments. A
172 Nafion™ dried the resulting droplets at RH below 25 % prior injection in the chamber. The target seed
173 concentration in the chamber was fixed at around 6000-8000 cm⁻³. An aerodynamic aerosol classifier (AAC,
174 Cambustion) was used to select monodisperse particles of 300 nm aerodynamic diameter (corresponding to ~219
175 nm mobility diameter assuming spherical particles of density 1.776 g cm⁻³).

176 2.1.3 Instrumentation

177 2.1.3.1 Thermodynamic Measurements

178 Temperature and relative humidity (RH) were monitored using Vaisala® humidity and temperature sensors
179 (HMP234, Humicap®). The sensors measured the RH with an accuracy of 3% in pressurized and vacuum
180 conditions. One has to note that the time resolution of the temperature sensors was too low to allow for accurate
181 measurements during the fast chamber evacuation at 100 lpm, i.e. during most of each cloud event. As the cloud
182 formation was strongly depends on air temperature, four additional T-type thermocouples were installed at various
183 locations of the sensing volume of the chamber (see Fig. 1) to measure the air temperature variation before, during,
184 and after each cloud event, with an accuracy of ± 0.5 °C. The wall temperature was also monitored using four
185 additional T-type thermocouples to ensure that the wall temperature was above the dew point so to prevent
186 condensation. The top, middle-upper, middle-lower, and bottom wall temperatures were measured with T₁, T₃, T₅,
187 and T₇ sensors, respectively, whereas T₂, T₄, T₆, and T₈ sensors recorded the chamber's top, middle-upper, middle-
188 lower, and bottom air temperatures, respectively. All T sensors are installed so they do not have direct exposure
189 to incoming light to prevent from artificial heating. In addition, the thermocouples for the air temperature
190 measurements are fastened at an appropriate distance from the wall to avoid the influence of the wall temperature.
191 Additionally, a hygrometer (Chilled Mirror, Michell Optidew model 501) was henceforth connected to the
192 chamber to record the dew point temperature and the gas-phase water content, i.e. absolute humidity.

193 2.1.3.2 Aerosol and Cloud Microphysical Properties

194 The size distribution of cloud droplets was continuously measured during the experiments with a time resolution
195 of 10-s using a white light optical particle counter (OPC) (Welas® 2000, Palas, flow rate: 2 l min⁻¹) (Brégonzio-
196 Rozier et al., 2015). It measured the cloud droplet's size distribution from 0.25 to 17.17 µm in optical size, using
197 the refractive index of water (1.33 ± 0i). It was calibrated by means of a calibration dust called CalDust 1100,
198 whose refractive index was (1.59 ± 0i). The Welas measured concentrations per size are corrected for sampling
199 losses in the tubes (von der Weiden et al., 2009), as well as for losses on the chamber walls and dilution (Wang
200 et al., 2011).

201 The AS seed particle size distribution was continuously recorded at 3-min time resolution using a Scanning
202 Mobility Particle Sizer (SMPS), consisting of a Differential Mobility Analyzer (DMA, TSI, model 3080) coupled

203 with a Condensation Particle Counter (CPC, TSI, model 3010). The instrument is operated at a flow rate of 1 l
204 min⁻¹ resulting in a nominal mobility size range of 19.5 – 881.7 nm. The SMPS was operated without dryer. The
205 sampling tube from the chamber to the SMPS was kept as short as possible, so that the measured size distribution
206 represented nearly the seed particle size distribution in the humidified chamber.

207 3 Data Analysis

208 3.1 Cloud Formation Properties (CFPs)

209 A significant part of our data analysis aimed at distinguishing between two (hydrated/inactivated particles and
210 cloud droplets) populations. In addition, the dry seed particle size distribution was not measured; therefore, due to
211 this limitation, it was necessary to retrieve the dry size distribution.

212 The Köhler theory (Köhler, 1936) considers that a seed aerosol particle becomes activated into a cloud droplet
213 when its dry or hydrated/wet size is similar to or larger than a threshold dry particle and droplet diameter,
214 respectively. These dry and wet diameters are respectively called critical dry diameters (D_{crit}) of a seed particle
215 and threshold droplet diameter ($D_{drop,thres}$). Characterizing these two parameters is the key to describe the
216 supersaturation state of the studied environment. To do so, various approximation techniques are reported in the
217 literature. Prabhakaran et al. (2020) and Shawon et al. (2021) reported $D_{drop,thres}$ as the separation diameter between
218 the inactivated/hydrated aerosol particles and cloud droplets in the cloud particle size distribution (measured by
219 Welas) as well as in the derived probability density function from the distribution. However, the lognormal size
220 distribution sometimes exhibits no distinct dip to characterize the threshold diameter. Instead, Hammer et al.
221 (2014) used the surface size distribution than the number size distribution to calculate $D_{drop,thres}$. Elias et al. (2015)
222 found that the inactivated/hydrated aerosol and fog droplets could be identified in the two modes of the volume
223 lognormal distribution aerosol particles measured by a Welas at ambient conditions, and defined $D_{drop,thres}$ as the
224 intersection/transition diameter between these two modes. However, in the present study, none of these approaches
225 lead to identifying a robust and stable dip in size/surface/volume distribution. To overcome this difficulty, an
226 alternative iterative approach, illustrated in Fig.2, was adopted to derive CFPs like cloud droplet concentration
227 (N_{drop}), critical dry diameter of seed particle (D_{crit}), cloud droplet threshold diameter ($D_{drop,thres}$), and peak
228 supersaturation ratio (S_{peak}).

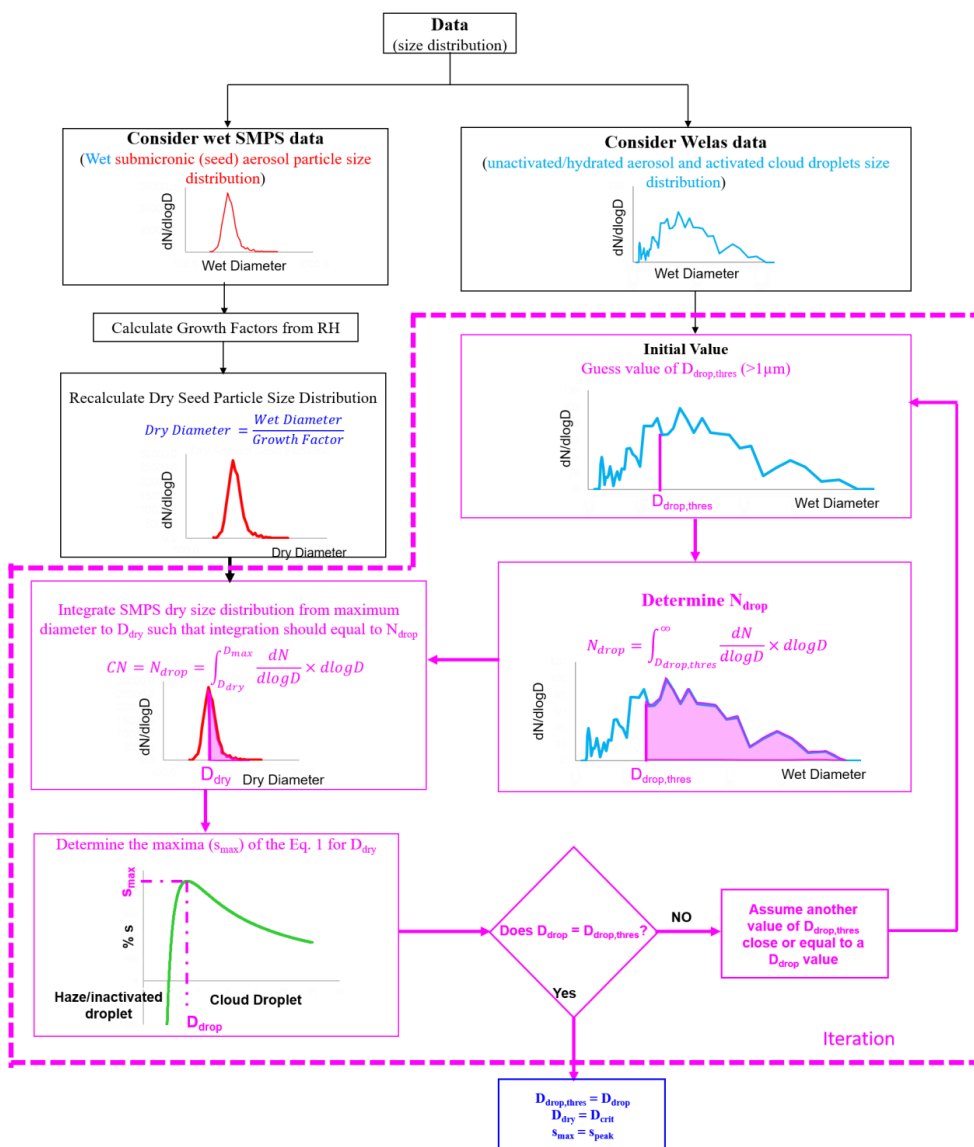

229

230

231

232

233

234

235 **Figure 2: Algorithm of the iterative scheme used to retrieve cloud formation properties (CFPs) from the wet particle**
 236 **size distribution.**

237

238 The model starts by considering the dry seed aerosol particle diameter (D_{dry}) and droplet diameter (D_{drop}), which
 239 are linked to the peak supersaturation ratio (s) and aerosol hygroscopicity parameter (κ) through the κ -Köhler
 240 equation (Petters and Kreidenweis, 2007) (Eq.1).

241
$$s = \frac{D_{\text{drop}}^3 - D_{\text{dry}}^3}{D_{\text{drop}}^3 - D_{\text{dry}}^3(1 - \kappa)} \exp\left(\frac{4 \times \sigma \times M_w}{R \times T \times \rho_w \times D_{\text{drop}}}\right) - 1, \quad (1)$$

242 Where σ is the surface tension at the droplet surface/air interface assumed equal to the surface tension of pure
243 water, R is the universal gas constant, M_w is the molecular weight of water, T is the chamber air temperature in
244 Kelvin, ρ_w is the density of water, and κ is the hygroscopicity parameter of the CCN (in our case, for AS, $\kappa = 0.61$).
245 It should be noted that our experiments did not benefit from CCN counter data hence the number concentration
246 of the CCN was not measured by set equal to the number of droplets (N_{drop}).

247 During our experiments it was observed that middle down (T_6) air temperature sensor was the most sensitive to
248 the T changes during the adiabatic expansions. Therefore, T_6 was used to determine the CFPs. The CFPs were
249 derived for each cloud as follows: N_{drop} was set to a corresponding initial guess value of $D_{\text{drop,thres}}$ ($> 1 \mu\text{m}$), and
250 determined by integrating cloud droplet number concentration above $D_{\text{drop,thres}}$ using loss and dilution corrected
251 Welas measurements. The dry SMPS number size distribution was recalculated by the wet SMPS size distribution
252 considering the growth factor of AS particles. Hereafter, the measured dry SMPS size distribution represents the
253 retrieved one from the measured wet SMPS size distribution in the subsequent text. D_{dry} was approximated by
254 integrating SMPS dry particle number size distribution from the maximum size (D_{max}) to a lower limit diameter at
255 which the estimated CCN matched the droplet number concentration (N_{drop}), as done by Lamb and Verlinde,
256 (2011), who calculated N_{drop} according to Eq. (2).

$$257 \quad N_{\text{drop}} = \int_{D_{\text{dry}}}^{D_{\text{max}}} \frac{dN}{d\log D} \times d\log D, \quad (2)$$

258 D_{drop} was calculated by numerical searching the maximum of Eq.1 for D_{drop} . This threshold diameter of the cloud
259 droplet ($D_{\text{drop,thres}}$) define the size separation between the non-activated droplets. This parameter was assumed to
260 reach instantaneous equilibrium with the chamber effective supersaturation, and the activated cloud droplets, either
261 growing or shrinking in response to the chamber effective supersaturation to which they were exposed. The
262 resulting D_{dry} , called D_{crit} , indicates that the seed aerosol particles larger than D_{crit} in size were activated into cloud
263 droplets equal or larger than $D_{\text{drop,thres}}$ in size.

264 The peak supersaturation ratio (s_{peak}) can be further determined by combining D_{crit} and seed particle hygroscopicity
265 (for AS, $\kappa = 0.61$) using the κ -Köhler equation (Petters and Kreidenweis, 2007) as Eq. (3):

$$266 \quad s_{\text{peak}} = \frac{2}{\kappa^{0.5}} \times \left(\frac{4 \times \sigma \times M_w}{3 \times R \times T \times \rho_w \times D_{\text{crit}}} \right)^{\frac{3}{2}}, \quad (3)$$

267 The peak supersaturation can be described as a combination of the source and sink of the water vapour in the
268 chamber. N_{drop} is the total cloud droplet concentration at effective supersaturation ratio, s_{peak} . Thus, iterations are
269 performed on $D_{\text{drop,thres}}$ until $D_{\text{drop,thres}}$ equals to D_{drop} . A solution to the iteration only exists in one trio point of N_d ,
270 D_{crit} , and D_{drop} , which is related to s_{peak} . The iterations were performed for every time step of the expansion and
271 corresponding derived CFPs. Panel (c) in Fig. 3 shows the cloud droplet size distribution using this iterative
272 approach.

273 Furthermore, as a result of the iterative model, the particle activation ratio (A_{cd}) can be calculated using Eq. (4),
274 as performed by (Frey et al., 2018):

$$275 \quad A_{\text{cd}} = \frac{N_{\text{drop}}}{N_s}, \quad (4)$$

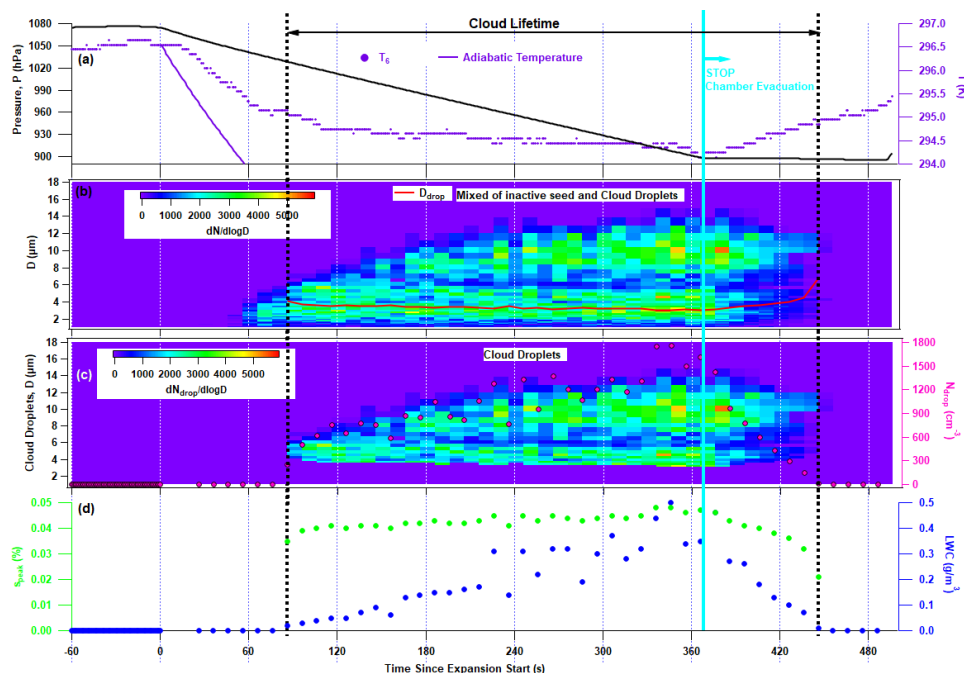

276 where N_{drop} is the cloud droplet number concentration and N_s is the pre-expansion aerosol seed particle number
277 concentration. Here, N_s indicates the actual seed particle present in the CESAM for cloud formation, not corrected
278 for particle losses on the chamber walls and neither by dilution. The idea is that the N_s indicates the actual number
279 of seed particles present in the CESAM available for cloud droplet formation processes.

280 4 Results and Discussion

281 The timeline of a typical cloud run is shown in Fig. 3. The chamber evacuation, indicated by the pressure drop in
282 the chamber, results in an adiabatic temperature drop in the air for the initial minute (Fig. 3a) but then, when the
283 liquid water content starts raising (Fig. 3d), the temperature decreases more slowly (Fig. 3a). This change in the
284 cooling rate can be due to the heat released by water condensation or/and by heat exchange with the chamber walls.
285 Initial fast cooling through adiabatic expansion creates the supersaturation ($s_{\text{peak}} \geq 0.035\%$; Fig. 3d) required to
286 activate the AS seed particles into cloud droplets. Then the fractional activation of seed particles into cloud droplets
287 leads to a mixture of non-activated particles and cloud droplets, as shown in Fig. 3b. It can be observed that the
288 wet seed particles exhibit a bimodal size distribution, with a mode around 3–4 μm and another one around 10–12
289 μm . The first mode suggests a mixture of hydrated but not fully activated particles and activated particles, i.e.,
290 droplets. Even if supposedly homogeneous physical conditions applied to a single aerosol distribution should lead
291 to a single droplet size distribution, it is an experimental fact that it is not the case here. Following the iterative
292 method mentioned in the previous section 3.1, the threshold droplet diameter that was determined and is shown in
293 panel (b) (solid red line). As a result, panel (c) shows the time series of the size distribution and total number of
294 activated cloud droplets.

295 Two types of experiments were conducted, one in presence of UV-vis irradiation, Irradiated Cloud (IC), and
296 another one without UV-vis irradiation, Non-Irradiated Cloud (N-IC). In IC and N-IC experiments, respectively 3
297 and 2 adiabatic expansions (cloud runs) were successively carried out, named IC-1, IC-2, and IC-3 for light
298 conditions and N-IC-1 and N-IC-2 for dark conditions (Table 1). Besides, N-IC-3* is marked with a star as it was
299 performed in a separate experiment. Following the cloud generation protocol mentioned in section 2.1.2, the cloud
300 lifetimes were found to range between 7.0 ± 0.8 and 6.3 ± 1.4 min in the presence and absence of light, respectively,
301 which is satisfying considering those in the atmosphere (2–30 min (Colville et al., 1997)).

302 The key parameters for each cloud run are reported in Table 1. The initial RH was calculated considering chamber
303 air temperature (T_6) and absolute humidity measured by the Optidew. The chamber evacuation rate (100 lpm) was
304 the same for all cloud runs to avoid any impact of the cooling rate on the CFP. In addition, Δp represents the net
305 pressure drop during the chamber evacuation, and ΔT indicates the net temperature drop as a result of quasi-
306 adiabatic expansion. It is interesting to note that ΔT increased in successive cloud runs in each experiment (e.g.
307 N-IC-1 to N-IC-2 and IC-1 to IC-2 and IC-2 to IC-3). The duration of the pressure drop was manually controlled,
308 thus explaining the different ΔP values shown in Table 1. Notably, the initial temperature for a cloud run increased
309 in the successive cloud runs during an experiment, especially during IC experiments, due to the heat generated by
310 the lamps, despite the IR filtering. Considering the net temperature drop during the expansion, the mean cooling
311 rate for N-IC-1 (0.36 °C/min) was found to be comparable to that for IC-1 (0.33 °C/min), while the 0.42 °C/min
312 cooling rate for IC-2 and IC-3 was nearly similar to N-IC-2 (0.43 °C/min).

313

314 **Figure 3:** Example of a cloud formation process on 215 nm ammonium sulfate seed particles. Panel (a) shows the
 315 pressure drop and a nearly adiabatic temperature drop during the initial minute following slow temperature drop, (b)
 316 size distribution of hydrated/non-activated seed particles and droplets, (c) size distribution and total number
 317 concentration of droplets, (d) peak supersaturation (S_{peak}) and cloud liquid water content (LWC) versus time.

318

319 **Table 1. Initial parameters for all cloud runs** – IC and N-IC denote cloud runs performed under Light and Dark conditions
 320 respectively. The numbers correspond to successive expansions within 1 experiment, except for N-IC-3* which was performed
 321 in a separate experiment. ** indicate the RH value measured using Vaisala sensor. The error indicates the measurement error.

Parameter	Cloud Run					
	N-IC-1	N-IC-2	N-IC-3*	IC-1	IC-2	IC-3
p (hPa)	1078.6	1078.0	1150.0	1074.7	1070.9	1099.3

322

323 4.1 Cloud Runs without UV-vis Irradiation

324 The cloud formation properties (CFPs) and the timeline of the non-irradiated cloud run N-IC-1 are illustrated in
 325 Fig. 4 (N-IC-2 and N-IC-3* cloud runs are illustrated in the Supplementary material). The initial time (0 s) in the
 326 panels indicates the starting time of the expansion. The upper panel (Fig. 4(a)) shows the dry seed particle size
 327 distribution, measured by the SMPS before and after chamber evacuation. The total seed particle concentration

328 was 5240 cm^{-3} just before and 3683 cm^{-3} after the chamber evacuation. The difference, of the order of 30%, is in
329 agreement with the loss of seed particles due to the combination of the dilution in the chamber during its evacuation
330 (nearly 12 %), the wall losses and the sedimentation losses of cloud droplets, jointly accounting for the remaining
331 18%. The lifetime of particles in the 200 nm diameter range is in the order of 2 to 3 days in the CESAM chamber,
332 but of a few minutes only for droplets of several micrometres in diameter (see Fig. S1 in Lamkaddam, 2017). For
333 comparison, Chang et al. (2016) reported that approximately 83% of seed particles may be lost due to cloud
334 droplets losses, excluding dilution. This much larger loss can be explained by two factors; first, in Chang et al.
335 (2016) the droplets were larger (approximately 5–20 μm due to higher supersaturation and more hygroscopic seed
336 particles (NaCl)) and second, their chamber was smaller with a different shape, inducing larger wall losses.

337 The other panels in Fig. 4 exhibit the time series of the parameters during cloud development. The cloud droplet
338 growth starts from at 42 s onwards, evidenced by the significant enhancement of all the parameters shown in Fig.
339 4c, 4d, and 4e. The time elapsed to achieve the s_{peak} value required to start seed particle activation highly depends
340 upon the initial chamber conditions before the evacuation (Frey et al., 2018) as well as upon the rate of evacuation
341 and thus the cooling rate (that was fixed to 100 lpm in our case). This elapsed time cannot be attributed to the
342 transit time through the sampling tube from the chamber to the Welas instrument as it is lower than one second in
343 our set up. In agreement with Möhler et al. (2003) we rather explain this to chamber boundary layer effects as the
344 chamber air near the walls could remain cloud-free because the wall temperature is maintained slightly higher than
345 inner air. This delay between the start of the evacuation and the first droplets detection was observed for all the
346 cloud runs, in the range from 50 to 110 s, in agreement with similar studies (Frey et al., 2018).

347 An initial high concentration of tiny cloud droplets (1.9–8.8 μm) is observed (orange to reddish colors in Fig. 4(c))
348 when approximately all seed particles are activated into droplets. These tiny droplets then grow as the cloud run
349 proceeds while the small droplet mode vanishes. The initial high RH (99%; Table 1) is probably responsible for
350 reaching a sufficient supersaturation ($> 0.078\%$) in the chamber to activate all the seed particles into droplets after
351 50 s initiation time. The chamber peak supersaturation varied from 0.025 to 0.079% (Fig. 4(d)), however, the
352 maximum s_{peak} could be even higher than 0.079% in the chamber because this value is the limit constrained by our
353 method to calculate s_{peak} as cloud droplets could not be more than seed particles. Any fluctuations in the s_{peak} values
354 could be explained by chamber turbulences (Prabhakaran et al., 2020) which proportionately also impacts the
355 cloud evolution (e.g. LWC values fluctuations in Fig. 4c).

356 The cloud droplets' volume mean diameter (MVD) ranged from 6.1 μm (at the initial stage) to 11.8 μm , with a
357 mean value of $9.4 \pm 2.0 \mu\text{m}$ (Table 2), which is consistent with the values reported by Frey et al. (2018) for liquid
358 clouds droplets formed on AS seed particles. As smaller droplets grow into larger ones or coagulate, they make up
359 the LWC that reaches a maximum of 1.8 g m^{-3} (Fig. 4(d)) after 250 s, when a significant fraction of the formed
360 droplets grow to bigger droplets which correlates well with the maximum MVD. However, the mean LWC was
361 $1.0 \pm 0.4 \text{ g cm}^{-3}$, significantly higher than 0.5 g m^{-3} (maximum) reported by Frey et al. (2018) for non-irradiated
362 cloud. The significantly higher LWC in the present study was found due to the higher seed and droplet
363 concentration.

364 The detailed values of all cloud formation parameters are mentioned in Table 2. For N-IC-1, the mean (\pm std)
365 values for particle activation ratio (A_{cd}) was observed at 0.98 ± 0.37 . Fig. 5e shows that A_{cd} values were frequently
366 higher than 1, which could be due to the instrument margin errors (Frey et al., 2018). Finally, cloud N-IC-1

367 sustained for 6 min 50 s (thus 78 s after the stop of the chamber evacuation), well within a typical atmospheric
368 cloud droplet lifetime of 2-30 min (Colvile et al., 1997; Herrmann, 2003).

369 Assuming that successive cloud runs did not impact the chemical composition of seed particles, we compare in
370 the following all the N-IC cloud runs as independent runs and/or experiments. The microphysical properties of N-
371 IC-2 and N-IC-3* are illustrated in Fig. S2 and S3, respectively. N-IC-2 displayed a 6 min lifetime, shorter than
372 N-IC-1 (7 min 50 s), while N-IC-2 showed significantly ($p < 0.05$) lower A_{cd} and MVD than N-IC-1 (Table 2). This
373 could be due to the significantly ($p < 0.05$) lower peak supersaturation which was always $\leq 0.050\%$ in N-IC-2 (Fig.
374 S2), while it was probably often higher than the maximum value (0.079%) in N-IC-1. It is worth noting that the
375 initial temperature and RH values for N-IC-1 are respectively slightly lower and higher than in N-IC-2, as shown
376 in Table 1. This could support the higher s_{peak} achieved in N-IC-1. In addition, the pressure drop (Δp) was nearly
377 the same for both clouds, while cooling (ΔT) was higher for N-IC-2. It indicates that even high cooling in N-IC-2
378 could not generate a sufficiently high degree of supersaturation that could lead to a high activation ratio. It is thus
379 likely that the observed different supersaturations were mainly due to the initial RH conditions. In addition, N-IC-
380 3* (Fig. S3), with a lower seed concentration, shows lower cloud droplet concentrations even though the
381 supersaturation ratio is comparable to N-IC-2, negatively impacting LWC. Notably, the mode of dry seed size
382 distribution in N-IC-3* was 17 nm lower than that of N-IC-2, which could be the reason for lower A_{cd} in N-IC-3*
383 than in N-IC-2 at nearly the same s_{peak} , because lower size particles require higher supersaturation to activate into
384 droplets (Köhler, 1936). In N-IC-3*, Fig. S3 shows that N_{drop} was extremely low and variable, as well as LWC,
385 and thus it is difficult to provide any information on the droplet's growth. All these observations explain why N-
386 IC-3* showed a significantly lower MVD ($p < 0.05$) than the two other dark clouds.

 411 particles. Panel (a) shows the SMPS size distributions of seed particles obtained before and after the cloud run, (b)
 412 shows the pressure drop and a nearly adiabatic temperature drop during the initial minute, following slow temperature
 413 drop, (c) time series of cloud droplet size distribution and volume mean diameter (MVD) measured by WELAS, (d)
 414 time series of cloud droplet concentration (N_{drop}) and LWC, and (e) time series of seed particle activation ratio (A_{cd})
 415 and chamber peak supersaturation ratio (S_{peak}).

416

417 4.2 Cloud Runs under UV-vis Irradiation

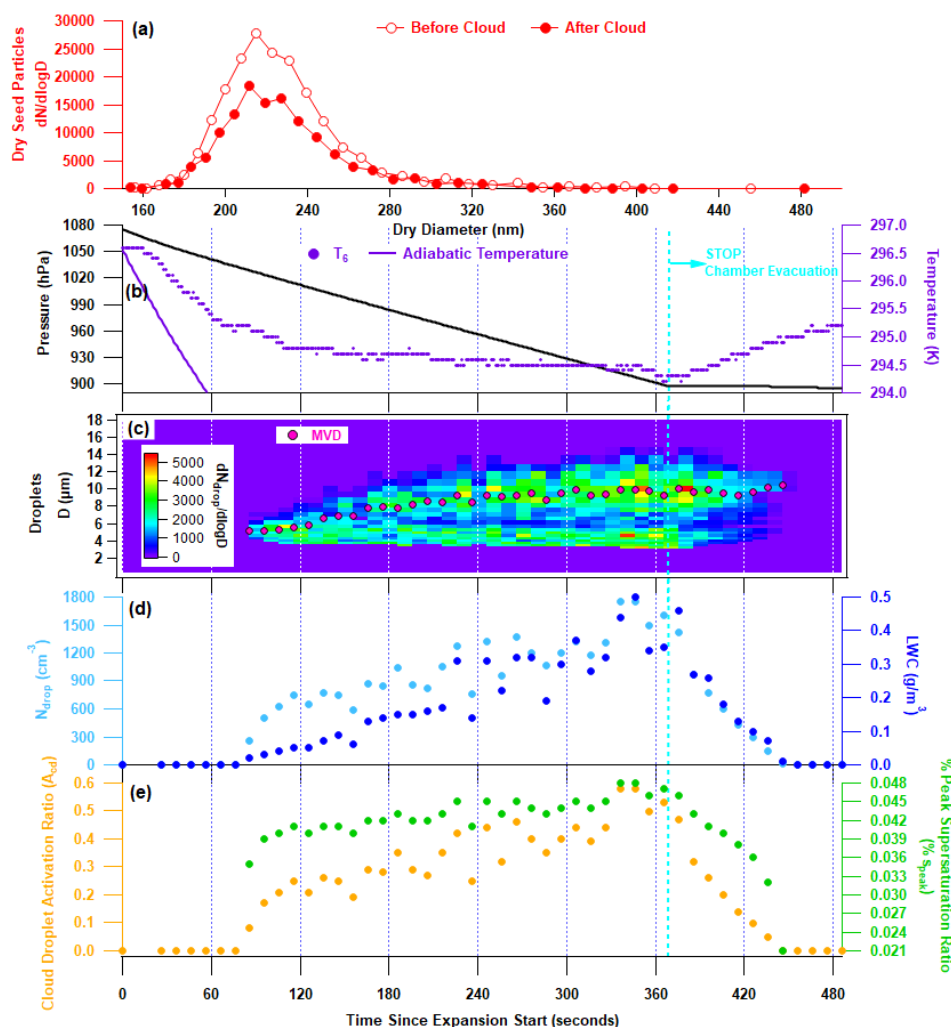

418 Fig. 5 illustrates the IC-1 cloud run. IC-1 was carried out by reducing the pressure by 176.9 hPa from 1074.7 hPa,
 419 leading to a temperature drop of 2.4 °C. The initial temperature and RH were 23.4 °C and 93.7 %, respectively
 420 (Table 1). The temperature decay at the beginning of the expansion is nearly parallel to the adiabatic temperature.
 421 The total number concentration of seed aerosol particles was 2987 cm^{-3} before the cloud run, significantly

422 decreasing to nearly 1942 cm^{-3} (35% loss) due to seed particle loss and dilution. The dilution would only have
423 reduced the concentration to 2615 cm^{-3} (12 %) the remaining seed particles must have been removed from the
424 chamber due to cloud droplet sedimentation and/or wall loss. The critical dry diameter of the seed particles reached
425 nearly 219 nm when maximum 58% seed particle were activated into droplets, as shown in panel 5(a), leading to
426 s_{peak} values reaching upto 0.048% during the cloud formation process. The value of 219 nm is in the lower range
427 of the number-size distribution measured after the chamber's evacuation and re-pressurization. This suggests that
428 some seed particles activated into cloud droplets while smaller ones did not. Chang et al. (2016) observed a similar
429 feature in their experiments with NaCl seed particles.

430 The droplet number size distribution during the cloud formation is shown in Fig. 5c. No cloud droplets are observed
431 until 85 s after expansion, when a few seed particles (253 cm^{-3}) activated to droplets at a size range of 3.9-4.2 μm .
432 Afterwards, the cloud development accelerates, and small droplets are formed. As the cloud run proceeds, the
433 droplet size distribution shifts to a larger size, while the small droplet mode slightly decreases (Fig. 5c). After the
434 first 4 min, the MVD stabilises at $8.2 \pm 1.6 \mu\text{m}$. The growth of the large droplets is well reflected by the increasing
435 LWC, which maximum value is consistent with the approximate value of 0.5 g m^{-3} reported by Frey et al. (2018)
436 although their study was conducted in the dark. The peak supersaturation (s_{peak}) reached 0.048% when 58% of
437 seed particles were activated into cloud droplets. The s_{peak} builds up as the cloud run proceeds and reaches its
438 maximum value just before the end. The fluctuations in s_{peak} value can be explained by the inhomogeneous RH
439 and temperature profiles in the chamber. Despite continuous mixing, the chamber walls temperature is kept at
440 controlled values while the center of the chamber cools quasi-adiabatically during a chamber air evacuation. This
441 can develop a temperature gradient inside the chamber, a high temperature to lower temperature at the centre of
442 the chamber, causing a humidity gradient (Hinds, 1999), which impacts cloud microphysics. In addition, the
443 evacuation creates turbulences in the chamber (as mentioned in the previous section) and causes a mixing inside
444 the chamber, creating inhomogeneities in the temperature and RH profiles. This turbulence also leads to a
445 broadening of droplets distribution, A_{cd} , and s_{peak} (Abade et al., 2018; Prabhakaran et al., 2020). The cloud droplet
446 activation ratio, A_{cd} , varied from 0 to 0.58. Further, cloud IC-1 persisted for nearly 5 min, which is shorter than
447 dark cloud N-IC-1. As they were performed under very similar initial T and RH conditions (Table 1), both IC-2
448 and IC-3 cloud runs (Figures S4 and S5) showed no significant differences in the mean value of particle activation
449 ratios, peak supersaturation ratios, and liquid water contents.

467

468 4.3 Comparison between with and without Irradiated Clouds

469 Interestingly, there is a significant difference in the formation pattern between non-irradiated clouds (N-IC) and
 470 irradiated clouds (IC) (Fig. 4 and 5). The N-IC clouds exhibit a flash activation of all or maximum fractional seed
 471 particles into cloud droplets in the first minute following the start of expansion. Then a decrease followed by a
 472 nearly stable trend are observed in the cloud droplets and other microphysical properties. This flash activation

473 correlates well with the build-up of high supersaturation ratio (s_{peak}) at the initial stage. On the contrary, during
474 irradiated clouds (IC), microphysical parameters increase steadily during the expansion and reach their maximum
475 values at the last stage of each cloud run. This is the case for the supersaturation ratio s_{peak} and the cloud droplet
476 activation ratio A_{cd} . Consequently, the LWC and cloud droplet number increased simultaneously as the cloud run
477 proceeds under irradiation conditions. Conversely, during N-IC, after the initial flash activation of all seed
478 particles, N_{drop} decreases while the LWC increases (Fig. 4d and S2d), indicating that cloud droplets are coagulating
479 into bigger droplets after the initial activation. At a later stage (i.e. after ~ 150 s in Fig. 5b, when N_{drop} remains
480 roughly constant while LWC still increases), these droplets grow due to water vapor condensation. However, under
481 irradiation conditions, activated droplets grow due to condensation throughout the cloud run without any
482 coagulation of smaller size droplets to bigger ones, as shown by the continuous increase of N_{drop} and LWC (Fig.
483 5d, S4d and S5d). One of the possible reasons for these activation patterns could be that the heating of the chamber
484 air by the lamps counteracts the adiabatic cooling, leading to a reduced supersaturation at the beginning of the
485 cloud event, causing less droplets and less droplet growth. However, this direct heating effect is unlikely for two
486 reasons. First, the temperature measurements contradict this hypothesis (Fig. 5), as the temperature decay at the
487 beginning of the expansion is nearly parallel to the adiabatic temperature and show no significant difference with
488 the temperature decays recorded during the experiments without irradiation; Second, air is not an efficient light
489 absorber and, in our case, only water vapour could play the role of a greenhouse gas. Nevertheless, the light used
490 to irradiate the chamber was filtered by ca. 25 cm of liquid water removing the largest part of potentially warming
491 infrared radiation.

492 A second potential explanation is that ammonium sulphate enriched deliquescent particles absorb the remaining
493 (non-filtered) infrared radiation of the incoming light that warms them up, resulting in higher temperature than in
494 surrounding air. This causes a longer duration to stabilize the equilibrium between the droplet and the surrounding
495 atmosphere. This droplets/haze particle heating restricts the initial flash activation of seed particles and also
496 restricts the supersaturation at the initial stage of the cloud run. Nevertheless, when some droplets are formed, after
497 some time, the light seems to lose its importance so that the supersaturation and, thus, all related cloud parameters
498 could continuously increase with time. The incoming radiation is probably more reflected by the droplets, so the
499 interstitial chamber air could further cool to create a higher supersaturation.

500 **5 Conclusions**

501 The control of cloud formation under dark and light conditions is a prerequisite for further multiphase
502 photochemical studies in chambers under realistic conditions. This work aimed at optimizing a controlled protocol
503 for generating quasi-adiabatic expansion clouds of liquid droplets under atmospherically relevant simulated non-
504 irradiated (dark) and irradiated (light) conditions in the CESAM chamber. Successful experiments provided the
505 formation of 1 to 3 successive clouds within a single experiment, using an optimized protocol employing
506 monodisperse ammonium sulfate seed particles under dark and light conditions. This firmly demonstrates that,
507 although extremely challenging, especially under light conditions, it is possible to perform cloud experiments
508 under reproducible conditions in the CESAM chamber.

509 The expansion liquid clouds were a mixture of inactivated deliquescent seed particles and droplets. To discriminate
510 between them, an iterative approach was proposed to filter the cloud droplets from the mixture of hydrated seed

511 particles and droplets without any CCN counter instrument. The method allowed to determine microphysical
512 parameters, i.e. critical dry activation diameter of seed particle, threshold droplet diameter, peak supersaturation
513 ratio, number of cloud droplets, and seed particle activation ratio. The cloud lifetimes were found to be 7.0 ± 0.8
514 and 6.3 ± 1.4 min in the presence and absence of light, respectively. It falls, in the range of the lifetime of
515 atmospheric droplets (2-30 min). Some of the successive clouds within a single experiment showed very similar
516 properties.

517 The characterization of the formed liquid clouds showed specific trends in the microphysics parameters. Notably,
518 the seed particle loss at the end of the cloud was found to be a function of the fractional contribution of the largest
519 droplets due to their lifetimes in the CESAM chamber. Moreover, the cloud's liquid water content (LWC) was well
520 associated with the number of grown/larger size droplets. In addition, the achieved supersaturation was observed
521 as a function of initial chamber air temperature and relative humidity.

522 Non-irradiated cloud (N-IC) witnessed the activation of all seeds or a maximum of seed particles into droplets
523 within the first 1-2 min of the cloud, while Irradiated cloud (IC) took longer to activate all or part of the seed
524 particles into droplets. While still hypothetical, we explain this difference in the formation patterns with the
525 absorption of infrared light by the hydrated seed particles, inducing steep temperature gradients between each
526 hydrated particle and its surrounding environment. This indirect warming effect leads to a longer stabilization of
527 the equilibrium between the droplet and the surrounding atmosphere. This heating of the hydrated particles particle
528 restricted the flash activation of all seed particles and the higher supersaturation at the initial stage of the IC cloud.
529 Overall, at the later stages, the light intensity inside the cloud decreases so that the supersaturation and, thus, all
530 related cloud parameters could continuously increase with time. The light reflections by the droplets may increase,
531 causing the interstitial air cooling and thus higher supersaturation. This phenomenon should also impact the
532 air/water partitioning of semi-volatile compounds, and it should be considered for further studies, especially in
533 further multiphase photochemical studies implying water soluble volatile organic compounds in the CESAM
534 chamber.

553 conceptualization, perform experiments, data analysis, methodology, funding acquisition, project administration,
554 supervision, writing (review and editing).

555 **Competing interest.** At least one of the (co-)authors is a member of the editorial board of Atmospheric
556 Measurement Techniques.

557 **Acknowledgements.** The AERIS data center (www.aeris-data.fr) for distributing and curing the data produced by
558 the CESAM chamber through the hosting of the EUROCHAMP datacenter (<https://data.eurochamp.org>). The
559 authors are also thankful to Mr. Nicolas Brun and Brice Temime-Roussel, Aix Marseille Université, CNRS, LCE,
560 Marseille, France and Majda Mekic, Leibniz Institute for Tropospheric Research, Leipzig (TROPOS), 04318,
561 Germany for helping in the experiments in the CESAM multiphase simulation chamber.

562 **Financial Support.** This work has received funding from the French National Research Agency (ANR) and the
563 German research Foundation (DFG) through the bilateral research project PARAMOUNT under the grant number
564 ANR-18-CE92-0038. It has received support from the European Union's Horizon 2020 research and innovation
565 program through the EUROCHAMP-2020 Infrastructure Activity under grant agreement no. 730997. CNRS-
566 INSU is gratefully acknowledged for supporting the CESAM chamber as a national facility as part of the French
567 ACTRIS Research Infrastructure.
