23 **Abstract**

24

25 A large convection cloud chamber has the potential to produce drizzle-sized droplets, thus offering
26 a new opportunity to investigate aerosol-cloud-drizzle interactions at a fundamental level under
27 controlled environmental conditions. One key measurement requirement is the development of
28 methods to detect the low concentration drizzle drops in such a large cloud chamber. In particular,
29 remote sensing methods may overcome some limitations of in situ methods.

30

31 Here, the potential of an ultra-high-resolution radar to detect the radar return signal of a small
32 drizzle droplet against the cloud droplet background signal is investigated. It is found that using a
33 small sampling volume is critical to drizzle detection in a cloud chamber to allow a drizzle drop in
34 the radar sampling volume to dominate over the background cloud droplets signal. For instance, a
35 radar volume of 1 cubic centimeter (cm^3) would enable the detection of drizzle embryos with
36 diameter larger than $40\ \mu m$. However, the probability of drizzle sampling also decreases as the
37 sample volume reduces, leading to a longer observation time. Thus, the selection of radar volume
38 should consider both of the signal power and the drizzle occurrence probability. Finally,
39 observations from the Pi Convection-Cloud Chamber are used to demonstrate the single drizzle
40 particle detection concept using small radar volume. The results presented in this study also
41 suggest new applications of ultra-high-resolution cloud radar for atmospheric sensing.

52 **1. Introduction**

53 Drizzle formation is one of the most important microphysical processes in warm clouds. Yet the
54 processes controlling drizzle formation remain poorly understood (Wood, 2012). The most
55 challenging aspect is the initial formation of drizzle embryos with diameter around $30 \mu\text{m} \sim 50$
56 μm . The formation of small drizzle particles in this range can neither be adequately explained by
57 the traditionally-defined condensation growth process nor by the traditionally-defined collision-
58 coalescence (C-C) process owing to their low efficiency (Yau and Rogers, 1996). Several
59 mechanisms have been hypothesized to explain the efficiency of these processes including i) fine-
60 scale turbulence in cloud (Pinsky and Khain, 1997; Shaw, 2003); ii) giant cloud condensation
61 nuclei (GCCN) (Johnson, 1982; Feingold et al., 1999); and iii) longwave cooling (Roach,
62 1976; Harrington et al., 2000). Nevertheless, it remains unclear to which extent these proposed
63 mechanisms can adequately explain the origin of drizzle embryos.

64 Two main barriers that hinder our ability to investigate the drizzle initiation process are our
65 inability to isolate various effects in a real cloud and the lack of observations with sufficient
66 sensitivity and spatiotemporal resolution to detect the early growth of drizzle particles. As such an
67 instrumented large convection cloud chamber with well-controlled initial and boundary conditions
68 might help to improve our understanding of the drizzle initiation mechanism (Shaw et al., 2020).
69 Unlike other types of chambers, a convection-cloud chamber can generate a steady state cloud
70 system for hours in a turbulent environment by maintaining a warm saturated bottom surface, a
71 cold saturated top surface, and a constant aerosol injection rate (Chang et al., 2016). The Michigan
72 Tech Pi convection chamber with a dimension of 2 m x 2 m x 1 m (width x depth x height) has
73 been used to explore aerosol-cloud-turbulence interactions, however, the Pi Chamber is too small
74 to initiate drizzle embryos mainly due to the relatively short lifetime of cloud droplets therein.
75 Results from large eddy simulations indicate that drizzle can be initiated in a large convection-
76 cloud chamber with a height on the order of 10 m (Thomas et al., 2023). However, the drizzle
77 drops are sparse in a large chamber, so the detection of single drizzle embryos in a large cloud
78 chamber is challenging for in-situ probes that generally have a sampling volume of only a few
79 cubic centimeters. On the other hand, active remote sensors have the ability to rapidly sample large
80 volumes and thus offer an attractive option for the detection of small drizzle droplets in a cloud
81 chamber.

82

83 Here, we will demonstrate that the detection of an individual drizzle droplet in the presence of
84 numerous cloud droplets is possible with a radar that can achieve a very small sampling volume.
85 The detection of individual drizzle droplets is possible because the radar signal-to-noise ratio (SNR)
86 of a point target (drizzle droplet) is not affected by the radar observational volume, while the SNR
87 of a distributed target (cloud droplets) scales with the radar volume. In the following sections, the
88 detection limits of an individual drizzle particle are investigated using idealized particle size
89 distributions and real particle size distributions from the Michigan Tech Pi Chamber. In the end,
90 the potential of THz radars offering unprecedented sub-centimeter range resolution will be
91 discussed for developing the single drizzle detection radar (Cooper and Chattopadhyay, 2014).

92

93

94

95 **2. Drizzle detection using radar**

96

97 The detection of early drizzle particles in clouds has been the topic of extensive research. First, the
98 radar needs to have sufficient sensitivity to detect cloud and drizzle droplets. This is typically
99 accomplished using millimeter-wavelength radar (Kollias et al., 2007). Early methodologies for
100 the detection of drizzle drop in clouds employ the use of reflectivity thresholds, ranging
101 from -15 to -20 dBZ, to identify drizzle existence (Frisch et al., 1995; Liu et al., 2008; Comstock
102 et al., 2004). Kollias et al. (2011) introduced the use of the radar Doppler spectra skewness as a
103 more sensitive method for detecting the presence of small drizzle droplets (Acquistapace et al.,
104 2017; Zhu et al., 2022). The radar Doppler spectra technique improved the detection of drizzle
105 droplets that can produce as low as -30 dBZ (Zhu et al., 2022).

106

107 However, the use of the radar Doppler spectra technique in a cloud chamber is challenging. First,
108 this will require that the radar point vertically to take advantage of the differential velocity between
109 cloud and drizzle droplets. If we assume a monodisperse droplet size distribution (DSD) and
110 Rayleigh scattering conditions, a drizzle detection limit of -30 dBZ is equivalent to a concentration
111 of 10^{-3} cm^{-3} of drizzle droplets with diameter equal to $100 \mu\text{m}$ or a concentration of 6.4×10^{-2}
112 cm^{-3} of drizzle droplets with $50 \mu\text{m}$ diameter. In the former case, the drizzle particle size is quite

113 large and not quite an early drizzle droplet detection. In the latter case, the concentration of drizzle
114 droplets is much higher than the concentration observed in nature ($\sim 10^{-4} \text{ cm}^{-3}$) (Zhu et al., 2022).
115 Furthermore, the conventional cloud radar has range resolution of tens of meters, which is not
116 applicable in a chamber facility which may be on the order of several meters (approaching the
117 collision mean free path).

118

119 As a result, we consider alternative methods to increase the probability of early drizzle droplet
120 detection against the cloud droplet signal. As the number concentration of drizzle particle is low,
121 by applying a small radar sampling volume V_{Radar} , it is possible that only one drizzle droplet is
122 present in V_{Radar} . In this case, the drizzle particle can be considered as a point target with
123 backscattering cross section $\sigma(\text{m}^2)$ and the received radar echo power P_r (mW) is commonly
124 expressed as (Battan, 1973):

125

$$126 \quad P_{r,\text{drizzle}} = P_t \frac{G^2 \lambda^2}{(4\pi)^3 r^4} \sigma(D_d) \quad (1)$$

127

128 where P_t is the transmit peak power (mW), G is the antenna gain, r (m) is the range of the target
129 relative to the radar receiver and λ (m) is the radar wavelength. It is noteworthy that P_r for a point
130 target does not depend on the radar sampling volume V_{Radar} . For distributed targets such as a cloud
131 droplet population described by a droplet size distribution (DSD) that represents the number
132 concentration of cloud droplets as a function of diameter, the received radar echo power is given
133 by:

134

$$135 \quad P_{r,\text{cloud}} = P_t \frac{G^2 \lambda^2}{(4\pi)^3 r^4} \cdot V_{\text{Radar}} \cdot \sum_{i=0}^n N_c(D_i) \sigma(D_i) \Delta D_i \quad (2)$$

136

137 Where n is the number of cloud droplets in the radar volume and $N_c(D)$ is the DSD with units of
138 m^{-4} . In this case, the received radar echo power depends on the radar sampling volume, which is
139 given by the following expression:

$$140 \quad V_{\text{Radar}} = \pi \left(\frac{r \theta_{3dB}}{2} \right)^2 \cdot \Delta R \quad (3)$$

141

142 where θ_{3dB} is antenna radiation pattern 3-dB beamwidth in radians and ΔR is the range resolution.
143 Assuming Rayleigh scattering, the backscatter cross section of the drizzle and cloud droplets is
144 proportional to the sixth power of the particle diameter and inversely proportional to the fourth
145 power of the wavelength ($\sigma(D) \sim D^6/\lambda^4$). Combing Eq. 1 and Eq. 2, the ratio of radar received
146 echo power from drizzle and cloud is given by the following expression:

147

$$148 \quad \frac{Signal}{Background} = \frac{P_{r,drizzle}}{P_{r,cloud}} = \frac{1}{V_{Radar}} \cdot \frac{D_d^6}{\sum_{i=0}^n N_c(D_i) D_i^6 \Delta D_i}. \quad (4)$$

149

150 Eq. 4 indicates that the probability of detecting a single drizzle droplet in the radar sampling
151 volume increases inversely to the radar sampling volume (point vs distributed target).

152

153 3. Detection requirement

154

155 Here, we will evaluate how small the radar sampling volume needs to be to detect drizzle drops
156 with different diameters against three background (cloud) conditions: i) monodisperse cloud DSD,
157 ii) cloud DSD from a theoretical model and iii) observed cloud DSD from the Michigan Tech Pi
158 Chamber. For simplicity, we will assume that a drizzle drop is detectable if its radar return power
159 is equal to that of the background echo contributed from cloud droplets.

160

161 3.1. Monodisperse cloud DSD

162

163 We first construct an idealized scenario by considering two categories of droplets, i.e. cloud droplet
164 with a diameter of D_c and a single drizzle drop with a diameter of D_d , the number concentration
165 of cloud droplets in the radar sampling volume is N_c (m^{-3}).

166

167 In this case, Eq. 4 is simplified as:

168

169

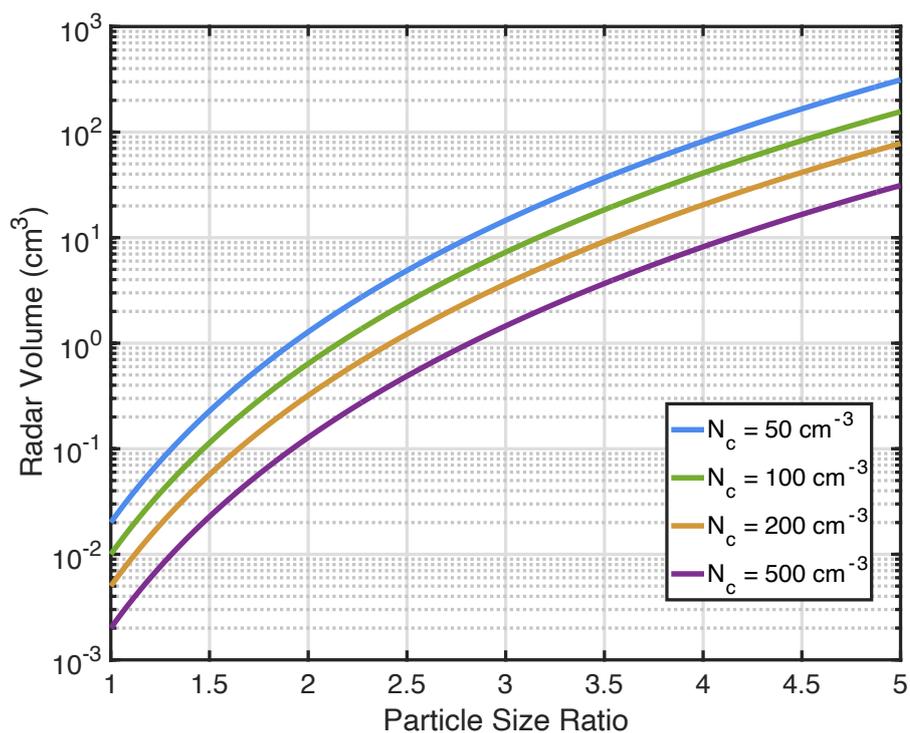

170

$$\frac{Signal}{Background} = \frac{1}{V_{Radars}} \cdot \frac{D_d^6}{N_c \cdot D_c^6} \quad (5)$$

171

172 When the signal power equals to the background, the radar sampling volume enabling single
173 drizzle particle detection is estimated as a function of the size ratio $x = \frac{D_d}{D_c}$ shown in Fig. 1. The
174 results are shown for various cloud droplet concentrations. It is noted that the required radar
175 volume for detection depends on the drizzle drop size and the cloud number concentration. Larger
176 radar volume would be required for drizzle detection as the particle size ratio increase; for a given
177 particle size ratio, decreasing cloud number concentration can enhance the required radar volume.
178 For example, if the cloud number concentration is 50 cm^{-3} and the mean cloud diameter (D_c) is
179 $20 \mu\text{m}$, then the detection of a drizzle particle with diameter of $40 \mu\text{m}$ ($x = 2$) requires radar
180 volume around 1 cm^3 . Such sampling volume are not achievable with traditional radar systems
181 that employ sampling volumes of the order of 1000 m^3 or more (Kollias et al., 2016).

182

183

184 Figure 1: Radar observational volume for single-drizzle-drop detection as a function of particle
 185 size ratio $x = \frac{D_d}{D_c}$. Lines of different color represent clouds number concentration (N_c): 50 cm^{-3}
 186 (blue), 100 cm^{-3} (green), 200 cm^{-3} (yellow) and 500 cm^{-3} (purple).

187

188

189 3.2 Drizzle detection against an idealized cloud droplet background

190

191 In a realistic cloud chamber environment, we expect a population of cloud droplets with various
 192 sizes that can be represented by a DSD. Particularly, when condensation and fallout are the main
 193 sources and sinks for the evolution equation for the DSD, the DSD in the cloud chamber can be
 194 approximately described by theoretically derived distributions (Saito et al., 2019; Chandrakar et al.,
 195 2020; Krueger, 2020). Here we adapt the theoretical DSD formula derived by Krueger (2020) to
 196 investigate the ability of a radar to detect a drizzle embryo present in a small sample volume under
 197 different chamber environment conditions. To better represent the cloud DSD under different
 198 environments, the analytical DSD is rearranged to be expressed as a function of liquid water
 199 content (LWC_c ; $g \text{ m}^{-3}$) and number concentration (N_c ; m^{-3}) as:

200

$$201 \quad N(D_c) = \frac{2N_c D_c}{\pi^{1/2}} \left(\frac{4\Gamma\left(\frac{5}{4}\right) \pi^{1/2} \rho_l N_c}{3LWC_c} \right)^{2/3} \exp \left(- \left(\frac{4\Gamma\left(\frac{5}{4}\right) \pi^{1/2} \rho_l N_c}{3LWC_c} \right)^{\frac{4}{3}} \left(\frac{D_c}{2} \right)^4 \right) \quad (6)$$

202

203 where ρ_l is liquid water density ($g \text{ m}^{-3}$), and D_c is cloud droplet diameter (m). $N(D_c)$ represents
 204 the number concentration of cloud droplet for the given diameter ($\text{cm}^{-3} \mu\text{m}^{-1}$).

205

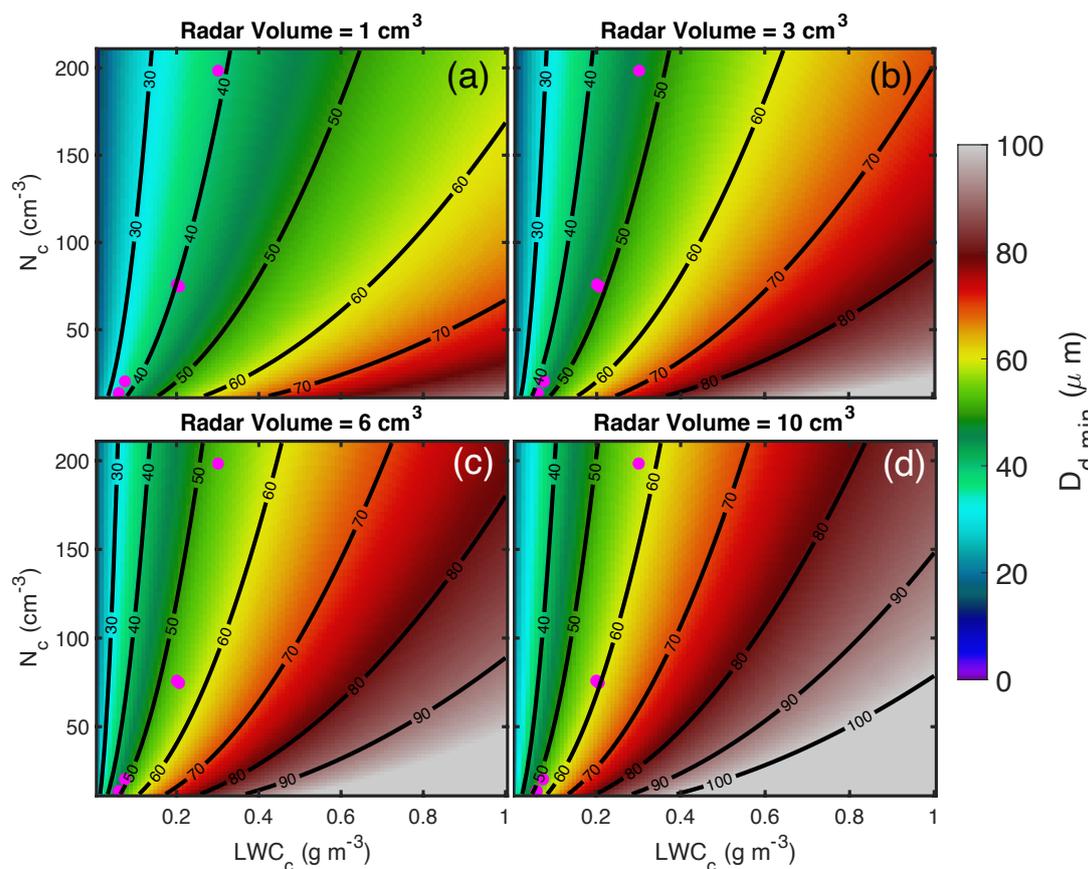

206 Here we define the minimal drizzle drop ($D_{a,min}$) as the size of particle with radar return power
 207 equal to the total return power from cloud droplets in a given radar volume (V). Given the cloud
 208 DSD described by Eq. 6, $D_{a,min}$ can be estimated as:

209

$$210 \quad D_{a,min}^6 = \int VN(D_c)D_c^6 dD \quad (7)$$

211

212 Figure2: The minimal detectable drizzle particle ($D_{d,min}$) under different LWC_c and N_c conditions
213 with radar sampling volume of (a) 1 cm^3 , (b) 3 cm^3 , (c) 6 cm^3 and (d) 10 cm^3 . The black lines are
214 the $D_{d,min}$ contour of $30 \mu\text{m}$, $40 \mu\text{m}$, $50 \mu\text{m}$, $60 \mu\text{m}$, $70 \mu\text{m}$. The magenta dots indicate the LWC_c
215 and N_c observed in the Pi-cloud chamber.

216

217 Fig. 2 illustrates $D_{d,min}$ under different LWC_c and N_c combinations for various radar volumes. For
218 a given steady-state cloud in a convection chamber (i.e., fixed LWC_c and N_c), $D_{d,min}$ generally
219 increases as the radar volume increases. This is because larger radar volumes contain more cloud
220 droplets that produce stronger background power, thus only a larger drizzle particle with a higher
221 backscattering signal would be detectable. On the other hand, for a given radar observational
222 volume, $D_{d,min}$ is jointly determined by LWC_c and N_c which are inversely proportional. As such,

223 $D_{d,min}$ increases rapidly with increasing LWC_c but slightly decreases with increasing N_c . This
224 contrasting relationship is caused by a larger sensitivity of radar reflectivity to particle size than to
225 number concentration. Thus, increasing LWC_c can increase mean cloud particle size and greatly
226 enhance the background power, leading to a larger detectable $D_{d,min}$. On the other side, when
227 LWC_c is fixed, increasing cloud total number concentration tends to decrease particle size. The
228 reduced cloud particle size would reduce the backscattering power and more than compensate for
229 the power enhancement contributed from the increased number concentration.

230

231 It should be noted that the actual LWC_c and N_c conditions in cloud chamber do not vary over the
232 full range shown in Fig. 2. Instead, the LWC_c and N_c often exhibit a positive covariance
233 relationship. To understand the typical value of these two quantities in the chamber environment,
234 we refer to typical measurement data from the Pi Chamber (magenta dots in Fig. 2). The data are
235 from experiments conducted by Chandrakar et al. (2018). We can notice that for this specific
236 experiment set up, drizzle embryos with diameter ranging from $40 \mu m$ to $60 \mu m$ can be detected
237 using radar observational volume from $1 cm^3$ to $10 cm^3$.

238

239 The aforementioned estimation is conducted under the assumption that signal (drizzle) power is
240 equal to the background (cloud) power. In practice, to reduce the probability of detection false
241 alarms, the drizzle signal should be larger than the backgrounds. Here we define the signal to noise
242 ratio (SNR) to investigate the drizzle detectability in the chamber environment:

243

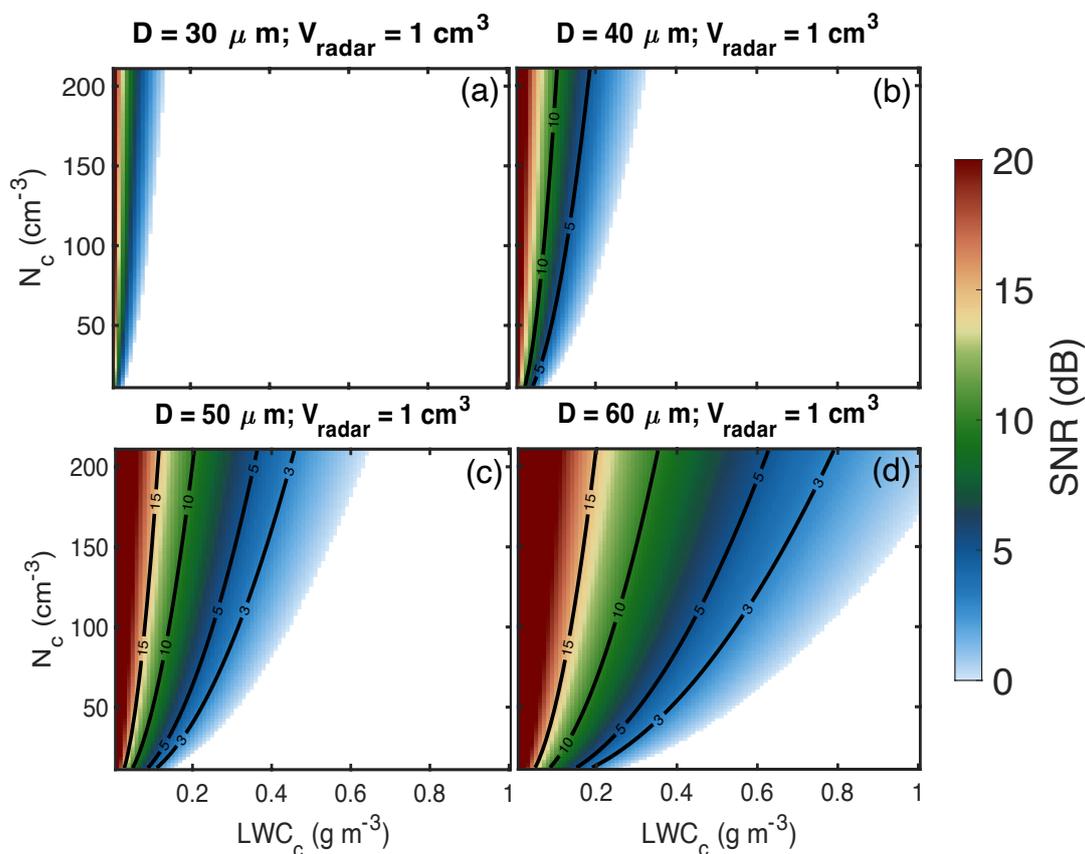

$$244 \quad SNR = 10 \log_{10} \left(\frac{D_d^6}{\int VP(D_c) D_c^6 dD} \right). \quad (8)$$

245

246 Fig. 3 shows the estimated SNR for four drizzle particles under varying LWC_c and N_c conditions
247 with a radar volume of $1 cm^3$. Generally, a smaller LWC_c and a larger N_c correspond to a large
248 SNR, which is preferable for drizzle detection. If we arbitrarily choose $SNR > 3$ as the detection
249 threshold, to detect a drizzle drop with diameter of $50 \mu m$ in a radar volume of $1 cm^3$ (Fig. 3c),
250 LWC_c in the cloud chamber should be lower than $0.3 g m^{-3}$ and N_c should be high than $90 cm^{-3}$.
251 The required LWC_c and N_c would be different for different drizzle particle targets: to detect drops
252 with diameter of $60 \mu m$, LWC_c should be lower than $0.5 g m^{-3}$ and N_c should be higher than 90

253 cm^{-3} . It should be noted that although a drizzle drop is more likely to be detected by the radar at a
254 lower LWC_c , drizzle initiation is generally more likely to occur at a higher LWC_c because the
255 collision-coalescence rate is thought to be proportional to the square of LWC (Kostinski and Shaw,
256 2005). This suggests appropriate LWC_c and N_c combinations should be achieved such that drizzle
257 can form by the C-C process in a convection cloud chamber and it can also be detected by radar in
258 a small sampling volume. It is also noted that the results shown in Fig.3 are based on a radar
259 volume of 1 cm^3 , and the estimated SNR would change if a different radar volume size is applied.
260 For instance, increasing the radar volume will enhance the background power thus decreasing the
261 SNR for the given cloud chamber environment.

262

263 Figure 3: SNR of the drizzle signal under different LWC and N conditions in a 1 cm^3 radar sample
264 volume for drizzle diameters of $30 \mu\text{m}$, $40 \mu\text{m}$, $50 \mu\text{m}$, $60 \mu\text{m}$, and $70 \mu\text{m}$. The black lines are
265 SNR contours of 3 dB, 5 dB, 10 dB and 15 dB. SNR lower than 0 is indicated as the blank region.

266

267

268 4. Probability of detection due to drizzle concentration

269

270 In the previous section, it was demonstrated that a radar with very small sampling volume ($\sim \text{cm}^3$)
271 can plausibly achieve the detection of single drizzle droplets against a cloud background signal.
272 On the other hand, the smaller the radar volume, the lower the probability of a drizzle particle
273 encountering the volume. To illustrate this trade-off scenario, we define the probability of drizzle
274 occurrence in the radar volume ($p(D_d)$) as:

275

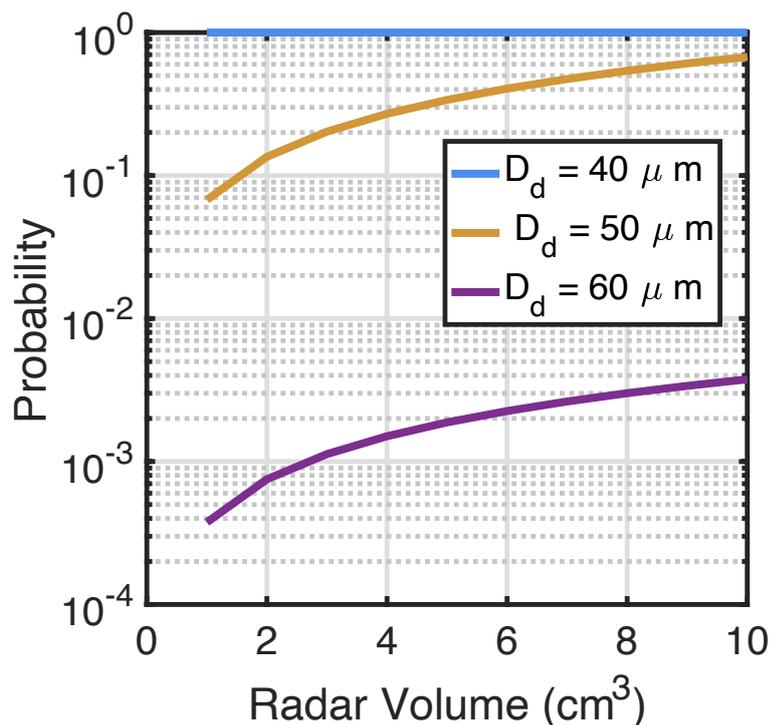

$$276 \quad p(D_d) = \begin{cases} 1, & VN(D_d)\Delta D \geq 1 \\ VN(D_d), & VN(D_d)\Delta D < 1 \end{cases} \quad (9)$$

277

278 Specifically, the product of V and $N(D_d)$ represents the expected number of drizzle drops in the
279 radar volume. If the product is smaller than 1, it indicates the probability of the occurrence of
280 drizzle particle in a given volume; while if the product is larger than 1, it means, statistically, at
281 least one drizzle drop with a diameter of D_d exists in the radar volume, and thus we set $p(D_d)=1$.

282

283

284

285 Figure 4: The probability of drizzle occurrence as a function of radar observational volume. The
286 blue, yellow, and purple lines indicate the drizzle particle with diameters of 40 μm , 50 μm , and 60
287 μm .

288

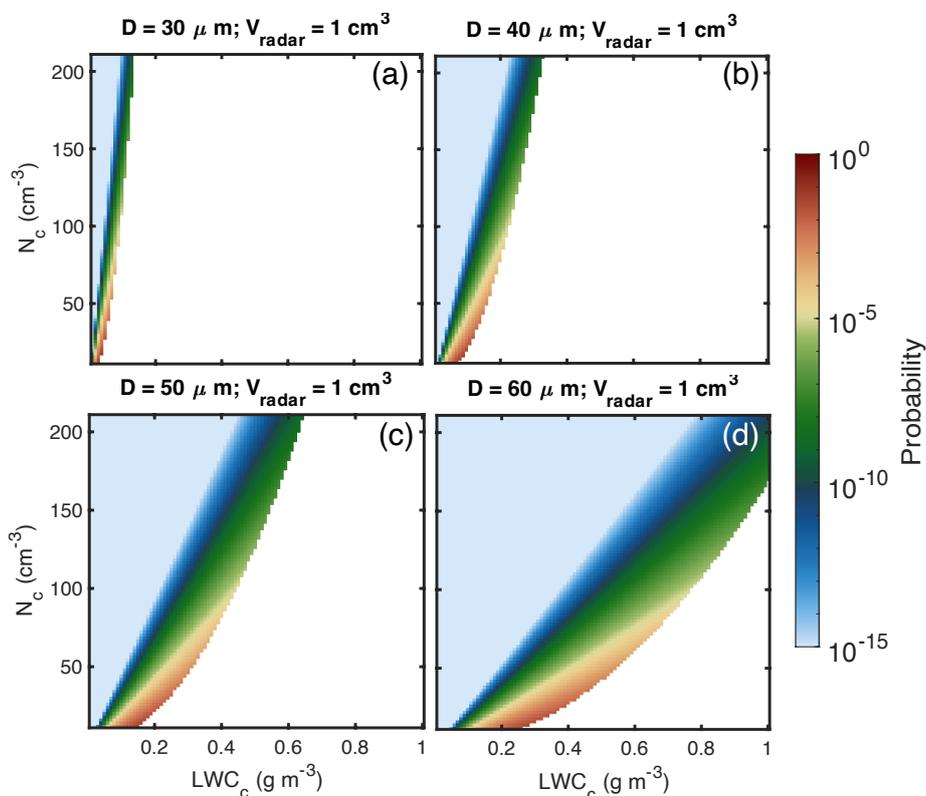

289 The probability of occurrence for three selected drizzle particles as a function of radar volume is
290 shown in Fig. 4. The $N(D)$ in Eq. 9 is adapted from the size distribution described by Eq.6, with
291 LWC_c and N_c set as 0.5 g m^{-3} and 50 cm^{-3} , respectively. For these conditions, drizzle droplets with
292 a diameter of 40 μm have sufficiently high concentration to be on average always present in
293 volumes larger than 1 cm^3 . For drizzle droplets with a diameter of 50 μm or 60 μm , their
294 concentration is low enough that their probability of being found in a 10 cm^3 volume is on average
295 below 1. It is also noticed that the occurrence probability is strongly sensitive to the particle size:
296 the probability of drizzle with 60 μm diameter occurring in the volume is almost two magnitudes
297 smaller than that for a particle with 50 μm diameter. A smaller drizzle occurrence in the volume

298 indicates that a larger number of radar samples would be required to find one particle, leading to
299 a longer observational time.

300

301 The probability of a drizzle drop to be in the radar sampling volume or passing through the radar
302 volume within a finite time period should be an important consideration for a practical
303 measurement system. Fig. 5 shows the probability of the occurrence of drizzle particle under
304 different chamber environments same as Fig. 3. The blank region in Fig. 5 indicates the
305 corresponding SNR shown in Fig. 3 is lower than 0 (i.e., cannot be detected by the radar even they
306 exist in the sampling volume). Generally, it is noticed that the probability of occurrence differs in
307 various chamber environment for different droplet size: large droplets have lower occurrence
308 probability under small LWC and high N conditions.

309 Figure 5: Drizzle occurrence probability under different LWC and N conditions for a 1 cm^3 radar
310 volume with particle diameter of (a) $30 \mu\text{m}$, (b) $40 \mu\text{m}$, (c) $50 \mu\text{m}$, and (d) $60 \mu\text{m}$. The blank region
311 indicates that the associated SNR is smaller than 0 (Fig. 3).

312

313 Comparison of Fig. 3 and Fig. 5 reveals that conditions that favor high radar SNR (i.e., larger drops
314 or smaller radar sampling volume) are associated with a lower probability of occurrence of the
315 drizzle droplet in the radar volume and subsequently increase the radar sampling time. For example,
316 to detect a drizzle particle of $50 \mu\text{m}$ diameter under the condition of LWC_c and N_c of 0.3 g m^{-3} , 90
317 cm^{-3} , the particle occurrence probability is on the magnitude of 10^{-8} (Fig. 5c) for SNR equals to 3
318 (Fig. 3c). A 1 dB enhancement of SNR threshold would decrease the occurrence probability to 10^{-
319 11 . This implies that on average, a volume of air equal to 10^{11} times the size of the radar sampling
320 volume needs to be sampled before a drizzle droplet will be detected. Assuming an air mean flow
321 within the cloud chamber of 1 m s^{-1} , this implies that a radar sampling volume with a typical
322 dimension of 1 cm will be updated (through advection) 100 times per second. If the radar is
323 sampling along 1000 range gates (i.e. assuming a chamber with height of 10 m), this suggests that
324 the radar can sample a volume equal to 10^5 its radar sampling volume each second. To reach the
325 average required sampling volume (10^{11}), it will take 10^6 seconds or 11.5 days. This is an
326 unrealistically long observational time. For practical application, we want to work with sampling
327 configurations that will not require to sample more than 10^9 times the radar sampling volume ($\sim 10\text{s}$
328 of minutes).

329

330 Another factor to consider in estimating the probability of drizzle occurrence with a certain
331 diameter in a specific volume is the realism of using Eq. 6 for describing the $N(D)$ in a cloud
332 chamber. Eq. 6 describes the cloud droplet distribution controlled by the condensation process
333 alone, thus the results may underestimate the actual drizzle occurrence as condensation is
334 inefficient to produce large drizzle particle. In nature or in a large convection cloud chamber, the
335 C-C mechanism is expected to be a more efficient process to increase the size and concentration
336 of drizzle droplets.

337

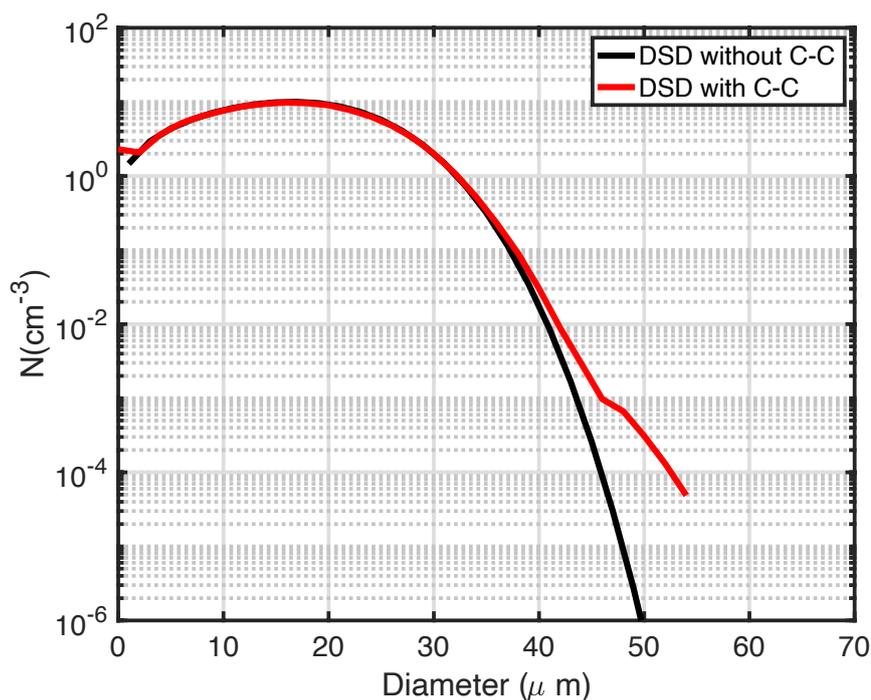

338 Here we apply the ClusColl model to demonstrate that Fig. 4 and Fig. 5 may underestimate the
339 drizzle occurrence probability with the collision-coalescence process being activate. ClusColl is a
340 simulation method for describing droplet motions and collisions in turbulent flows (Krueger and
341 Kerstein, 2018). ClusColl simulates the movement of individual droplets in a vertical column due
342 to turbulence and gravitational sedimentation. The unique capability of the ClusColl model is its

343 capability to efficiently simulate the droplet collisions and coalescence process. Fig. 6 shows the
344 simulated DSD with and without the collision-coalescence process for a 10-*m*-height cloud
345 chamber and with cloud number concentration of 100 cm^{-3} . The temperature difference between
346 top and bottom walls is 40 °C. Noticeable differences can be identified at the right tail of the
347 distribution, particularly for droplet diameter larger than 40 μm : more larger droplets are generated
348 if the collision-coalescence process is active. The higher concentration of large drops results in a
349 significantly shorter waiting time for detection compared to what was calculated for the
350 condensation-only examples given in the earlier part. For instance, for the generated particle with
351 diameter of 50 μm , the C-C process can generate number concentration more than 100 higher than
352 the one without C-C process included. Reviewing the earlier estimation, to detect drizzle particle
353 with diameter of 50 μm with SNR higher than 4, the required 10^6 s becomes 10^4 s which is
354 approximately 3 hours, which is much more achievable for laboratory experiment. Thus, the
355 estimation based on the condensation-only distribution (Eq. 6) is the most-conservative scenario.
356 The actual radar measurement time would likely to be much shorter when the C-C process is
357 activated.
358

359

360

361

362 Figure 6: DSD simulated from the ClusColl model with (red line) and without (black line) droplet
363 growth by collision-coalescence. In both cases, growth by condensation in a uniform
364 supersaturation field, and removal by size-dependent droplet sedimentation are calculated.
365 Therefore, the black line is described by the distribution given by Equation 6.

366

367

368

369 5. Evaluation from cloud chamber observations

370

371 In a cloud chamber and in the real atmosphere, the DSD in the radar sampling volume is expected
372 to be time dependent due to turbulent fluctuations. To better quantify the particle backscattering
373 power and its fluctuation in a small volume, observations made in the Pi Chamber using a
374 holographic system (Holo-Pi) are used. Holo-Pi uses the principle of in-line digital holography to

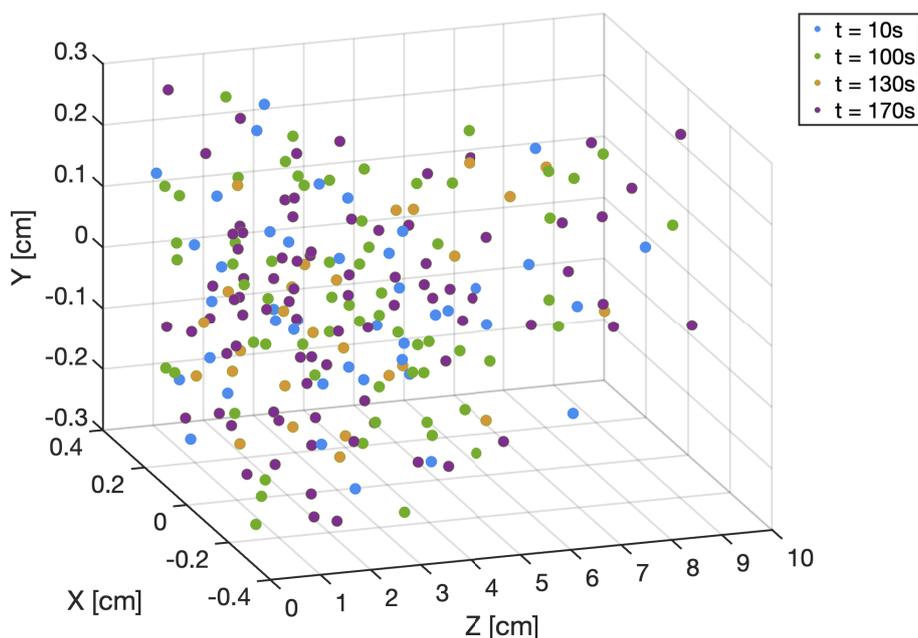

375 measure the spatial distribution and sizes of cloud particles (Fugal and Shaw, 2009;Beals et al.,
376 2015), and is specifically designed for the Pi-chamber environment (Desai et al., 2018). In contrast
377 to the typical measurement strategy of single particle detections requiring time averaging, Holo-
378 Pi captures instantaneous snapshots of all cloud droplets in the sample volume of 3.6 cm^3 (0.6 cm
379 $\times 0.6 \text{ cm} \times 10 \text{ cm}$) and is well suited to measure the temporal variations of cloud droplet
380 populations within a sample volume similar to plausible radar sample volumes. The inability to
381 resolve the smallest cloud droplets in the size distribution is not expected to be a significant
382 limitation as the backscattering radar power is more sensitive to larger particle diameters. For the
383 results presented here, cloud droplets are formed in the Pi Chamber by activation of size-selected
384 sodium chloride aerosol particles (dry particle diameter $\approx 130 \text{ nm}$) injected into a supersaturated
385 turbulent flow sustained by an unstable temperature difference of 20 K. An illustration of the 3D
386 view of the cloud droplets measured by Holo-Pi at different time instants in the Pi-chamber is
387 shown in Fig. 7. The sample volume used for our calculations is limited to a vertical extent of 5
388 cm as particle detectability falls off beyond this point; this results in a total sample volume of 1.8
389 cm^3 . The Holo-Pi system is set up to capture a hologram every 10 seconds during a 720-s period.
390 For the optical configuration used here, the Holo-Pi has a lower size resolution of $12 \mu\text{m}$
391 throughout its sample volume.

392

393

394

395

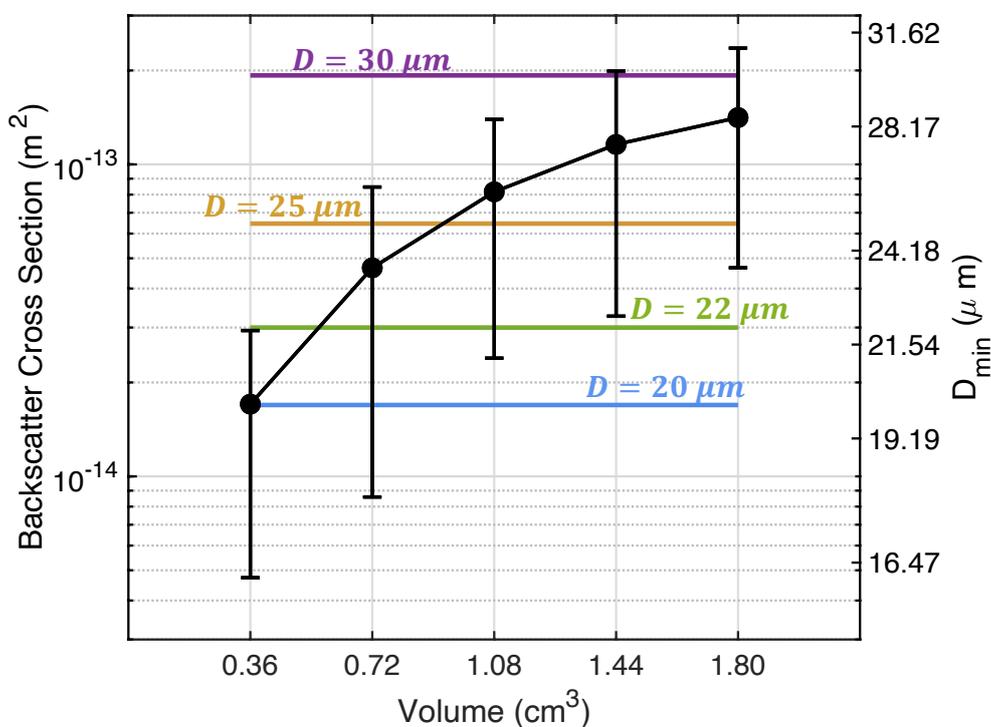

396 Figure 7: A 3D view of the particle locations observed by Holo-Pi in the Pi Chamber. Different
397 colors represent observations taken at different timesteps.

398

399 The Holo-Pi observational volume is divided into five sub volumes with the cross section of 0.36
400 cm^2 and the depth increasing from 1 to 5 cm with an increment of 1 cm , thus, corresponding to a
401 volume of 0.36 , 0.72 , 1.08 , 1.44 and 1.8 cm^3 . Within each sub-volume at each time step, the total
402 backscattering cross section for the detected droplets is estimated using a THz radar with
403 wavelength of 0.44 mm . The calculated radar backscattering cross section as a function of volume
404 size is shown in Fig. 8. Similar to the previous estimation, we see that the background power
405 increases with volume size due to the increment of cloud droplets. Importantly, the uncertainty
406 bars shown in Fig. 8 represent the standard deviation of the backscattering cross section during the
407 observational time, which indicates the background power fluctuations. We notice that the cloud
408 distribution in a small radar sampling volume is highly heterogeneous in time, and the magnitude
409 of the background fluctuation varies by approximately a factor of 10. In order to detect drizzle
410 drops, the backscattering power of the drizzle drop should be larger than the range of background

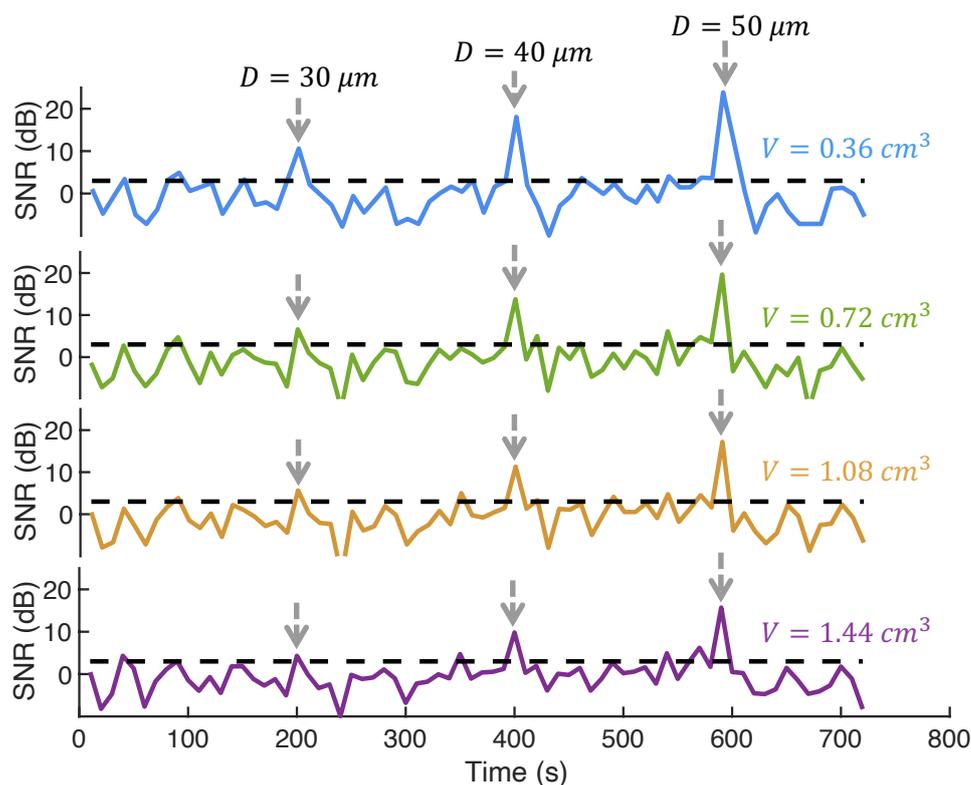

411 fluctuations. For example, a radar volume smaller than 0.36 cm^3 should be utilized to detect a
412 droplet with a diameter larger than $22 \mu\text{m}$, and a radar sampling volume smaller than 1 cm^3 is
413 needed to detect droplet with diameter larger than $30 \mu\text{m}$ for this particular Pi Chamber experiment
414 set up.
415

416
417 Figure 8: Dots and uncertainty bars indicate the mean and standard deviation of the total
418 backscattering cross-section (with units of m^2) of droplets measured in different volumes by Holo-
419 Pi during the observational period. The right axis and the horizontal lines represent the diameter
420 of a single drizzle drop with backscattering power equivalent to the background.

421 To further demonstrate the single drizzle detection concept using a small radar volume, a pseudo-
422 radar observation experiment is conducted based on the Holo-Pi measurements. The Holo-Pi
423 observational volume is divided into 4 sub-volumes indicated as different lines shown in Fig. 9. In
424 each volume, we consider the mean radar backscattering power from all cloud particles sampled
425 during the observational period as the background noise, and the power estimated at each time step
426 as the signal, such that the SNR as a function of observation time is estimated. To simulate the
427 drizzle occurring events, artificial drizzle droplets with diameter of $30\ \mu\text{m}$, $40\ \mu\text{m}$, $50\ \mu\text{m}$ are
428 added to the volume at 200 s, 400 s, and 600 s, respectively, and the associated SNR is estimated.
429 Fig. 9 shows a clear SNR enhancement when the drizzle droplets are added. The signal
430 enhancement is more significant when using a small sampling volume and for larger drizzle drop
431 diameter, which is consistent with the theoretical estimation in Sec. 3. For instance, a drizzle drop
432 with a diameter of $50\ \mu\text{m}$ can have a SNR of 23 dB with a volume of $0.36\ \text{cm}^3$ while it has a SNR
433 of 15 dB with a volume of $1.44\ \text{cm}^3$. For a drizzle drop of $30\ \mu\text{m}$, the SNR with a volume of $0.36\ \text{cm}^3$
434 cm^3 can reach to 10 dB, which is an adequate SNR value for radar detection, while with a volume

435 of 1.44 cm^3 , the drizzle drop SNR is overwhelmed by background fluctuation and it is unable to
436 be detected.

437

438 Figure 9: Simulated SNR of radar measurements during the Holo-Pi observational period using
439 four sampling volumes: 0.36 cm^3 (blue line), 0.72 cm^3 (green line), 1.08 cm^3 (yellow line) and
440 1.44 cm^3 (purple line). The grey arrows indicate an artificial drizzle particle is added at the
441 indicated time step. The black dashed line indicates a SNR of 3, which is used as a threshold to
442 distinguish the signal (drizzle) from the background (clouds) in Fig. 3.

443

444 6. Summary

445

446 Recent simulation results suggest that drizzle initiation could occur in a large convection-cloud
447 chamber. Such a facility would provide measurements in a controlled environment that can
448 advance our understanding of warm rain formation in clouds. One of the critical measurements in
449 a large convection-cloud chamber is the detection of low-concentration drizzle droplets in the
450 presence of numerous cloud droplets. Early in the drizzle initiation, those drizzle drops are rare
451 and in-homogeneously distributed in the chamber, presenting a significant detection challenge for
452 conventional in-situ probes. Here, the potential of a radar with ultra-fine sampling volume for
453 drizzle detection is investigated. It was demonstrated that if the radar sampling volume becomes
454 orders of magnitude smaller (e.g., several cm^3), compared to those typically available in research
455 radars ($\sim 10^3\text{-}10^6 \text{ m}^3$), isolated drizzle particles can be detected against the cloud background signal.
456 This concept is based on the notion that the SNR of point targets (i.e., drizzle droplet) is
457 independent of the radar sampling volume while the SNR of background (i.e., high concentration
458 cloud droplets) scales with the sampling volume.

459

460 A theoretical DSD was adapted to represent the distribution of cloud droplets in a convection cloud
461 chamber and to estimate properties of a detectable drizzle particle. It was shown that the minimum
462 size of an isolated drizzle droplet that can be detected with such a radar depended on the radar
463 sampling volume and the strength of the background signal (i.e., cloud droplets radar return), that
464 in turn, depends on LWC and N_c . To minimize the false alarm drizzle detection, we require that
465 the backscattering power from a drizzle particle should be larger than the backscattered power

466 contributed from the cloud particles ($\text{SNR} > 1$). It is demonstrated that the application of a small
467 radar volume can significantly enhance SNR under a given chamber environment. On the other
468 hand, the smaller the radar sampling volume the lower the probability of an isolated drizzle droplet
469 to be sampled. Thus, the determination of the radar volume for drizzle detection should account
470 for the size of drizzle particle of interest, the environment conditions that favor drizzle initiation
471 and the required observational time.

472

473 In addition to analytical estimates, real observations from the MTU Pi convection-cloud chamber
474 are used to demonstrate the single drizzle particle detection framework. The Holo-Pi system (Desai
475 et al., 2018) is applied to provide detailed 3D imaging of the cloud particles in the cloud chamber,
476 from which the fluctuations of the backscattering power in a small volume can be well estimated.
477 Generally, the observational results are consistent with the theoretical estimation showing that the
478 background power is decreased and the ability to detect drizzle particles is enhanced as radar
479 sample volume is decreased. It is also noticed that the magnitude of the background fluctuation is
480 comparable to the mean power, which indicate that the distribution of cloud droplets is highly
481 inhomogeneous in the small volume. Thus, the power from a drizzle particle should at least
482 dominate the background power fluctuation in order to be detected. With the cloud chamber
483 environment from the experiment, drizzle particles with diameter larger than $30 \mu\text{m}$ can be
484 confidently detected using a radar sampling volume of 1 cm^3 or lower.

485

486 The key remaining question is the technological feasibility of building a radar that can operate
487 within a box (large convection cloud chamber) and achieve the required ultra-fine range resolution.
488 In fact, the effort of using “small” radar volumes for single particle detection has already been
489 achieved in previous studies. For example, Schmidt et al. (2012) utilized a C-band radar with a 14-m^3
490 observational volume and successfully detected the trajectories of rain droplet with diameter
491 down to 0.5 mm . In our case, the required radar sampling volume for drizzle detection is much
492 smaller (with several cm^3). Such ultra-fine range resolution can be achieved using a THz radar
493 operating at 340 or 680 GHz that can support wide bandwidth waveforms and thus enable sub-
494 centimeter range resolution (Cooper and Chattopadhyay, 2014). If the radar operates at a very high
495 carrier frequency (THz) it can afford a very wide bandwidth for pulse modulation. In this case, the
496 range resolution is not dictated by the pulse length but from the radar bandwidth (Cooper and

497 Chattopadhyay, 2014). The ultra-fine range resolution along with a reflector that minimizes the
498 angular spread of the radar beam can result in radar sampling volumes of a few cm^3 . Such radar
499 imaging capabilities have been extensively used for security screening at airports, for example. In
500 our context, additional complexity is introduced by the fact that this radar needs to operate in a
501 chamber with typical dimension of ~ 10 m. These technical design issues will be the focus of a
502 follow-up paper study that will include real observations of drizzle droplets from a THz radar
503 system.

504

505 To conclude, we outline three issues that will need to be properly addressed before a radar can be
506 applied to the drizzle-detection problem in a cloud chamber:

507

508 1) Does the radar have enough sensitivity to detect a single drizzle particle? With the
509 development of the THz technology, radar with centimeter resolution is achievable,
510 however, the currently developed THz radars are mainly used to detect relatively hard
511 targets that do not require ultra-high sensitivity. For the purpose of drizzle detection,
512 however, the backscattering cross-section is on the order of $10^{-13} m^2$; such lower receiving
513 power would require the radar to have a much higher transmitting power or a larger antenna
514 size. Fortunately, an advantage for the drizzle detection in a cloud chamber is that the radar
515 detection range is only several meters depending on the size of the chamber. According to
516 Eq. 1, radar receiving power is inversely proportional to the fourth power of the target
517 distance. Thus, the small detection range may greatly relieve the demand for high
518 sensitivity in the radar design. In addition, recent advancements in THz transmitters allow
519 us to utilize higher power output transmitter (~ 50 to $200 mW$) at THz frequencies such as
520 340 GHz.

521

522 2) What are the appropriate radar sampling strategies for drizzle detection in a cloud chamber
523 facility? Most of the cloud radars applied in the atmosphere are vertically pointing and can
524 provide continuous observation at a given location along the radar beam. However as
525 discussed in the paper, drizzle occurrence in the chamber is extremely rare and
526 inhomogeneous in space and time. If the radar is vertically pointing, with the radar beam
527 of several cm width, it may wait significant time for the radar to detect one drizzle drop.

528 Adding a scanning capability to the radar may provide a more efficient way to observe and
529 detect drizzle in the cloud chamber.

530

531 3) How to eliminate or reduce the degradation effect of the chamber environment on a radar
532 signal? In particular, the cloud chamber is a humid environment with liquid particles
533 continually falling towards the bottom. Accumulation of water on the radar antenna can
534 also severally attenuate the transmitting power and degrade the radar detectability.
535 Furthermore, the chamber walls and the in-situ instruments mounted inside would produce
536 strong backscattering signals and pollute the backscattering signal from hydrometeors.
537 Thus, the design of the radar should also account for radar instrument design and sampling
538 strategies that minimize these noise sources so that the best possible detection capability
539 can be achieved.

540

541 In short, this paper demonstrates the conceptual feasibility of THz radars for rare drizzle detection
542 in a laboratory context. Undoubtedly, the development of a high-resolution radar for drizzle
543 detection in a cloud chamber needs close collaborations between cloud physics scientists and radar
544 engineers moving forward.

545

546 **Competing interests.**

547 **P. K.** is an associate editor of AMT.

548 The authors have no other competing interests to declare.

549

550 **Code/Data availability**

551 The codes and observations used to conduct all the analyses in this study are available upon
552 request.

553

554

555 **Author contributions**

556 Zeen Zhu conceptualized and implemented the method, performed the analysis, produced the
557 figures, and wrote the initial draft of the manuscript. Pavlos Kollias and Fan Yang contributed to
558 the conceptualization and provide guidance on the analysis. Raymond A. Shaw and Alex B.
559 Kostinski contributed to the simplified model described in Section 3.1. Steve Krueger provided
560 the ClusColl model. Nithin Allwayin provided the Holo-Pi measurements from the Pi Chamber.
561 All authors read the manuscript draft and contributed comments and manuscript editing.
