Abstract. Aerosol-Cloud interactions (ACI) result in the largest uncertainties in the global radiation budget so far. To improve the current consideration of ACI in global circulation models, it is necessary to characterize the 3-D distribution of
15 dust-related Cloud Condensation Nuclei Concentration (CCNC) and Ice Nucleating Particle Concentration (INPC) globally. This can potentially be realized using the POLIPHON (Polarization Lidar PHOtometer Networking) method together with spaceborne lidar observations. However, dust-related conversion factors to convert bulk aerosol optical properties from lidar measurements to aerosol microphysical properties, are still less constrained in many regions, which limits the applications of POLIPHON method. Here we retrieve the essential dust-related conversion factors at the remote oceanic/coast sites using the
20 historical AERONET (AErosol RObotic NETwork) databases. Depolarization-ratio-based dust ratios R_d at 1020 nm are applied to identify the dust-occurring cases so that it can be possible to contain fine-mode dust dominated cases (after the preferential removal of large-size dust particles during transport), study the evolution of dust microphysical properties along the transoceanic pathway, and mitigate occasional interference of large-size marine aerosols. The newly proposed scheme is proven to be valid and feasible by intercomparisons with previous studies at nine sites in/near the deserts. The dust-related
25 conversion factors are calculated at 20 oceanic/coast sites using both PD (pure dust) and PD+DDM (dust-dominated mixture) datasets. At nearly half sites, the conversion factors are solely calculated using the PD data sets; while at the rest sites, the participation of DDM datasets is required to ensure enough data points in the calculation. Evident variation trends in conversion factors are found for $c_{v,d}$ (extinction-to-volume, gradually decrease), $c_{250,d}$ (extinction-to-particle (with radius $>250\text{nm}$) number concentration, gradually increase) and $c_{s,d}$ (extinction-to-surface area concentration, plunge of
30 decrease) along both the transpacific and transatlantic dust transport pathways. The retrieved dust-related conversion factors are anticipated in inverting 3-D dust-related CCNC and INPC distribution globally to improve the understanding of ACI in atmospheric circulation models.

1 Introduction

35 Clouds are widely present in the Earth's atmosphere, covering approximately 2/3 of the Earth's surface. They play an essential role in weather, hydrology, climate, air chemistry, and several practical applications (Spänkuch et al., 2022). Clouds modify the radiation budget of the Earth by governing the incoming solar radiation and outgoing longwave radiation, thus significantly affecting the global climate. The level of induced net radiation is closely associated with the microphysical characteristics of cloud particles (either cloud drops or ice crystals), i.e., size, concentration, phase, shape, and so on, which
40 are greatly influenced by aerosol-cloud interactions (ACI), also known as 'aerosol indirect effects', resulting in the largest uncertainties in the global radiation budget so far (IPCC, 2013; Rosenfeld et al., 2014).

For liquid-water clouds, aerosols serve as cloud condensation nuclei (CCN) to alter the drop size and albedo (Twomey, 1974) as well as to postpone the initiation of rainfall and increase the lifetime and coverage of clouds (Albrecht, 1989). For mixed-phase and ice clouds, heterogeneous nucleation is another crucial effect in which proper aerosol particles may act as
45 ice-nucleating particles (INP) to trigger the in-cloud ice formation (from either vapor or liquid water) (Ansmann et al., 2019a, 2019b, 2021; Murray et al., 2012; Cziczo et al., 2013; Yin et al., 2021). In the ACI study, it is of great importance to quantify the number concentration of CCN and INP. In recent years, aerosol optical depth (AOD) and aerosol index (AI) are evaluated to be not accurate enough to serve as CCN proxies (Shinozuka et al., 2015; Stier, 2016), thus motivating the scientific community to estimate CCN concentration (CCNC) (Mamouri and Ansmann, 2016; Choudhury and Tesche, 2022;
50 Patel et al., 2022; Lenhardt et al., 2022). INP concentrations (INPC) are also estimated in many studies to conjecture the initial in-cloud ice crystal number concentration (ICNC) via primary heterogeneous nucleation (Ansmann et al., 2019a; He et al., 2022a). Besides, the constraint of ambient INPC can promote an accurate representation of cloud microphysical processes and reduce the uncertainties in estimating the climate feedback associated with ice and mixed-phase clouds in climate models (Li et al., 2022).

55 To estimate the CCNC and INPC, POLIPHON (POLarization LIdar PHOTometer Networking) method was developed by Ansmann et al. (2012) and has been improved for years in several field campaigns (Mamouri and Ansmann, 2014, 2015, 2016, 2017; Marinou et al., 2019). As a remote sensing approach, it has been well verified through comparisons with simultaneous in-situ measurements (Marinou et al., 2019; Wieder et al., 2022); hence, it is applicable for the analysis of long-term observations. In the POLIPHON method, the lidar-derived aerosol extinction coefficient profiles are first divided
60 into the respective contribution from different aerosol types (Tesche et al., 2009; Mamouri and Ansmann, 2016, 2017). Then, these aerosol-type-dependent extinction coefficient profiles are converted into CCNC and INPC profiles by employing the photometer-data-derived conversion factors and different CCN and INP parameterizations. Conversion factors connect the lidar-retrieved aerosol optical properties and aerosol microphysical properties and thus can be used to estimate CCNC and INPC straightforwardly.

65 Dust aerosol is the most abundant aerosol type by mass in the atmosphere (Kok et al., 2021a) and is considered both
effective CCN and INP (Mamouri and Ansmann, 2016; He et al., 2021a, 2021b, 2022a, 2022b; Murray et al., 2012; Kanji et
al., 2017). Therefore, dust-related CCNC and INPC estimations should be especially focused on. Numerous field campaigns
have been conducted to study the regional CCNC and INPC profiles (Haarig et al., 2019; Hofer et al., 2020; Engelmann et al.,
2021; He et al., 2021b). Benefiting from the spaceborne lidar, e.g., CALIOP (Cloud-Aerosol Lidar with Orthogonal
70 Polarization) launched in April 2006 (Winker et al., 2007) and EarthCARE mission in progress (Illingworth et al., 2015), it
allows us to characterize the 3-D distribution of dust-related CCNC and INPC at a global scale and in turn to improve the
current consideration of ACIs in global circulation models (Mamouri and Ansmann, 2015; Froyd et al., 2022).

To do this, the first challenge is to retrieve the global dust-related conversion factors. However, they are generally
regional-dependent and relevant to the microphysical properties of dust particles. Mamouri and Ansmann (2015) first
75 calculated the dust-related conversion factors based on the sun/sky photometer data during several field campaigns,
including SAMUM-1 (Saharan Mineral Dust Experiment), SAMUM-2, and SALTRACE (Saharan Aerosol Long-range
Transport and Aerosol-Cloud Interaction Experiment) and long-term observations in Limassol. Subsequently, Ansmann et al.
(2019b) obtained the dust-related conversion factors using AERONET (Aerosol Robotic Network) data at the typical sites
near the main deserts. They assumed the predominate contribution of dust in the atmospheric column and systematically
80 applied the column-integrated Ångström exponent (AE for 440–870nm) < 0.3 and AOD at 532nm > 0.1 as the criteria in
selecting dust presence cases. However, there are still many gaps in the downstream areas along dust transport pathways due
to insufficient data points fulfilling the criteria. Besides, the Ångström-exponent-based dust selection scheme may exclude a
part of fine-mode dust particles, resulting in a potential deviation in the conversion factors. The two major gaps are the
remote oceans and those polluted city regions (He et al., 2019b; Zhang et al., 2022). The ocean areas are less affected by
85 complicated anthropogenic aerosols and may always be intruded by long-range transoceanic dust plumes (Yu et al., 2021;
Dai et al., 2022), which are thus preferentially focused on in this study.

To retrieve the dust-related conversion factors at the oceanic/coast sites, we plan to adopt another scheme to select data
points, which are representative of dust presence from AERONET databases. The new scheme is based on the particle linear
polarization ratio in AERONET Version 3 aerosol inversion product, which is considered a better indicator for non-spherical
90 dust particles (Shin et al., 2018, 2019). Three factors motivate us to do so rather than to use the method raised by Ansmann
et al. (2019b). First, applying AE < 0.3 to select the dust-occurring data may somewhat exclude some data points
representative of fine-mode dust particles that are proven to be present and cannot be ignored (Mamouri and Ansmann, 2014;
Shin et al., 2019). Second, tracing the variations in dust-related conversion factors at different oceanic/coast sites may
provide us with more information on the evolution of dust microphysical properties along with transoceanic transport routes
95 (Rittmeister et al., 2017). In addition, marine aerosols that mainly consist of sea spray aerosols may occasionally show small
AE, which may confuse dust identification by using AE < 0.3 as a criterion (Smirnov et al., 2011; Yin et al., 2019).

In this study, we estimate the dust-related conversion factors in the POLIPHON method at those remote oceanic/coast
sites using the AERONET databases, which is considered an important step pushing forward to the study on dust

INPC/CCNC at a global scale and subsequent dust-induced ACI. The paper is organized as follows. We first briefly
100 introduce the POLIPHON method and dust-related conversion factors as well as the AERONET data and dust data
identification scheme. In section 3, we compare the dust-related conversion factor at the sites near deserts with a previous
study, represent the dust-related conversion factors at the ocean and coast sites, and discuss the possible reason behind the
variation in conversion factors along the transoceanic transport. In the last section, summaries and conclusions are given.

2 Data and methodology

105 2.1 POLIPHON method and conversion factors

The POLIPHON method is able to retrieve the height profiles of particle microphysical properties (i.e., particle number,
surface area, and volume concentration) and then, the height profiles of particle mass, CCN, and INP concentration for
several aerosol types using the combination of polarization lidar and sun photometer (Mamouri and Ansmann, 2014, 2015,
2016; Marinou et al., 2019). It has been widely used in the estimations of CCN- and INP-relevant aerosol parameters for the
110 aerosol types including dust (Ansmann et al., 2019a; Hofer et al., 2020; He et al., 2021b, 2022a, 2022b), marine aerosol
(Mamouri and Ansmann, 2016, 2017; Haarig et al., 2019), continental aerosol (Mamouri and Ansmann, 2016, 2017), smoke
(Ansmann et al., 2021; Haarig et al., 2019). In this study, we focus on the dust-related CCN- and INP properties.

In detail, the calculation has been given in Table 1. First, the dust backscatter β_d and extinction α_d coefficient can be
derived by polarization lidar observations based on the inversion method from Fernald (1984) and the dust-component
115 separation method from Tesche et al. (2009) as shown by the following equation:

$$\beta_d(z) = \beta_p(z) \frac{(\delta_p(z) - \delta_{nd})(1 + \delta_d)}{(\delta_d - \delta_{nd})(1 + \delta_p(z))} \quad (1)$$

where $\delta_d = 0.31$ and $\delta_{nd} = 0.05$ are dust and non-dust particle depolarization; δ_p and β_p are the lidar-derived particle
depolarization ratio and backscatter coefficient, respectively. The lidar ratio for dust usually ranges from 30 sr to 60 sr
depending on the different dust sources (Müller et al., 2007; Mamouri et al., 2013; Hu et al., 2020; Peng et al., 2021). Then,
120 the dust extinction coefficient can be converted into particle mass concentration M_d , particle number concentration $n_{250,d}$
($r > 250$ nm) and $n_{100,d}$ ($r > 100$ nm), and particle surface concentration s_d and $s_{100,d}$ ($r > 100$ nm) by multiplying their
corresponding conversion factors, i.e., $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and $c_{s,100,d}$. Finally, the dust-related INP concentration $n_{INP,d}$ can be
retrieved by inputting $n_{250,d}$ and S_d into different INP parameterization schemes (DeMott et al., 2010, 2015; Niemand et al.,
2012; Steinke et al. 2015; Ullrich et al., 2017). In addition, $n_{100,d}$ is considered a good proxy for dust-related CCN
125 concentration $n_{CCN,ss,d}$ as discussed by Mamouri and Ansmann (2016). Thus, $n_{CCN,ss,d}$ can be obtained by multiplying $n_{100,d}$
by a water supersaturation-dependent factor $f_{ss,d}$, which is 1.0 for a typical liquid-water supersaturation value of 0.2%.

In the POLIPHON method, as introduced above, a series of conversion factors are essential to the conversion from the
dust extinction coefficient to dust microphysical parameters regarding CCN and INP concentrations. The conversion factors

are pre-calibrated from the historical database of sun photometer observations (denoted as j for each data point, counting from 1 to J_d). The calculation processes are shown below (Ansmann et al., 2019b):

$$c_{v,d} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{V_{d,j}/D}{\tau_j/D} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{v_{d,j}}{\alpha_{d,j}} \quad (2)$$

$$c_{250,d} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{N_{250,j}/D}{\tau_j/D} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{n_{250,d,j}}{\alpha_{d,j}} \quad (3)$$

$$c_{s,d} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{S_j/D}{\tau_j/D} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{s_{d,j}}{\alpha_{d,j}} \quad (4)$$

$$c_{s,100,d} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{S_{100,j}/D}{\tau_j/D} = \frac{1}{J_d} \sum_{j=1}^{J_d} \frac{s_{100,d,j}}{\alpha_{d,j}} \quad (5)$$

where D is an introduced thickness for a given aerosol layer and τ is the sun-photometer-measured aerosol optical depth at 500 nm. V_d and N_{250} are the column particle volume concentration and column large particle (radius >250 nm) number concentration, respectively; S and S_{100} (radius >100 nm) are the column particle surface area concentrations. V_d , N_{250} , S , and S_{100} are derived from the particle size distribution data in AERONRT aerosol inversion products, which are introduced in detail in section 2.2. α_d is the layer-mean aerosol extinction coefficient at 550 nm; v_d and $n_{250,d}$ are the layer-mean volume concentration and large particle (radius >250 nm) number concentration, respectively; s_d and $s_{100,d}$ (radius >100 nm) are the layer-mean particle surface area concentrations. The subscript 'd' denotes 'dust', which is considered the major contribution in column aerosol loading for the selected sun photometer data.

In addition, it is considered that the estimation of CCN concentration is a challenging task since the ability of aerosol particles to serve as CCN is complicatedly related to the particle hygroscopicity (associated with particle size and chemical composition) and water supersaturation level (Wang et al., 2010; Moore et al., 2012). As suggested by Shinozuka et al. (2015), a log-log regression analysis was performed to retrieve the CCN-relevant conversion factor $c_{100,d}$ with the following equation:

$$\log(n_{100,d}) = \log(c_{100,d}) + \chi_d \log(\alpha_d) \quad (6)$$

In general, dust-related conversion factors have a regional-dependent characteristic, associated with the origin of dust regions as well as the specific local anthropogenic dust emissions (Philip et al., 2017). To extend the POLIPHON method towards global dust applications, Ansmann et al. (2019b) provided the dust-related conversion factors at 20 AERONET sites in/near the typical desert regions, where other types of aerosols contribute less or even negligible to the aerosol properties of the atmospheric column. Therefore, the obtained conversion factors can be considered the representatives of pure or quasi-pure dust situations. To pick out the dust-occurring datasets for calculation, they adopted the constraints of column-integrated Ångström exponent (for 440–870nm) <0.3 and aerosol optical depth (at 532nm) >0.1. Due to the influence of

anthropogenic aerosols, dust-occurring data points available are insufficient for calculating the conversion factors. To solve this issue, He et al. (2021b) applied the simultaneous polarization lidar observation to assist the filtration of dust-occurring datasets in Wuhan (30.5N, 114.4E), a central Chinese megacity impacted by both local anthropogenic aerosol emissions and long-range transported dust (He and Yi, 2015; He et al., 2022c; Liu et al., 2022).

160 Dust plumes can also realize transoceanic transport in the Northern Hemisphere; there are two well-known pathways, i.e., the transatlantic route from the Saharan desert to America (Yu et al., 2021; Dai et al., 2022) and the transpacific route from Asian dust sources (Taklimakan Desert and Gobi) to America (Guo et al., 2017; Hu et al., 2019). However, dust-related conversion factors over the ocean are rarely reported. Sea spray aerosols usually have a large size, presenting a similar small Ångström exponent as dust particles (Haarig et al., 2017). To avoid the interference of sea spray aerosol, we here use another
165 scheme to identify the dust-occurring datasets, taking advantage of the particle linear depolarization ratio (PLDR) in AERONET aerosol inversion products (Shin et al. 2019). Therefore, sufficient available dust data points can be picked out even at those remote oceanic sites.

2.2 AERONET data and depolarization-ratio-based dust data points selection

AERONET is a global ground-based aerosol monitoring network and has provided more than 25 years of aerosol column
170 property observations. The employed CE-318 sun-sky photometers allow the direct measurements of solar irradiance generally at 340, 380, 440, 500, 675, 870, 1020, and 1640 nm and directional sky radiance to retrieve the spectral-resolved AODs, and in turn, the additional aerosol inversion products. Moreover, the latest applied CE318-T can also perform nighttime measurements of the spectral lunar irradiance. In this study, the AERONRT database (Holben et al., 1998; Dubovik et al., 2000; Dubovik and King, 2000) was employed in retrieving the dust-related conversion factor at 9 sites
175 near/in the deserts (to compare with the values given in Ansmann et al. (2019b), as a validation of newly-proposed dust selection scheme) and at 20 oceanic/coast sites influenced by long-range transported dust (see figure 1). The oceanic/coast sites can be classified into five regional clusters, i.e., Pacific, Pacific coast, Atlantic, Indian Ocean, and Arctic Ocean, representing dust characteristics in different regions.

We used the quality-assured level-2.0 AOD at 500 nm in AERONET Version 3 aerosol optical depth-solar products (Giles et al., 2019). Moreover, the particle volume size distribution with 22 size bins (radius) ranging from 50 nm to 15 μm and PLDR in AERONET Version 3 aerosol inversion products are also used for calculating V_d , N_{250} , S , and S_{100} as described in section 2.1 (Sinyuk et al., 2020). The specific calculation processes can be found in Mamouri and Ansmann (2015) and Ansmann et al. (2019b). For the near/in desert sites, level-2.0 (quality-assured) aerosol inversion products are applied; while,
185 level-2.0 PLDR data are unavailable. The basic information of the selected sites is shown in Table 2, including period, longitude, latitude, and the number of data points for total, dust-dominated mixture, and pure dust.

In the AERONET retrieval, based on the aerosol spheroid model, the combination of the particle size distribution and complex refractive index can be used to further compute the two elements of the Müller scattering matrix, i.e., $F_{11}(\lambda)$ and

190 $F_{22}(\lambda)$ (Bohren and Huffman, 1983; Dubovik et al., 2006; Shin et al., 2018), which can then be used to derive the
backscattering PLDR with the following formula:

$$\delta_{\lambda}^p = \frac{1 - F_{22}(\lambda, 180^{\circ})/F_{11}(\lambda, 180^{\circ})}{1 + F_{22}(\lambda, 180^{\circ})/F_{11}(\lambda, 180^{\circ})} \quad (7)$$

AERONET PLDR data is a good indicator of dust occurrence, which has been verified to be well correlated with lidar-
derived values (Noh et al., 2017). Shin et al. (2018) found that PLDR values at 870 and 1020 nm are more reliable according
to the comparison with those from lidar observations for pure dust particles. Therefore, we here use PLDR at 1020 nm δ_{1020}^p
195 (only denote as 'PLDR' hereafter) to pick out the dust-occurring data points for POLIPHON conversion factor calculation
(Shin et al., 2019). Note that the overestimation of near-infrared PLDR is reported by comparing with concurrent
polarization lidar observations (Toledano et al., 2019; Haerig et al., 2022), possibly attributing to the assumption of spheroid
particle in AERONET inversion. Nevertheless, δ_{1020}^p values are only used to qualitatively identify the dust presence with the
presupposed threshold values. Its validity will be verified by comparing the derived conversion factors with those from
200 Ansmann et al. (2019b) in Section 3.1.

To represent the contribution of dust component to the total particle backscatter, it is defined as a variable, column-
integrated dust ratio ($R_{d,1020}$) as below:

$$R_{d,1020} = \frac{(\delta_{1020}^p - \delta_{nd}^p)(1 + \delta_d^p)}{(\delta_d^p - \delta_{nd}^p)(1 + \delta_{1020}^p)} \quad (8)$$

It should be noted that the dust (δ_d^p) and non-dust (δ_{nd}^p) particle depolarization ratios are set to be 0.30 and 0.02, respectively,
205 to be consistent with the value proposed by Shin et al. (2019). These two values are slightly different from those used in the
POLIPHON method in Eq. (1). According to the scheme from Shin et al. (2019), we classify data points with $R_{d,1020}$ values
of >0.89 as pure dust (PD) and 0.53-0.89 as dust-dominated mixture (DDM, also can be considered 'mixed dust' as in He et
al. (2019b). Note that in this study DDM includes the combination of the sectors B (FMF=0–0.4), C (FMF=0.4–0.6), and E
(FMF=0.6–1.0) in Shin et al. (2019). A flow chart is given as seen in figure 2. For the near/in desert sites, we presented the
210 results from the PD cluster, which is adequate to calibrate the conversion factors; whilst, for the oceanic/coast sites, the
results from both the PD and PD+DDM clusters are provided for comparison.

3 Dust-related conversion factors from the AERONET database

3.1 Intercomparison of dust-related conversion factors near deserts with retrievals in Ansmann et al. (2019b)

To validate the performance of the newly-proposed dust datasets selection scheme, we chose 9 out of 20 AERONET sites
215 used in Ansmann et al. (2019b) to compare the obtained conversion factors. They are mainly from three typical regions,
including North Africa, the Middle East, and Asia. It should be mentioned that $c_{100,d}$ values tend to be divergent when the
aerosol extinction coefficient is larger than 600 Mm^{-1} . Hence, the validations were only performed for $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and

$c_{s,100,d}$. Figure 3 shows the scatters regarding the relationships between 500-nm aerosol extinction and $n_{250,d}$, v_d , s_d , and $s_{100,d}$ for pure data situations at Cape Verde, Dushanbe, and Mezaira'a. The conversion factor values are also given accordingly. Here level 2.0 AOD and aerosol inversion products data were employed. PD datasets selected with the method from Shin et al. (2019) perform well as highly linear correlation can be found, with linear Pearson correlation coefficients exceeding 0.9.

Besides the three sites in figure 3, the conversion factors for the rest six sites are shown in Table 3 as well. The results for both PD and PD+DDM clusters are provided here. Generally, the regional differences in dust characteristics can be found in different dust sources. $c_{v,d}$, $c_{250,d}$, and $c_{s,d}$ calculated from PD and PD+DDM datasets are almost consistent with each other, suggesting the absolute dominance of dust particles at these near/in desert sites. It should be mentioned that the large discrepancy in $c_{v,d}$ between PD and PD+DDM clusters at Dalanzadgad is attributed to the few available data points (10 for DDM and 12 for PD). Interestingly, there are larger differences in $c_{s,d}$ and $c_{s,100,d}$ between PD and PD+DDM clusters at two Middle East sites, i.e., Eilat and Mezaira'a. After a careful check, it is noted that the DDM datasets have aerosol extinction coefficient values of 300-600 Mm^{-1} and show significantly larger s_d and $s_{100,d}$ than those for PD datasets (see figure A1). The special pattern reflects the involvement of a specific type of local aerosol in the dust-dominated mixture. Moreover, the PD-DDM differences are even larger for $c_{s,100,d}$ at both sites, indicating that the additional involved aerosols may play a vital role at the particle size spectral of >100 nm. According to furthermore examination, this special pattern generally can be found at partial sites from Middle East, Africa, and polluted European cities, which, however, are rarely present at the sites from East Asia, Australia, South America, and North America.

For comparison, we also plot the conversion factors in figure 4 together with those given by Ansmann et al. (2019b). $c_{v,d}$ and $c_{250,d}$ calculated from three dust datasets (DDM, DDM+PD, and A-19) coincide with each other very well. $c_{s,100,d}$ calculated from PD datasets are substantially consistent with those in Ansmann et al. (2019b), except for Dalanzadgad due to few available PD data points. $c_{s,d}$ calculated from PD datasets at two sites (CV and DK) are relatively larger than those in Ansmann et al. (2019b). Using either fine mode fraction (FMF) (Lee et al., 2010) or Ångström exponent (Ansmann et al., 2019b) in the AERONRT data as dust criterion implies an assumption that dust is constrained to the coarse mode. However, the proportion between fine and coarse mode dust may alter during transport due to the quicker removal of dust particles with larger size (Yu et al., 2021); hence, the dust criterion $AE < 0.3$ may exclude a portion of fine-mode dust (with radius <100 nm) dominated cases, resulting in an underestimation of $c_{s,d}$ at these two sites. Furthermore, region-featured emissions of non-dust small particles are also possibly responsible for this discrepancy.

3.2 Dust-related conversion factors $C_{v,d}$, $C_{250,d}$, $C_{s,d}$, and $C_{s,100,d}$ at the ocean and coast sites

In this study, we chose 20 ocean and coast AERONET sites, which were classified into five region categories including the Pacific, Pacific coast (both east and west coast), Atlantic, Indian Ocean as well as Arctic Ocean (Huang et al., 2015; Zhao et al., 2022). Figure 5 shows the scatters regarding the relationships between 500-nm aerosol extinction and $n_{250,d}$, v_d ,

250 s_d , and $s_{100,d}$ for both PD (in orange and red) and PD+DDM (in blue and light blue) situations at Mauna Loa (middle of Pacific), Shirahama (west coast of Pacific), Tudor Hill (west Atlantic), and Amsterdam Island (south Indian Ocean). The conversion factor values are also given accordingly. To eliminate abnormal values and retain the available dust data as much as possible, the data points with aerosol extinction of $>20 \text{ Mm}^{-1}$ participate in the calculation. PD data points generally show a good linear correlation. As for the PD+DDM cluster, three island sites show a similar good correlation except for
255 Shirahama, attributed to the small contribution of marine aerosols to total column aerosol loading (usually with a global mean AOD of ~ 0.05 , Smirnov et al., 2009). At the Shirahama site, it is conjectured that anthropogenic aerosols considerably contribute to the column aerosol loading and lead to the spread of scatters, which reflect variations in the characteristics (size distribution, refractive index, and so on) of other aerosol components in the dust-dominated mixture.

The conversion factors $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and $c_{s,100,d}$ at the other oceanic/coast sites are also provided in Table 4. Results
260 for both PD and PD+DDM clusters are listed in case the number of PD data points is inadequate to retrieve a valid conversion factor at some sites. We also plot these dust-related conversion factors in figure 6 for comparison. According to the estimation in section 3.1, it is suggested to preferentially use the PD datasets in the calculation to avoid the potential contribution of specific local aerosols, e.g., the special pattern in $c_{s,d}$ and $c_{s,100,d}$ at Eilat and Mezaira'a (see section 3.1). Nevertheless, PD+DDM datasets may take part in the calculation, as a suboptimal option, if the sole use of PD datasets
265 cannot guarantee the validity of conversion factors (10 out of 20 sites).

As seen in figure 6, $c_{250,d}$ mainly ranges from 0.17 to 0.24 Mm cm^{-3} ; the $c_{250,d}$ values calculated from PD and PD+DDM datasets agree with each other very well except for Midway Island and Nauru, indicating that few non-dust aerosols are contributing to the particle size spectral of $>250 \text{ nm}$ and $c_{250,d}$ is a relatively stable factor from region to region. For $c_{s,d}$ and $c_{s,100,d}$, their values from DDM+PD datasets mainly have a systematically positive deviation ($<25\%$), compared with those
270 from PD datasets, which may be affected by the marine aerosols. In addition, $c_{s,d}$ and $c_{s,100,d}$ values at coast sites (especially at Shirahama, Osaka, and Hokkaido University) are considerably larger than those at remote ocean sites, revealing their higher sensitivity (compare with $c_{250,d}$) to the involvement of other aerosols. However, large differences in $c_{v,d}$ values are found not only between PD and PD+DDM datasets but also from region to region. He et al. (2019b) also reported that mixed dust in Wuhan has a smaller $c_{v,d}$ than pure dust near the source region of Asian dust. Another interesting finding for $c_{v,d}$ is
275 that the values in the Arctic are only half of those in other regions. PD data points are rarely identified in the Arctic and conversion factors are all calculated from the DDM datasets here; abundant other aerosol types in the Arctic, e.g., smoke, anthropogenic aerosol, and marine aerosol (Engelmann et al., 2021; Zhao et al., 2022), may account for the low $c_{v,d}$ values. Nevertheless, $c_{v,d}$ can be beneficial to the validation of the mass extinction efficiency, a variable combining $c_{v,d}$ and dust density, in the 3-D global dust model (Adebiyi et al., 2020; Kok et al., 2021b; Wang et al., 2021).

280 3.3 Dust-related conversion factors $C_{100,d}$ and χ_d at the ocean and coast sites

In addition to the INP-relevant conversion factors, the relationship between 500-nm aerosol extinction and CCN-relevant parameters $n_{100,d}$ is also studied in this section. The analysis is based on the relationship between $\log(n_{100,d})$ and $\log(\alpha_d)$ as reported by Shinozuka et al. (2015). Figure 7 shows the relationship between the aerosol extinction and particle number concentration (radius >100 nm) $n_{100,d}$ at nine oceanic/coast sites. The data points representing PD (in blue) and DDM+PD (in orange) are both plotted. Ansmann et al. (2019b) found that $\log(n_{100,d})$ and $\log(\alpha_d)$ have a good correlation when taking data points with α_d at the range of 100-600 Mm^{-1} into consideration; while, correlation strength significantly decreases and the data points trends to be dispersive once α_d values exceed 600 Mm^{-1} . The AERONET sites selected here generally show a clear atmospheric environment with limited pollution aerosols and can fulfill the constraint of $\alpha_d < 600 \text{Mm}^{-1}$ except for those coast sites, e.g., Shirahama and Osaka. To retain sufficient data points, we adopted data points with α_d values ranging from 20 to 600 Mm^{-1} in our calculation.

Table 5 lists the values of $c_{100,d}$ and χ_d for both PD and DDM+PD datasets. Considering the regression coefficient >0.6 as valid analysis, attention should be paid when using the results at the coast sites Osaka, American Samoa, and Amsterdam Island. It is found that PD and DDM+PD datasets generally show a similar slope (corresponding to χ_d) in regression analysis, except for the Osaka site for which an evident intersection between two fitted lines appears, attributed to the insufficient PD data points available for fitting.

3.4 Variations in conversion factors along dust transport paths

The dust-related conversion factors may significantly vary along the way of dust transport due to the potential modifications of dust microphysical properties caused by the particle sedimentation, aging process, external mix with other aerosols, and so on. There are two main transoceanic paths of dust transport, i.e., the transatlantic one from the Saharan desert to America (Rittmeister et al, 2017; Yu et al., 2021; Dai et al., 2022) and the transpacific one from Asian dust sources (Taklimakan Desert and Gobi) to America (Guo et al., 2017; Hu et al., 2019). Here we selected several sites along these two paths to evaluate the variations of conversion factors. For the transpacific transport, six sites from Asian dust sources to America were selected, including Dushanbe, SACOL in Lanzhou, Shirahama, Midway Island, Mauna Loa, and Trinidad Head. For the Transatlantic transport, four sites from North Africa to America were selected, including Dakar, Cape Verde, ARM Graciosa, and Tudor Hill.

Figure 8 shows the conversion factors $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and $c_{s,100,d}$ at the selected sites along the two dust transport paths. It is noted that the microphysical properties of dust particles originating from the Saharan Desert and Asian dust sources are very different. Moreover, with the increase in transport distances, an evident variation tendency is observed for all the conversion factors at both transoceanic paths. $c_{v,d}$ values show a significant decline along with the transport, indicating that the proportion of dust particles in the atmospheric column tends to be smaller owing to the sedimentation. He et al. (2021b) also observed a relatively smaller $c_{v,d}$ of $0.52 \times 10^{-12} \text{Mm m}^3 \text{m}^{-3}$ at the downstream area in central China compared with the

value obtained near the sources of Asian dust. $c_{250,d}$ values show a gradual increase trend along with the transport, suggesting the increased contribution of large-size sea spray aerosols in the atmospheric column. As for $c_{s,d}$, a sharp decline is observed between the values before and after transoceanic transport. The plunge of $c_{s,d}$ is more prominent for the
315 transpacific path than the transatlantic path. In contrast, $c_{s,100,d}$ values just show an inapparent enhancement. This suggests that particles with radius <100 nm should be responsible for the plunged $c_{s,d}$ after transoceanic transport.

4 Summary and conclusions

To improve the current consideration of ACIs in atmospheric circulation models, it is necessary to characterize the 3-D distribution of dust-related CCNC and INPC at a global scale. The combination of CALIOP spaceborne lidar observations
320 together with the POLIPHON method has the potential to realize this purpose. In this study, as the first step, we retrieved the essential dust-related conversion factors at the remote ocean sites where these parameters are less constrained. The historical AERONET databases were employed to calculate the conversion factors. Depolarization ratios at 1020 nm from AERONET version 3 aerosol inversion product were used to calculate the column-integrated dust ratios $R_{d,1020}$, which were further applied for identifying the dust presence within the atmospheric column (Shin et al., 2018, 2019). Compared with the use of
325 the Ångström exponent (Ansmann et al., 2019b), this treatment is beneficial for containing the fine-mode dust dominated cases (after the preferential removal of large-size dust particles during transport), mitigating the occasional interference of large-size marine aerosols, and studying the evolution of dust microphysical properties along the transoceanic transport path.

It is found that $c_{v,d}$, $c_{250,d}$, and $c_{s,100,d}$ are generally well consistent with those provided by Ansmann et al. (2019b) at nine sites near the deserts. However, $c_{s,d}$ obtained in this study are systematically larger than those given by Ansmann et al.
330 (2019b), which is attributed to the possible miss of fine-mode dust particles with radius <100 nm. For all the dust-related conversion factors, PD and PD+DDM datasets give similar results except for two Middle East sites, i.e., Eilat and Merzaira'a. Then, we calculated all the dust-related conversion factors at 20 oceanic/coast sites using both PD and PD+DDM datasets. Only 10 sites have adequate PD data points to retrieve $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and $c_{s,100,d}$. Among them, $c_{v,d}$ values are more sensitive to the influence of other aerosols involved in the atmospheric column and show large differences between PD and
335 PD+DDM clusters as well as from region to region. In addition, only 9 sites successfully obtain the CCN-relevant factors $c_{100,d}$ and χ_d in the regression analysis. Moreover, $c_{v,d}$ values are gradually decreased along with the transoceanic transport; in contrast, $c_{250,d}$ values show an increasing trend. A plunge of $c_{s,d}$ can be found after transoceanic transport, which, however, is not observed for $c_{s,100,d}$, suggesting that the discrepancy may be owing to the influence of particle size spectral of <100 nm (radius).

340 For the ocean sites, the depolarization-ratio-based method for selecting the dust-occurring data is proven to be valid and feasible. The PD data sets are suggested to be the preferential option to calculate the dust-related conversion factors. In case the available PD data points are insufficient, the PD+DDM cluster would be a suboptimal option allowing us to obtain the

conversion factors with certain accuracy and robustness. In the following work, we will conduct some case studies on dust-
cloud interaction over the ocean with CALIOP spaceborne lidar observations and the dust-related conversion factors used in
345 this study. In addition, the dust-related conversion factors in polluted city sites will be examined with the same method;
under this situation, the application of PD or PD+DDM data sets needs to be further discussed in depth. After that, the 3-D
view of global CCNC and INPC can be anticipated to improve our current consideration of ACIs in atmospheric circulation
models.

Appendix A: Additional analysis

350

Figure A1: Relationship between aerosol extinction coefficient at 500 nm and surface area concentration s_d and $s_{100,d}$ (only considering particles with radius >100 nm) for pure dust (PD) and dust-dominated mixture (DDM) at two Middle East sites, i.e., (a) and (b) for Eilat, and (c) and (d) for Mezaira'a. The PD and DDM data points are determined by the AERONET V3 database (level-2.0 AOD products and level-2.0 aerosol inversions) according to the method from Shin et al. (2019). The corresponding dust-related conversion factors $c_{s,d}$ and $c_{s,100,d}$ are also given,
355 **respectively.**

Data availability

All data used in this work can be accessed through the AERONET home page at <https://aeronet.gsfc.nasa.gov/> (AERONET, 2022).

360 **Author Contributions**

Yun He conceived the research, analyzed the data, acquired the research funding, and wrote the manuscript. Zhenping Yin conceived the research, participated in scientific discussions, and reviewed and proofread the manuscript. Albert Ansmann reviewed the manuscript and participated in scientific discussions. Fuchao Liu and Longlong Wang reviewed and proofread the manuscript. Dongzhe Jing and Huijia Shen participated in the data processing.

365 **Competing interests**

The authors declare that they have no conflict of interest.

Acknowledgments

The authors thank all PIs of the AERONET sites used in this study for maintaining their instruments and providing their data to the community.

370 **Financial support**

This research has been supported by the National Natural Science Foundation of China (grant nos. 42005101, 41927804, and 42205130), the Fundamental Research Funds for the Central Universities (grant no. 2042021kf1066), and the Meridian Space Weather Monitoring Project (China).

630 **Table 1.** Dust-related parameters of optical properties, cloud condensation nuclei, and ice-nucleating particles calculated by the POLIPHON method (Tesche et al., 2009; Marinou et al., 2019; Ansmann et al., 2019b). D10, D15, U17, N12, and S15 refer to the respective INP parameterization in DeMott et al. (2010), DeMott et al. (2015), Ullrich et al. (2017), Niemand et al. (2012), and Steinke et al. (2015). The subscript ‘ss’ denotes water supersaturation.

Dust-related parameters	Computation	Uncertainty	References
Dust backscatter β_d ($\text{Mm}^{-1} \text{sr}^{-1}$)	$\beta_d(z) = \beta_p(z) \frac{(\delta_p(z) - \delta_{nd})(1 + \delta_d)}{(\delta_d - \delta_{nd})(1 + \delta_p(z))}$ $\delta_d = 0.31, \delta_{nd} = 0.05$	10-30%	(Tesche et al., 2009)
Dust extinction α_d (Mm^{-1})	$\alpha_d(z) = LR_d \times \beta_d(z)$	15-25%	(Ansmann et al., 2019b)
Dust mass conc. M_d ($\mu\text{g m}^{-3}$)	$M_d(z) = \rho_d \times \alpha_d(z) \times c_{v,d}$ $\rho_d = 2.6 \text{ g cm}^{-3}$	20-30%	(Ansmann et al., 2019b)
Particle number conc. ($r > 250 \text{ nm}$) $n_{250,d}$ (cm^{-3})	$n_{250,d}(z) = \alpha_d(z) \times c_{250,d}$	25-35%	(Ansmann et al., 2019b)
Particle surface conc. S_d ($\text{m}^2 \text{cm}^{-3}$)	$S_d(z) = \alpha_d(z) \times c_{s,d}$	30-40%	(Ansmann et al., 2019b)
Particle surface conc. ($r > 100 \text{ nm}$) $S_{100,d}$ ($\text{m}^2 \text{cm}^{-3}$)	$S_{100,d}(z) = \alpha_d(z) \times c_{s,100,d}$	20-30%	(Ansmann et al., 2019b)
$n_{\text{INP},d}$ (L^{-1}) from $n_{250,d}$	INP parameterization D10 and D15	50-500%	(DeMott et al., 2010, 2015)
$n_{\text{INP},d}$ (L^{-1}) from S_d and $S_{100,d}$	INP parameterization U17, N12 and S15	50-500%	(Niemand et al., 2012; Steinke et al. 2015; Ullrich et al., 2017)
$n_{\text{CCN},ss,d}$ (L^{-1}) from $n_{100,d}$	$n_{\text{CCN},ss,d}(z) = f_{ss,d} \times n_{100,d}(z)$	50-200%	(Mamouri and Ansmann, 2016)

635 Figure 1: Overview of the ocean and coast AERONET sites used in this study. Labels for each site are taken from AERONET site list.

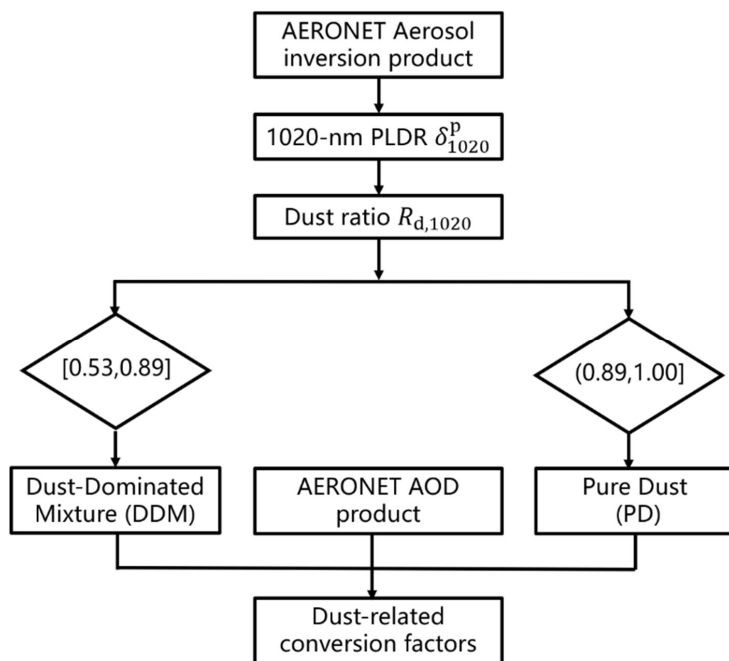

640

Table 2. Basic information of the AERONET sites selected for dust-related POLIPHON conversion factors calculation near the deserts (from North Africa, the Middle East, and Asia) and over the ocean and coast (from the Pacific, Pacific coast, Atlantic, Indian Ocean, and Arctic Ocean) regions, including the site name and abbreviation, period, and location. The available number of data points for total, dust-dominated mixture (DDM), and pure dust (PD) in AERONET version 3 aerosol inversion products (level 2.0 for near-desert cluster and level 1.5 for oceanic/coast cluster) are also given, respectively.

	Site (Abbreviation)	Period	Location	Total Obs.	DDM Obs.	PD Obs.

645 **Figure 2:** Flow chart for retrieving the dust-related POLIPHON conversion factors.

Figure 3: Relationship between aerosol extinction coefficient at 500 nm and large particle (with radius >250 nm) number concentration $n_{250,d}$ and volume concentration v_d , and surface area concentration s_d and $s_{100,d}$ (only considering particles with radius >100 nm) for pure dust at three typical sites, i.e., (a) and (d) for Cape Verde, (b) and (e) for Dushanbe, and (c) and (f) for Mezair'a. The pure dust data points are selected from the AERONET V3 database (level-2.0 AOD products and level-2.0 aerosol inversions) using the threshold of particle linear depolarization ratio derived with the method given by Shin et al. (2019). The corresponding dust-related conversion factors $c_{v,d}$, $c_{250,d}$, $c_{s,d}$ and $c_{s,100,d}$ are also given, respectively.

655

Table 3. POLIPHON dust-related conversion factors $c_{v,d}$ (10^{-12} Mm), $c_{250,d}$ (Mm cm^{-3}), $c_{s,d}$ (10^{-12} Mm $\text{m}^2 \text{cm}^{-3}$) and $c_{s,100,d}$ (10^{-12} Mm $\text{m}^2 \text{cm}^{-3}$) for DDM+PD and only PD, respectively. The respective standard deviations are also provided. The sites are classified into three regional clusters, including North Africa, the Middle East, and Asia.

	Site	$C_{v,d}$ (10^{-12}Mm)		$C_{250,d}$ (Mm cm^{-3})		$C_{s,d}$ ($10^{-12}\text{Mm m}^2\text{cm}^{-3}$)		$C_{s,100,d}$ ($10^{-12}\text{Mm m}^2\text{cm}^{-3}$)

665 **Figure 4: Intercomparison of dust-related conversion factors at nine sites (as shown in Table 2) near the deserts (a) $c_{v,d}$ and $c_{250,d}$, and (b) $c_{s,d}$ and $c_{s,100,d}$ calculated with the dust (both PD+DDM and PD) data selection scheme (based on particle linear depolarization ratio) in this study with those derived with the constraints of Ångström exponent for the 440–870 nm wavelength range $AE_{440-870} < 0.3$ and aerosol optical depth at 532 nm $AOD_{532} > 0.1$ given by Ansmann et al. (2019b) (denoted as ‘A-19’).**

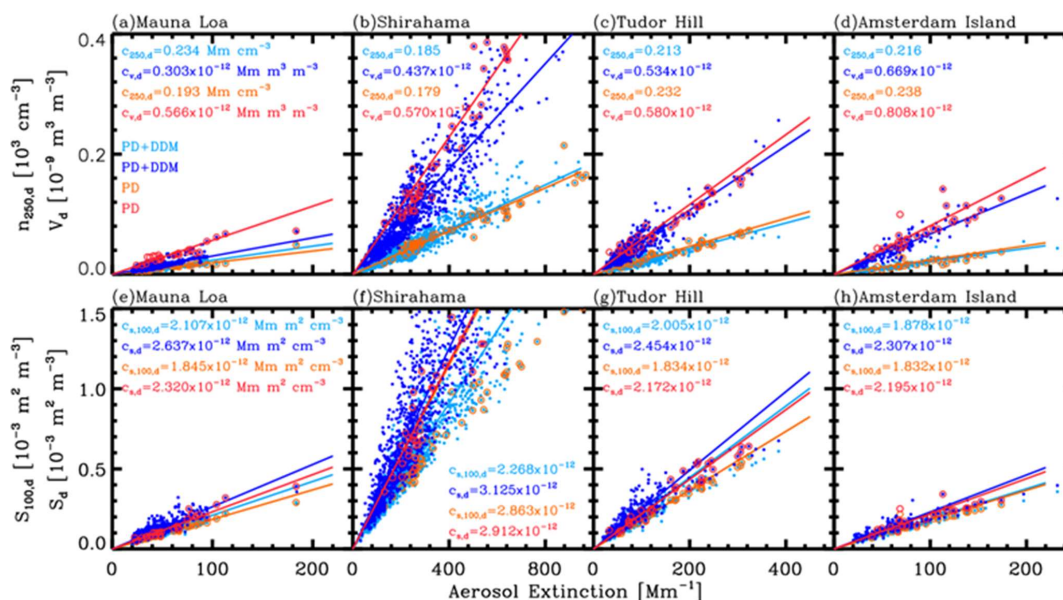

Figure 5: Relationship between the aerosol extinction coefficient at 500 nm and large particle (radius >250 nm) number concentration $n_{250,d}$ and volume concentration v_d , and surface area concentration s_d and $s_{100,d}$ (radius >100 nm) for DDM+PD and PD at four typical ocean and coast sites, i.e., (a) and (d) for Mauna Loa, (b) and (f) for Shirahama, (c) and (g) for Tudor Hill, and (d) and (h) for Amsterdam Island. The PD and DDM data points are selected from the AERONET Version 3 database (level-2.0 AOD products and level-1.5 aerosol inversion products) using the dust ratio threshold derived with the method given by Shin et al. (2019). The corresponding values of dust-related conversion factors $c_{v,d}$, $c_{250,d}$, $c_{s,d}$, and $c_{s,100,d}$ are also given, respectively.

680 **Table 4. POLIPHON dust-related conversion factors $c_{v,d}$ (in 10^{-12} Mm), $c_{250,d}$ (in $Mm\ cm^{-3}$), $c_{s,d}$ (in 10^{-12} $Mm\ m^2\ cm^{-3}$) and $c_{s,100,d}$ (in 10^{-12} $Mm\ m^2\ cm^{-3}$) for DDM (dust-dominated mixture) +PD (pure dust) and only PD based on the AERONET data analysis. The respective standard deviations are also provided. The sites are classified into five regional clusters, including the Pacific, Pacific coast, Atlantic, Indian Ocean, and Arctic Ocean.**

	Site	$C_{v,d}$ ($10^{-12}Mm$)		$C_{250,d}$ ($Mm\ cm^{-3}$)		$C_{s,d}$ ($10^{-12}Mm\ m^2cm^{-3}$)		$C_{s,100,d}$ ($10^{-12}Mm\ m^2cm^{-3}$)
