Abstract

18 Organic sulfur and sulfate compounds, tracers for sources and atmospheric processes, are not
19 currently measured in national monitoring networks such as the Interagency Monitoring of
20 Protected Visual Environments (IMPROVE). The goal of this paper is to begin to assess the
21 stability of organic sulfur and sulfate containing compounds on polytetrafluoroethylene (PTFE)
22 filters and the suitability of Fourier-transform infrared (FT-IR) spectroscopy to measure these
23 compounds. Stability assessment is needed because PTFE samples collected by IMPROVE are
24 typically stored 6-9 months prior to analysis. For this study, two organosulfur compounds,
25 methanesulfonic acid (MSA) and hydroxymethanesulfonate ion (HMS), and two organosulfate
26 compounds, methyl sulfate (MS) and 2-methyltetrol sulfate (2-MTS), are collected individually
27 on PTFE filters. Gravimetric mass measurements is used to assess mass stability over time. FT-
28 IR spectra are evaluated to assess the capability of measuring the compound from PTFE filters by
29 assessing the compound stability or chemical changes over time. Ion chromatography (IC) and
30 Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) are used as an additional
31 tool to assess stability or chemical changes over time. MS has the highest potential to be measured
32 by FT-IR in IMPROVE samples. For MS, a simple organosulfate, the mass changes are within
33 measurement uncertainty and FT-IR spectra indicate no compositional change over a 4-month
34 period, suggesting MS can be measured using FT-IR. IC and ICP-OES support the conclusion
35 that MS is stable on the filter. However, for 2-MTS, the other organosulfate measured in this study,
36 spectral changes after a month on the filter suggests it decomposes into other organosulfates or an
37 inorganic sulfate. MSA in IMPROVE samples can be measured, but only as a lower bound, due
38 to volatility off of the filter as indicated by FT-IR and gravimetry. FT-IR and IC both show that
39 MSA is not chemically changing over the course of the study. Measurements by all methods

40 indicate HMS is unstable on PTFE filter and IC and FT-IR indicate that it likely converts to
41 inorganic sulfate. Future work includes the evaluation of these compounds in as ambient aerosol
42 sample matrix to determine any differences in stability and identify interferences that could limit
43 quantification.

1. Introduction

44
45

46 Organic sulfur compounds exist in particulate form in the atmosphere and can be the result of
47 natural processes (e.g. marine sulfur, volcanic emissions) (Aneja and Cooper, 1989; Bates et al.,
48 1992) or activities of anthropogenic sources (e.g. combustion, sulfur-rich wastewaters, smelting)
49 (Grübler, 1998; Smith et al., 2011). Organic sulfur compounds can be categorized as
50 organosulfur compounds such as sulfones (RSO_2) and sulfonic acids (RSO_3^-) having C-S bonds,
51 while organosulfates (ROSO_3^-) have a C-O-S bond in the structure (Song et al., 2019). Two
52 sulfonic acid compounds, methanesulfonic acid (MSA), a tracer for marine aerosol, and
53 hydroxymethanesulfonate ion (HMS), measured in high haze conditions, along with two
54 organosulfates compounds, methyl sulfate (MS) and 2-methyltetrol sulfate (2-MTS) were
55 selected for evaluation.

56 Methanesulfonic acid forms from photochemical oxidation of dimethyl sulfide (DMS)
57 (Kwong et al., 2018b; von Glasow and Crutzen, 2004). DMS is a naturally occurring sulfur
58 species produced by marine algae or phytoplankton and is an important precursor of sulfur
59 dioxide, non-sea salt inorganic sulfate and organosulfur compounds, including MSA (Barnes et
60 al., 1994; Hoffmann et al., 2016). This makes MSA a tracer for marine aerosol (Allen et al.,
61 1997; Becagli et al., 2013; Saltzman et al., 1986). Ion chromatography (IC) has been used to
62 measure MSA in ambient aerosol collected on PTFE filters (Amore et al., 2022) and nucleopore
63 filters (Allen et al., 2002). MSA has also been measured in water soluble fractions of ambient
64 aerosol using proton nuclear magnetic resonance (HNMR) (Decesari et al., 2000). Fourier-
65 transform infrared spectroscopy (FT-IR) has been used to characterize liquid and solid MSA in
66 the laboratory studies (Chackalackal and Stafford, 1966; Lee et al., 2019; Zhong and Parker,
67 2018) as has Raman spectroscopy (Zhong and Parker, 2018), but to the best of our knowledge,

68 neither FT-IR or Raman spectroscopy have been used to measure MSA in complex mixtures like
69 ambient aerosol samples.

70 Hydroxymethanesulfonate (HMS), formed by sulfite and formaldehyde in aqueous phase,
71 is a strong acid that is stable at low pH (Seinfeld and Pandis, 2016) and is a tracer for aqueous
72 processes (Chen et al., 2022). During severe winter haze in the North China Plain, HMS was
73 measured using real-time single particle mass spectrum instruments and filter-based IC methods
74 during periods of high SO₂ and HCHO concentrations and low oxidant concentrations in
75 particles with high liquid water content (Ma et al., 2020). Very high concentrations of HMS
76 have been measured in Fairbanks, Alaska during pollution events in a cold, dark and humid
77 environment (Campbell et al., 2022). In the Interagency Monitoring of Protected Visual
78 Environments (IMPROVE) Network, there is evidence of an ubiquitous presence of HMS in ion
79 chromatograms of samples collected at 150 sites in the United States (Moch et al., 2020).

80 However, HMS can be challenging to measure (Moch et al., 2018). Single particle mass
81 spectrometry techniques have identified m/z 111 as characteristic for HMS (Chapman et al.,
82 1990; Lee et al., 2003; Song et al., 2019). However, methyl sulfate and other organic sulfur
83 compounds have the same characteristic m/z which makes quantifying HMS using mass
84 spectrometry challenging (Dovrou et al., 2019; Lee et al., 2003). High-resolution aerosol mass
85 spectrometry (HR-AMS) has been used to measure HMS and organosulfates, however the
86 majority of compounds mostly fragment into inorganic sulfate and a non-sulfur containing
87 organic fraction, leading to an underestimation of HMS and overestimation of inorganic sulfate
88 (Dovrou et al., 2019; Song et al., 2019). HMS has been measured in field and laboratory studies
89 by IC (Campbell et al., 2022; Dovrou et al., 2019), however notable challenges have been
90 documented. HMS and sulfate are not fully resolved in all IC methods (Campbell et al., 2022)

91 leading to poor resolution that can introduce error into the results for both HMS and sulfate
92 (Dovrou et al., 2019; Ma et al., 2020). In IC methods where HMS and sulfate are well resolved,
93 HMS and sulfite may be unresolved and co-elute with bisulfite (Moch et al., 2018; Wei et al.,
94 2020). Additionally, HMS may degrade to sulfite and formaldehyde at the high-pH eluent used
95 in IC (Moch et al., 2020). Degradation of both HMS and sulfite may occur in aqueous solutions
96 prior to analysis or in the column during analysis and it's suspected that some of the sulfite
97 oxidizes to sulfate in solution or in the column (Moch et al., 2020). The formation of HMS in
98 the atmosphere occurs at moderate pH and pH differences, between the filter and atmospheric
99 condition (e.g. cloud, fog, pH), can contribute to HMS sample mass loss off the filter leading to
100 an underestimation of HMS (Moch et al., 2020). With proper columns and eluent composition,
101 IC has been shown to separate HMS and sulfate peaks with only a small underestimation of
102 HMS due to sulfate conversion (Campbell et al., 2022; Dovrou et al., 2019). At least one
103 laboratory study (published in Japanese) has characterized HMS by FT-IR (Sato et al., 1984) but
104 FT-IR has not been used to measure HMS in ambient aerosol samples to the best of our
105 knowledge.

106 Organosulfates are the most abundant form of organic sulfur compounds in atmospheric particles
107 (Frossard et al., 2011; Hawkins et al., 2010; Hettiyadura et al., 2015; Olson et al., 2011; Stone et
108 al., 2012). Organosulfates are secondary organic aerosols (SOA) from oxidation of mostly
109 biogenic, but also some anthropogenic volatile organic compounds, in the presence of acidic
110 sulfate (Hettiyadura et al., 2015; Stone et al., 2012; Wang et al., 2021) and have been suggested
111 to be tracers for SOA (Chen et al., 2021; Wang et al., 2021). Organosulfates have been measured
112 in ambient aerosol globally including at four sites in Asia where on average they contribute <1%
113 of PM_{2.5}, 2.3% of organic carbon and 3.8% of total sulfate (Stone et al., 2012). In Arctic haze

114 aerosols in the spring, organosulfates contributed to 13% of organic matter (OM) (Hansen et al.,
115 2014) and contributed to OM at varying levels across the US, with higher levels in summer
116 (Chen et al., 2021). Most studies have used a liquid chromatography method coupled to a mass
117 spectrometer (LC-MS) for measuring organosulfates (Hettiyadura et al., 2015; Wang et al.,
118 2021). FT-IR has been used to measure total organosulfate functional groups (Hawkins et al.,
119 2010) and Raman (Bondy et al., 2018; Lloyd and Dodgson, 1961) and FT-IR (Lloyd et al., 1961)
120 have been utilized to characterize organosulfates in laboratory studies. FT-IR has been used to
121 measure the organosulfate functional group using peak fitting and showed that the organosulfate
122 functional group contributes up to 10% of organosulfate in the arctic region, when inorganic
123 sulfate concentrations are considered high (Frossard et al., 2011), and 4-8% of OM in the Pacific
124 marine boundary layer, during periods of high organic and sulfate concentrations (Hawkins et al.,
125 2010). While other studies showed little to no organosulfates, likely due to low sulfate
126 concentrations in Mexico City (Liu et al., 2009) and Bakersfield, CA (Liu et al., 2012).
127 Methyl sulfate is the smallest organosulfate (Kwong et al., 2018a) and measured mostly in trace
128 amounts (Hettiyadura et al., 2017, 2015; Wang et al., 2021). However, it is commercially
129 available and therefore useful for laboratory studies. 2-Methyltetrol sulfates are tracers for
130 secondary organic aerosols (SOA) formation in atmospheric particles derived from isoprene
131 (Chen et al., 2020; Surratt et al., 2010) and one of the most abundant organosulfates measured in
132 ambient aerosol. In the eastern US, 2-MTS accounts for the highest percentage summertime
133 particulate organosulfate (11%) (Chen et al., 2021). In Centreville, AL, 2-MTS accounts for
134 more than half of organosulfates during summer of 2013 (Hettiyadura et al., 2017). In Shanghai,
135 China (summer of 2015-2016, 2018-2019), 2-MTS was the most abundant organosulfate (31%)
136 of 29 organosulfates (Wang et al., 2021).

137 The IMPROVE network is a rural particulate matter monitoring network with ~165 sites
138 across the United States (<http://vista.cira.colostate.edu/improve/>). Polytetrafluoroethylene
139 (PTFE), nylon and quartz filters are used to collect PM_{2.5} every one in three days, have a field
140 latency period of up to 7 days and are analyzed by multiple analytical techniques. PTFE filters
141 are stored at room temperature and analyzed between 3 and 12 months after collection (typically
142 6 to 9 months) for PM mass, elements and filter-based light absorption. Recently, FT-IR
143 analysis, a non-destructive method, has been performed on IMPROVE samples to reproduce
144 routinely measured compositional data (Debus et al., 2022) and measure the functional group
145 composition of the organic fraction (Ruthenburg et al., 2014). FT-IR analysis has also been
146 conducted on other networks and in chamber and field studies to measure organic functional
147 groups (Boris et al., 2021, 2019; Laurent and Allen, 2004; Russell et al., 2011; Ruthenburg et al.,
148 2014; Yazdani et al., 2022). The extracts of nylon filters have been analyzed by ion
149 chromatography (IC) in the IMPROVE network for more than three decades to routinely
150 measure the inorganic ions, sulfate, nitrate, chloride and nitrite.
151 ([http://vista.cira.colostate.edu/improve/wp-content/uploads/2020/02/1_Anion-Cation-Analysis-](http://vista.cira.colostate.edu/improve/wp-content/uploads/2020/02/1_Anion-Cation-Analysis-by-Ion-Chromatography-SOP-revision-7.pdf)
152 [by-Ion-Chromatography-SOP-revision-7.pdf](http://vista.cira.colostate.edu/improve/wp-content/uploads/2020/02/1_Anion-Cation-Analysis-by-Ion-Chromatography-SOP-revision-7.pdf)). Although not routinely measured in IMPROVE
153 samples, HMS has been identified in IMPROVE samples using IC (Moch et al., 2020).
154 Organosulfates and MSA have been previously identified in extracts of IMPROVE samples
155 (Chen et al., 2021) using hydrophilic interaction liquid chromatography interfaced to
156 electrospray ionization high-resolution quadrupole time-of-flight mass spectrometry (HILIC-
157 ESI-HR-QTOFMS).

158 The goal of this paper is to assess the potential for using FT-IR analyses to measure
159 organic sulfur compounds collected on PTFE filters in the IMPROVE network. Measuring

160 organic sulfur compounds on a continuous basis across the US would provide a rich data set to
161 evaluate their sources, concentration, seasonality and trends over time. Four organic sulfur
162 compounds, two organosulfur compounds, methanesulfonic acid, hydroxymethanesulfonate, and
163 two organosulfates, methyl sulfate and 2-methyltetrol sulfate, are evaluated. For these
164 compounds to be measurable in IMPROVE by FT-IR, there must be minimal losses or other
165 changes to the compound during the latency period between collection and analysis (3 – 12
166 months), and there must be minimal interferences in the spectra. To achieve this goal, each
167 compound was dissolved in solution, aerosolized and collected on PTFE filters. Collected
168 samples were weighed and analyzed by FT-IR every few days for two months or more.
169 Characterization of the FT-IR spectra as well as changes (or lack therefore of) in the mass
170 loading and spectra over time indicate the potential for the compounds to be measured by FT-IR
171 in IMPROVE samples. Filter samples, extracted for IC analysis at different time points, indicate
172 stability or chemical changes in the compound on the filter, assists with interpreting gravimetric
173 mass and FT-IR spectra changes.

174 **2. Materials and Methods**

175 Two organic sulfur (C-S) compounds, MSA and HMS, and two organosulfates (C-O-S), MS and
176 2-MTS, were selected. The four compounds were selected for this study based on following
177 three criteria. The compound 1.) has been measured in atmospheric particulate matter and is of
178 interest to the atmospheric science community, 2.) is water soluble so it can be put into solution
179 for atomization, and 3.) is available in high purity form to minimize uncertainty in mass
180 measurement. Filter samples of the organic sulfur compounds were prepared for FT-IR,
181 gravimetry, IC and ICP-OES analyses by aerosolizing each compound individually and
182 collecting it on PTFE filters (Pall Corporation, 25 mm diameter). One set of filters was

183 generated for analysis by gravimetry and FT-IR at UC Davis and another set (or sets depending
184 on what was being evaluated) of filters were generated for analysis by IC and ICP-OES at
185 Research Triangle Institute (RTI) following gravimetric analysis at UC Davis. Analyses of
186 these laboratory filter samples were performed to characterize the compound within infrared
187 spectra and to determine the stability of these compounds over time.

188 2.1 Preparation of laboratory filter samples

189 Three commercially available standards were used for this study: HMS sodium salt
190 (>97% purity, TCI America), MSA (100% purity, Sigma Aldrich) and MS sodium salt (100 %
191 purity, Sigma Aldrich). 2-methytetrol sulfate ammonium salt was synthesized following a
192 published method (Cui et al., 2018). Each compound was collected on PTFE filters by first
193 preparing an aqueous solution with a concentration of 0.005 M. For HMS, the solution was
194 acidified with hydrochloric acid (HCl) prior to aerosolization to obtain samples with
195 atmospherically relevant pH (pH 2), as pH plays a role in the stability of HMS. 2 μ L of 1 M HCl
196 was added to HMS solution to obtain the final volume of 200 mL for aerosolization. Aerosols
197 were generated using an atomizer (Kamruzzaman et al., 2018; Ruthenburg et al., 2014) and dried
198 with a diffusion dryer (Model 3074B Filtered Air Supply, TSI Inc., St. Paul, MN). Dry particles
199 were collected on PTFE filters (Pall Corporation, 25 mm diameter) using an IMPROVE sampler
200 with varying collection times (40 to 720 s) at a flow rate of 22.4 L/min.

201 2.1.1 Gravimetric mass determination

202 Filter mass, before and after particle collection, was measured using an ultra-
203 microbalance (XP2U, Mettler-Toledo, Columbus, OH) with 0.1 μ g sensitivity. Ionizing
204 cartridges (Staticmaster® Model 2U500, Grand Island NY) housed on a flexible stand
205 (Staticmaster® Model BF2-1000, Grand Island NY) and Haug strip (Mettler Toledo 11140160,

206 Columbus, OH) were utilized to help eliminate static for more stable, accurate measurements.
207 Prior to particle collection, the mass of a filter was determined by the average of 5 mass
208 measurements taken on separate days. Only filters that weighed within measurements precision
209 for 25 mm filters ($\pm 6 \mu\text{g}$) for the 5 measurements were used. After particle collection, filters
210 were allowed to achieve equilibrium at room temperature for 24-hrs. Filters were weighed for
211 three consecutive days in the 1st week, twice per week during 2nd – 4th weeks and once in the
212 weeks thereafter. The experiment was ended when the weights were stable for a month or more.

213 2.2 Infrared spectra collection and processing

214 FT-IR spectra of the filter samples of each compound were collected using a Tensor II FT-IR
215 spectrometer (Bruker Optics, Billerica, MA) with a liquid nitrogen cooled cadmium telluride
216 (MCT) detector over the spectral range of $4\ 000\text{--}400\ \text{cm}^{-1}$. Filters were placed in a house-built
217 sample chamber that is purged of water and CO_2 (PureGas) for 4 min before spectra acquisition
218 (Debus et al., 2019). Measurements were made using 512 scans for each filter at $4\ \text{cm}^{-1}$
219 resolution and ratioed to the most recent (less than 1 h) background spectrum to obtain
220 absorbance spectra using OPUS software (Bruker Optics, Billerica, MA, (Debus et al., 2019)).

221 To better visualize functional groups in the organosulfur compounds, spectra were
222 baseline corrected from $1500\ \text{cm}^{-1}$ to $500\ \text{cm}^{-1}$, using blank correction and smoothing spline
223 fitting (Kuzmiakova et al., 2016). The spectral region from $4000\ \text{cm}^{-1}$ to $1500\ \text{cm}^{-1}$ were
224 baselined using an automated version of the Kuzmiakova et al., 2016 smoothing spline process in
225 AirSpec (Reggente et al., 2019). Regions with large PTFE absorption ($1300\text{--}1100\ \text{cm}^{-1}$, $700\text{--}600$
226 cm^{-1} and $500\text{--}420\ \text{cm}^{-1}$) were grayed out in spectra plots and are not considered for peak
227 identification. A baseline corrected spectrum of each compound is shown in supplemental
228 material Figure S1.

229 2.3 IC and ICP-OES sample analysis

230 PTFE filters of each organic sulfur and organosulfate sulfur compound were generated and
231 weighed at UC Davis prior to shipping the filters cold overnight to RTI for IC and ICP-OES
232 analysis. On the day the filters arrived at RTI, the filters were extracted in 50 ml of deionized
233 water ($18\text{M}\Omega\text{ cm}^{-1}$, Millipore Milli-Q Darmstadt, Germany), sonicated for 30 minutes in an ice
234 bath and placed on a shaker table in a cold room for 8 hours prior to analysis. The PTFE filter
235 remained in the extraction vial for the duration of these experiments.

236 IC analysis was performed on Dionex Thermo Scientific ICS-3000 and ICS-6000 (Sunnyvale,
237 CA) instruments using suppression and conductivity detection. For MSA, extracts were analyzed
238 using the AS19 analytical and AG19 guard columns (anion hydroxide method) for initial
239 extraction efficiency tests and AS28 analytical and AG28 guard columns (hydroxide method) for
240 the subsequent analyses to evaluate changes over time. HMS and MS extracts were analyzed
241 with AS12A analytical and AG12A guard columns (anion carbonate method), which has been
242 shown to provide sufficient separation of HMS and sulfate, but not separation of sulfite/bisulfite
243 and HMS (Dovrou et al., 2019). MS extracts were analyzed with AS12A analytical and AG12A
244 guard columns (anion carbonate method), the same method as HMS. An IC method for analyzing
245 2-MTS had not been developed and evaluated prior to this work. Eluent concentrations and flow
246 rates were optimized for best separation of all ions of interest.

247 ICP-OES, used to measure total sulfur on the filter, was performed on a Thermo Scientific iCAP
248 7600 duo analyzer (Bremen, Germany). The ICP-OES was run in axial mode using a sprint valve
249 and data were collected at 180.731 nm. The ICP-OES system was calibrated using the sulfate
250 calibration standards and validated using the sulfate calibration verification solutions described
251 below.

252 IC and ICP-OES systems were calibrated with calibration standards prepared via serial dilutions
253 of single source stock standards using a primary source. A secondary source was used to prepare
254 calibration verification solutions to validate the instrument calibration for all compounds except
255 for 2-MTS, for which a second source standard was unavailable.

256 Primary and secondary sources of National Institute of Standards and Technology
257 (NIST)-traceable solutions were purchased and used to prepare calibration standards and
258 calibration verification solutions respectively, for sulfate analyses by both IC and ICP-OES.
259 When NIST-traceable solutions were unavailable, salts were used to prepare calibration
260 standards and calibration verification solutions for MSA, HMS, and MS. Vendor information for
261 primary and secondary sources are provided in Table S2 in supplemental material. Certified
262 American Chemical Society (ACS)-grade sodium carbonate (Na_2CO_3) obtained from Fisher
263 Scientific (Fairlawn, NJ) and sodium bicarbonate (NaHCO_3) obtained from EMD Sciences
264 (Gibbstown, NJ) were used to prepare IC eluent when using anion carbonate methods for
265 analyses. Potassium hydroxide eluent generator cartridges purchased from Thermo Scientific
266 were used for eluent preparation for analyses conducted with anion hydroxide methods. NIST-
267 traceable, 1000 $\mu\text{g}/\text{mL}$ stock solutions of yttrium (Y) and cesium (Cs) obtained from High Purity
268 Standards (Charleston, SC) were used to for internal standard and ionization suppression,
269 respectively for ICP-OES measurements.

270 3. Results and Discussion

271 Methanesulfonic acid

272 Gravimetry
273 Mass changes, measured by gravimetry, for four methanesulfonic acid filter samples with masses
274 ranging from 64 μg to 80 μg are shown in Figure 1. Mass decreases steadily during the first

275 month to approximately 50% of the initial mass. During the second month of measurements, the
276 mass remains constant ($50 \pm 6\%$).

277

278 Figure 1. Change in mass of methanesulfonic acid (MSA) collected on PTFE filters over a 2-
279 month period under laboratory conditions ($24\text{ C}^\circ\text{C}$). Dotted vertical lines indicate FT-IR analysis.
280 Horizontal broken line indicates mass balance precision. Colors indicate initial masses of
281 samples.

282 FT-IR

283 Methanesulfonic acid ($\text{CH}_3\text{SO}_3\text{H}$) is composed of a methyl group attached to a sulfonic acid
284 [$\text{S}(=\text{O})_2\text{—OH}$], via a C-S bond. Methanesulfonic acid aerosols collected on PTFE filters have
285 peaks associated with CH_3 , SO_3 , S-OH and C-S bonds (Figure 2). Observed peaks (Figure 2)
286 can be ascribed to portions of the molecule based on previous FT-IR and Raman work
287 (Chackalackal and Stafford, 1966; Lee et al., 2019; Zhong and Parker, 2018). The peaks at 1342
288 cm^{-1} and 536 cm^{-1} arise from S=O bonds in MSA and are shifted compared to inorganic peaks at
289 1130 cm^{-1} , 620 cm^{-1} (Larkin, 2018) or organic sulfate SO_4 peaks at $\sim 1380\text{ cm}^{-1}$ (Larkin, 2018;

290 Lin-Vien et al., 1991). The peak at 895 cm^{-1} is attributable to S—OH (Zhong and Parker, 2018)
291 and the peak at 766 cm^{-1} is attributable to C-S (Lee et al., 2019). C-H peaks are observed at 3039
292 cm^{-1} , 2951 cm^{-1} , 1414 cm^{-1} and 987 cm^{-1} (Chackalackal and Stafford, 1966). The broad peak at
293 3248 cm^{-1} is suggested to be water as (Zeng et al., 2014) showed that this peak in MSA infrared
294 spectra increases with increasing RH. These peaks, particularly strong peaks, were similar to
295 spectral absorbance of MSA from reference spectra (AIST: SDBS, 2022), and Table S1 in
296 Supplemental Materials compares the observed and reference peaks.

297
298 Figure 2. Changes in the spectra of MSA over a 2- month period, denoted by number of elapsed
299 days. The shaded area indicates the absorbance regions of PTFE filter.
300 The MSA infrared peaks of SO_3 (1342 cm^{-1}), C—H (987 cm^{-1}), S—OH (895 cm^{-1}), C-S (766 cm^{-1})
301 1), and S=O (536 cm^{-1}) decrease rapidly in the first 30 days, consistent with the decline in mass
302 during that time. The spectra suggest that MSA is volatilizing off the filter, even though this is
303 inconsistent with the low vapor pressure of MSA (Knovel, 2014), 0.00022 mmHg at 20°C). The
304 three spectra obtained on days 30, 41 and 51 show only small decreases which is mostly
305 consistent with the lack of mass changes during those days.

306 Not all peaks show consistent loss during the first month and little change during the second
307 month. The C-H peaks at 3039 cm^{-1} and 2942 cm^{-1} behave slightly differently, reaching stability
308 (with some minor random variability) earlier (day 20) than most other peaks. The weak peak at
309 1414 cm^{-1} (ascribed to CH_3) increased and broadened to 1445 cm^{-1} - 1400 cm^{-1} after the initial
310 spectra was collected and remained fairly stable for the duration of the experiment. The peak at
311 3250 cm^{-1} , increased rapidly followed by fluctuations, and then varies somewhat but remained
312 fairly consistent for the duration of the experiment, not unlike the behavior of the 1414 cm^{-1}
313 peak. One possible cause for these spectra changes in the spectra is water vapor condensing on
314 the particles after collection. MSA is hygroscopic and although it effloresces at about $\text{RH} = 50\%$,
315 (Peng and Chan, 2001; Tang, 2020; Zeng et al., 2014), Zeng et al., 2014 shows that there is some
316 water associated with the particles below 50% RH, which is consistent with the FT-IR spectra
317 (Figure 3), particularly the 3248 cm^{-1} peak. If water is indeed the cause, the change in the 3248
318 cm^{-1} peak can be explained by a very low RH in the particle generation and collection system
319 (lower initial peak) and a higher RH ($\text{RH} = 30 \pm 10\%$) in the lab (increase in peak). The change
320 in the 1414 cm^{-1} peak above 1400 cm^{-1} behaves similarly, and can be associated with OH
321 suggesting uptake of water after the initial FT-IR spectra was collected.

322 Another possibility is that ammonia is absorbing onto the MSA. Ammonium absorbs in both the
323 3250 cm^{-1} and $1500\text{-}1400\text{ cm}^{-1}$ regions (Boer et al., 2007; Zawadowicz et al., 2015) and when
324 comparing MSA spectra to ammonium sulfate spectra, they show very similar peak absorbance
325 and shapes in these two regions suggesting. This suggests that the cause of these peaks is
326 ammonium (Supplemental Material, Figure S2).

327 A third possible cause for these changes is that MSA may be fragmenting into formaldehyde
328 (CH_2O), that partitions into the gas phase, and sulfite (SO_3) (Kwong et al., 2018b). However,

329 this would show a decrease in CHC-H peaks and a shift in the SOS=O peaks, neither of which
330 are observed in the spectra. The rapid decrease in peak height during the first month and then
331 little decrease or no trend during the second month, suggests that MSA is volatilizing off the
332 filter initially, but then has a slow decline, offset by increases in water or ammonium.

333 IC and ICP-OES

334 Twenty PTFE filters with MSA ($14 \mu\text{g} - 32 \mu\text{g}$; $60 \mu\text{g} - 144 \mu\text{g}$) were shipped to RTI for
335 extraction and analysis by IC and ICP-OES. Each extract was analyzed by both IC and ICP-OES.
336 Recoveries of MSA from PTFE filters was $55 \pm 5\%$ for IC and $51 \pm 5\%$ for ICP-OES.
337 Calibration verification solution recoveries were $96 \pm 5\%$ for IC and $101 \pm 3\%$ for ICP-OES
338 analyses, suggesting that the lower recoveries from the PTFE filter are due to incomplete
339 extraction and/or losses occurring during shipment. To evaluate losses during shipping, six
340 samples were collected, weighed, and analyzed by FT-IR, shipped to RTI and then sent back to
341 UC Davis and analyzed with gravimetric and FT-IR analysis 9 days after initial measurements.
342 The mass loss ($19 \pm 7\%$) during this period was similar to mass loss for filters that remained in
343 the UC Davis laboratory for ~ 8 days ($22 \pm 6\%$). Spectral changes in shipped filters were similar
344 to changes in spectra that occurred during the first week for filters that remained at UC Davis.
345 To evaluate changes in mass and composition on PTFE filters over time, 6 filters ($42 \mu\text{g} - 63 \mu\text{g}$)
346 were shipped to RTI and extracted on days 0, 30, and 61. These filters had consistent recoveries
347 over time of $57 \pm 6\%$ for IC and $55 \pm 6\%$ for ICP-OES. The IC results indicate that MSA did
348 not change chemically during this time period, supporting the FT-IR spectral results. The mass
349 and spectral data indicate that the lower extraction efficiency was not due to loss of MSA off the
350 filter during shipping and suggest that the limitation is extraction efficiency. Despite low
351 extraction efficiencies and difference in behavior over time from FT-IR measurement, the FT-IR,

352 gravimetry and IC results suggest that a lower-bound of MSA can be measured on PTFE filters
353 in IMPROVE by FT-IR.

354 **Hydroxymethanesulfonate**

355 Gravimetry

356 Mass changes in three hydroxymethanesulfonate sodium salt ($\text{HOCH}_2\text{SO}_3\text{Na}$) filter samples with
357 mass loadings of $\sim 62 \mu\text{g}$ per filter are shown (Figure 3). Mass decreases steadily for 1.3 months
358 to a maximum loss of 38% and then remains constant ($38 \pm 3\%$) for the rest of the experiment
359 (4.1 months). Similar results were obtained for filters weighing approximately $30 \mu\text{g}$ /filter of
360 HMS.

361

362

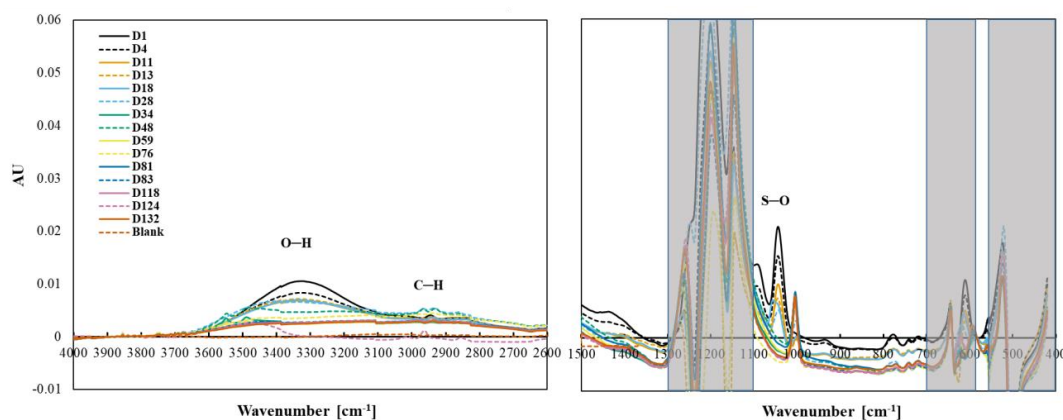

363 Figure 3. Mass behavior of hydroxymethanesulfonate (HMS) over 125 days under laboratory
364 conditions ($\sim 24^\circ\text{C}$). Dotted vertical lines indicate FT-IR analysis. Horizontal broken line
365 indicates mass balance precision.

366

367 FT-IR

368 HMS ($\text{HOCH}_2\text{SO}_3\text{H}$) is a sulfonic acid compound with C-S bond, where the S bond is part of a
369 sulfonic acid group [$\text{S}(=\text{O})_2\text{—OH}$], and the carbon is attached to an —OH functional group,
370 similar to MSA except with the OH functional group attached to the carbon. The chemical used
371 in our study has a sodium cation on the sulfonic acid group. HMS aerosol collected on PTFE
372 filters have three infrared peaks (1094 cm^{-1} , 1041 cm^{-1} , 611 cm^{-1}) between 1500 and 500 cm^{-1}
373 , although the peak at 611 cm^{-1} is obscured by PTFE absorption, and O-H and C-H peaks
374 between 4000 cm^{-1} and 1500 cm^{-1} (Figure 4).

375
376 Figure 4. Changes on the functional group frequency region of hydroxymethanesulfonate (HMS)
377 over 4.1 months.

378
379 Observed peaks at 1094 cm^{-1} and 1041 cm^{-1} are similar to the 1080 cm^{-1} and 1040 cm^{-1} peaks
380 identified as S-O or S=O bonds in FT-IR spectra of Na HMS (Sato et al., 1984) and of HMS
381 (Larkin, 2018; Shurvell, 2006). A weak band at 611 cm^{-1} is like due to C-S (Lin-Vien et al.,
382 1991; Sato et al., 1984) or S-O (Sato et al., 1984) but is obscured by PTFE absorbance. Above
383 1500 cm^{-1} and similar to many aliphatic organic molecules, an O-H (broad peak centered near
384 3300 cm^{-1}) and C-H (below 3000 cm^{-1}) peaks were observed (Pavia et al., 2008; Shurvell, 2006).

385 Observed peaks are similar to spectral absorbance, although not all peaks in the reference spectra
386 (AIST: SDBS, 2022, See Table S1 in Supplemental Material) are observed in the measured
387 spectra. HMS has a very low vapor pressure (0.00000073 mmHg), (U.S. EPA. Comptox
388 Chemicals Dashboard, 2022) indicating that HMS should not volatilize off the filter.
389 All peaks below 1500 cm^{-1} decrease and are no longer visible by day 34, consistent with the
390 decline but not the extent of decline in mass as the HMS peaks are completely gone and the mass
391 has only decreased by 40%. This behavior is most clearly observed in the peak at 1041 cm^{-1} , but
392 also observed in 1094 cm^{-1} peak (Figure 4). Similar to the S-O/S=O peaks, C-H peaks decline
393 during the first 34 days and then completely disappear. The O-H peak, centered around 3300 cm^{-1}
394 ¹, disappears more slowly, but like the S-O and C-H peaks, is gone by the end of the experiment.
395 Counter balancing the loss of mass, a new peak becomes visible at 1003 cm^{-1} after 11 days and
396 increases for the rest of the study. The peak at 1003 cm^{-1} is tentatively identified as bisulfate
397 (Boer et al., 2007; Krost and McClenny, 1994). The small peak centered around 3450 cm^{-1}
398 becomes evident as the O-H peak disappears and may indicate the presence of condensed water
399 (Boer et al., 2007).

400 IC and ICP-OES

401
402 Sixteen HMS PTFE filters were analyzed by IC with recoveries of $65 \pm 4\%$ and calibration
403 verification solution recoveries of $94 \pm 5\%$. ICP-OES analysis was not performed on these
404 filters. Eight additional HMS filters ($65\text{ }\mu\text{g} - 100\text{ }\mu\text{g}$) were shipped to RTI and 2 filters were
405 extracted and analyzed by IC and ICP-OES on each of the following days 0, 30, 61, and 101.
406 The sulfur mass losses in IC (Figure S3, Supplemental Material) over the 101 days is ~60% loss
407 from the initial weighed mass or about 39% loss assuming a constant extraction efficiency of
408 65% for all samples and is in agreement with the 38% decrease in mass on the filter measured by

409 gravimetry. Similar results were obtained for ICP-OES. IC analysis (Figure 5) confirms the
410 samples are mostly HMS on day zero but over time the HMS is converted to sulfate (sulfate and
411 bisulfate are indistinguishable in IC), supporting assignment of the 1003 cm^{-1} infrared peak to
412 inorganic bisulfate. A small amount of the HMS may be converting to sulfate in solution or the
413 column, but the measured changes are much larger than what is expected due to that mechanism
414 alone. The small amount of HMS that is measured by IC on day 60 and 101 are near detection
415 limits for IC which corroborate the absence of HMS in the FT-IR spectra after two months. The
416 IC and FT-IR results both show a conversion of HMS into sulfate indicating that HMS is not
417 stable and cannot be quantified reliably on PTFE filters in IMPROVE by either FT-IR or IC. In
418 Moch et al. (2020), HMS did not degrade over time under cold storage conditions on nylon
419 filters from IMPROVE suggesting that storage or perhaps filter type may play an important role
420 in HMS degradation on filters.

421

422 Figure 5. Percentage of HMS and sulfate measured by IC. Eight PTFE filters were extracted and
423 analyzed in pairs over 101 days.

424 Methyl sulfate

425 Gravimetry

426 Mass measurements of methyl sulfate salt over a 4 -month period were within measurement
427 uncertainty for the three filters loaded with approximately 30 μg of methyl sulfate (the change
428 over time was indistinguishable from zero). For the 60 μg filters (Figure 6), the first 2 months
429 and the last two weeks mass change were within measurement uncertainty ($\pm 6 \mu\text{g}$). However,
430 for about a month, between day 70 and 100, much of the data (except day 91) is outside of
431 measurement uncertainty, indicating mass loss of between 10 and 20%. During this period only
432 one spectrum (day 79) was collected, and it does not support mass loss. Day 100 spectra, and all
433 spectra collected through the end of the study, for all three 60 μg loadings, filter samples
434 confirms no changes in the MS compound. Mass and spectral data indicate stability of mostly
435 stable MS on filters under ambient laboratory condition (24°C).

436

437 Figure 6. Mass behavior of methyl sulfate (MS) standard over 4 months. Dotted vertical lines
438 indicate FT-IR analysis. Horizontal broken line indicates mass balance precision for PTFE 25-
439 mm diameter filters.

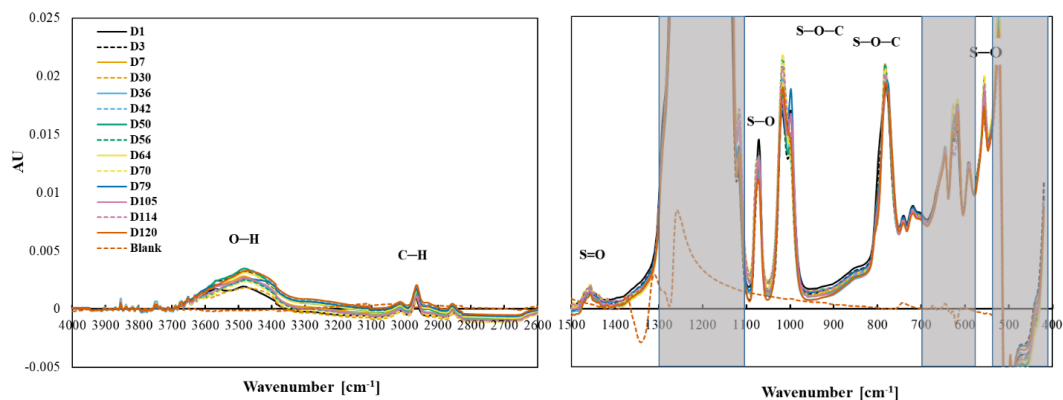

440 FT-IR

441 Methyl sulfate ($\text{CH}_3\text{SO}_4\text{H}$) is composed of a methyl (CH_3) group attached to a sulfate (SO_4)
442 group with C-O-S bond. The chemical used in this study is sodium methyl sulfate ($\text{CH}_3\text{SO}_4\text{Na}$).
443 Methyl sulfate aerosol collected on PTFE filters has two peaks between 4000 cm^{-1} and 2000 cm^{-1}
444 and eight peaks between 1500 and 500 cm^{-1} (Figure 7), similar to reference spectra in Table S1
445 (AIST: SDBS, 2022). The doublets observed at 1020 cm^{-1} , 1000 cm^{-1} and the nearly overlapping
446 peaks at 795 cm^{-1} and 784 cm^{-1} are identified as S-O-C by both FT-IR (Chihara, 1958; Lloyd et
447 al., 1961; Lloyd and Dodgson, 1961; Segneanu et al., 2012; Shurvell, 2006) and Raman
448 (Okabayashi et al., 1974). The S—O peaks from sulfate are observed around 1073 cm^{-1} and 591
449 cm^{-1} in the spectra, similar to the previous study where peaks from 591 cm^{-1} to 593 cm^{-1} , and at
450 1063 cm^{-1} (solid) and 1081 cm^{-1} (solution) were ascribed to sulfate in potassium methyl sulfate
451 (Chihara, 1958). There is a weak S=O peak at 1458 cm^{-1} (Segneanu et al., 2012). The O-H
452 group (assuming the Na ion was replaced by H for some of the molecules) at 3500 cm^{-1} is also
453 fairly weak. All collected spectra for one sample are shown, with the exception of day 91 data,
454 which appeared to be anomalous (Supplemental Material, Figure S4 all spectra including day
455 91).
456 The stability of the spectra over 4 months suggests that MS is stable when collected on a PTFE
457 filter. There were no major or consistent changes in peaks associated with S—O—C, S—O, Na-O
458 and C—H.

459 The pattern of change in the peak height of the 3500 cm^{-1} peak does not correlate with the
460 change in mass. Day 1 and day 30 spectra have smaller O-H peak intensities prior to mass
461 decline, compared to and the O-H peak in the spectrum from day 79, when mass had decreased
462 the mass is low, is higher than both. No consistent difference in the FT-IR spectra was observed
463 on day 79 (low gravimetric mass day) or the following days (days 105 – 120) suggesting that the
464 mass loss seen in the gravimetric data is erroneous. The high melting and boiling points of MS
465 are $96\text{ }^{\circ}\text{C}$ and $298\text{ }^{\circ}\text{C}$, respectively and the low vapor pressure of 0.0038 mmHg (U.S. EPA.
466 Comptox Chemicals Dashboard, 2022) indicating that MS is not volatilizing off the filter.

467

468

469 Figure 7. Changes in the spectra of MS over a 4- month period. The shaded area indicates the
470 absorbance regions of PTFE filter.

471 IC and ICP-OES

472 Sixteen PTFE samples, eight with mass loadings between $38\text{ }\mu\text{g}$ – $57\text{ }\mu\text{g}$ and eight with higher
473 mass loadings, between $98\text{ }\mu\text{g}$ – $118\text{ }\mu\text{g}$, were prepared for IC and ICP-OES analysis. Eight
474 PTFE filters were extracted on day 0 and recoveries were $60 \pm 1\%$ for IC and $87 \pm 3\%$ for ICP-
475 OES analyses. Recoveries of calibration verification solutions were $100 \pm 1\%$ for IC and $97 \pm$
476 6% for ICP-OES. Additional filters were extracted on day 39 and 61 showed recoveries

477 consistent with recoveries measured during the initial extracts, $59 \pm 2\%$ for IC and $86 \pm 4\%$ for
478 ICP-OES. The overall lower mass recovery is indicative that not all MS is extracted from the
479 filter and the lower recoveries by IC compared to ICP-OES, suggests that MS is converting to
480 another sulfur compound in solution. The consistency in recoveries over time indicates stability
481 of MS on PTFE over this time period, which is in agreement with the mass stability of as shown
482 by gravimetric over the course of the experiment. Unfortunately, filters were not extracted during
483 the time period when the gravimetric results show a small deviation from stability.

484 MS is stable on a PTFE filter as indicated by gravimetry, FT-IR and IC suggesting that at least
485 some atmospherically relevant organosulfates can be measured on PTFE filters in IMPROVE by
486 FT-IR.

487 **2-Methyltetrol sulfate**

488 Gravimetry

489 Mass changes in three 2-methyltetrol sulfate ($C_5H_{11}SO_7$) filter samples with concentrations from
490 $55 \mu\text{g}$ to $57 \mu\text{g}$ are shown in Figure 8. Mass decreases during the first 23 days to 73% of the
491 initial mass ($25\% \pm 2\%$). No additional mass loss was observed after 25 days. Mass behavior
492 indicates a loss of 2-MTS on filters under ambient laboratory condition (24°C). Similar results
493 were obtained for filters weighing approximately $40 \mu\text{g}$.

494

495 Figure 8. Change in mass of 2-MTS collected on PTFE filters over a 3-month period under
496 laboratory conditions. Dotted vertical lines indicate FT-IR analysis. Horizontal broken red line
497 indicates mass balance precision.

498 FT-IR

499 2-Methyltetrol sulfate ($C_5H_{11}SO_7$) is a branched compound with 3 units of $-OH$, one methyl
500 group and a sulfate group. Like methyl sulfate, 2-methyltetrol sulfate is an organosulfate and has
501 a C-O-S bond. 2-MTS collected on PTFE filters has broad, organic-related peaks between 4000
502 cm^{-1} and 2500 cm^{-1} and four peaks between 1500 and 500 cm^{-1} (Figure 9). Observed peaks can
503 be ascribed to functional groups with the molecule based on previous FT-IR and Raman work
504 (Bondy et al., 2018; Fankhauser et al., 2022; Lloyd et al., 1961; Lloyd and Dodgson, 1961).

505

506 Figure 9. Changes in the spectra of 2-MTS over a 3-month period. The shaded area indicates the
507 absorbance regions of PTFE filter.

508 The observed peak at 1041 cm^{-1} is ascribed to S-O stretch (Bondy et al., 2018; Fankhauser et al.,
509 2022), as it is similar to the peak of MS at 1050 cm^{-1} (Lloyd et al., 1961; Lloyd and Dodgson,
510 1961). The doublet at 908 cm^{-1} and 898 cm^{-1} correspond to symmetric and asymmetric stretch of
511 S-O of 2-MTS (Fankhauser et al., 2022). The weak peak at 827 cm^{-1} is tentatively assigned to C-
512 O-S stretch based on Raman spectra of 3-MTS (Bondy et al., 2018). The peak at 1446 cm^{-1} is
513 tentatively assigned to asymmetric S=O stretch based on density functional theory of FT-IR
514 spectra of 2-MTS (Fankhauser et al., 2022) and the assignment of S=O to peak at 1448 cm^{-1} in
515 methyl sulfate (Bondy et al., 2018). However, this peak was suggested to be due to C-H using
516 density functional theory of Raman spectra of 2-methyltetrol sulfates (Bondy et al., 2018) and
517 commonly ascribed to CH_2 in organic molecules at $\sim 1465\text{ cm}^{-1}$ (Pavia et al., 2008). We decided
518 to assign this to S=O because the sulfate related peaks are strong and the C-H peaks are very
519 weak in this molecule. In the higher frequency region, the very subtle peak at 2879 cm^{-1} is
520 ascribed to C-H stretch and the large broad peaks at 3065 cm^{-1} , 3210 cm^{-1} and shoulder at
521 3426 cm^{-1} may be attributable to -OH stretch (Bondy et al., 2018; Fankhauser et al., 2022;

522 Larkin, 2018; Shurvell, 2006) or inorganic -NH stretch (Boer et al., 2007; Larkin, 2018). Our
523 tentative peaks assignments of ammonium at 3210 cm^{-1} and 3065 cm^{-1} and OH at 3426 cm^{-1} are
524 based on changes in spectra discussed below.

525 Most of 2-MTS infrared peaks decreased and disappeared over time, consistent with the
526 decline in mass. The S-O peaks at 1041 cm^{-1} , 908 cm^{-1} and 898 cm^{-1} decreased and were gone
527 by day 40. The weak C-O-S peak at 827 cm^{-1} disappeared by day 26. The C-H region at 3000-
528 2800 cm^{-1} decreased, similar to the changes in S-O-C peaks. However, some peaks shifted or
529 new peaks formed. New peaks (or possibly shifts from 1041 cm^{-1} and 908 cm^{-1} doublet) at 1066 cm^{-1}
530 cm^{-1} and at 987 cm^{-1} appear on day 40 and then increase slightly over time. The S=O peak at
531 1446 cm^{-1} behaves differently from other 2-MTS peaks and increases slightly until day 33 when
532 the peak height increased significantly and shifted to 1420 cm^{-1} where it continues to grow
533 increase over time. Two peaks at 3210 cm^{-1} and 3065 cm^{-1} increased whereas the region around
534 $3450\text{-}3550\text{ cm}^{-1}$ decreased, indicating that the shoulder at 3450 cm^{-1} arises from a different bond
535 than the peaks at 3210 cm^{-1} and 3065 cm^{-1} .

536 The changes in the spectra indicate a change in the chemical composition on the filter. 2-MTS is
537 no longer present by mid-way through the experiment as evidenced by the disappearance of S-O,
538 C-O-S, C-H and O-H peaks. This result is supported by a study of ambient 2-MTS that showed
539 that the atmospheric lifetime of 2-MTS is to be about 16 days (Chen et al., 2020). Intermediate
540 oxidation products of 2-MTS transformation include other organosulfates such as 2-
541 methylglyceric acid organosulfate ($\text{C}_4\text{H}_7\text{SO}_7$, MGOS) and glycolic acid organosulfate ($\text{C}_2\text{H}_3\text{SO}_6$,
542 GAS) (Chen et al., 2020; Zhao et al., 2020) and the final product is likely inorganic $(\text{NH}_4)_2\text{SO}_4$
543 (Harrill, 2020; Zhao et al., 2020). Raman spectra of MGOS (Bondy et al., 2018) indicate that the
544 spectra at the end of the experiment could be 2-MGOS. The increased peak at 3210 cm^{-1} and

545 3065 cm^{-1} could be associated with -OH stretch and CH_3 asymmetric stretch of 2-MGOS and the
546 1420 cm^{-1} (C-H), 1066 cm^{-1} (S-O) and 987 cm^{-1} (SO_4^{2-}) match the final spectra well. The
547 carbonyl group in 2-MGOS is very weak in the Raman spectra and indistinguishable from a
548 blank filter in the final FT-IR spectra in this project. Alternatively, the final spectra could be
549 ammonium sulfate as indicated by peaks at 3210 cm^{-1} , 3065 cm^{-1} and 1420 cm^{-1} which are
550 indicative of ammonium, however, the 1066 cm^{-1} and 987 cm^{-1} peaks are lower than typically
551 observed for inorganic ammonium sulfate (Boer et al., 2007; Zawadowicz et al., 2015)
552 suggesting this is not inorganic sulfate. There are limited FT-IR or Raman spectra of the many
553 oxidation products of 2-MTS so definitive identification is not possible and it is likely that there
554 is a mixture of oxidation products present on the filter.

555 To further evaluate the possible compounds on the filter at the end of the experiment, mass loss
556 calculations were performed. If 2-MTS is converted completely to MGOS, the mass loss would
557 be only 7%. If 2-MTS is converted completely to GAS, the mass loss would be 28% and if 2-
558 MTS is converted completely to ammonium sulfate the mass loss would be 39%. These values
559 span the observed mass loss at 25% which suggesting that the compounds on the filter are of an
560 intermediate type and still in the organosulfate form not inorganic ammonium sulfate.

561 IC and ICP-OES

562 Sixteen PTFE samples, eight with mass loading between 11– 28 μg and eight with higher mass
563 loadings, between 37 – 46 μg were extracted immediately upon receipt at RTI. The IC showed
564 low sensitivity to 2-MTS detection and results are not reported so no additional information was
565 available about what compounds the 2-MTS may have change into. Given that ICP-OES
566 measures sulfur and not individual compounds, the results from this method do not provide

567 insight into chemical conversions on the filter but are briefly discussed in the supplemental
568 material (Figure S5).

569

4. Conclusions

570 The stability and therefore potential for FT-IR to measure organosulfur and
571 organosulfates collected on PTFE filters varies by compound. MS has the highest potential to be
572 measured on PTFE filters in IMPROVE samples by FT-IR, due to its minimal mass change and
573 no spectral changes. Consistent recoveries by IC and ICP-OES over multiple months of analysis
574 support the conclusion that MS is stable on the filters. Consistent results from analysis at UC
575 Davis and RTI suggest robustness to storage, shipping and handling conditions. MS is one of
576 many organosulfates observed in the atmosphere and not necessarily representative of
577 organosulfates in general as indicated by 2-MTS. Gravimetric mass suggests some (30%) mass
578 loss from 2-MTS samples on the PTFE filter, over a three-month period. FT-IR suggests that 2-
579 MTS is unstable on PTFE filter and changing into different compound(s), likely still an
580 organosulfate. FT-IR and gravimetry show that MSA can be measured from PTFE filters but
581 due to volatility off the filters a lower bound of MSA is measured (i.e., less than the amount of
582 MSA in the atmosphere). IC further confirmed that MSA did not chemically change while on the
583 filter. Infrared peaks in HMS spectra mid-way through the experiment indicate that HMS is not
584 stable on PTFE filters and likely converts to bisulfate. IC indicates that HMS is changing to
585 (bi)sulfate over time. Further investigations of measurements by FT-IR on PTFE of other
586 organosulfates are warranted to evaluate the extent to which the organosulfate functional group
587 can be quantified from IMPROVE PTFE filters. Further work to determine the stability and
588 ability to measure these compounds in aerosol mixtures as found in ambient samples is needed
589 before confidently using FT-IR on IMPROVE samples to measure organic sulfur compounds.
