Abstract.

The climate in the Arctic has warmed much faster in the last two to three decades than in the mid-latitudes, i.e., during the Arctic Amplification (AA) period. Radiative forcing in the Arctic is influenced both directly and indirectly by aerosols. However, their observation from the ground or with airborne instruments is challenging, and thus measurements are sparse.

5 In this study, total Aerosol Optical Depth (AOD) is determined from top-of-atmosphere reflectance measurements by the Advanced Along-Track Scanning Radiometer (AATSR) aboard ENVISAT over snow and ice in the Arctic using a retrieval called AEROSNOW for the period 2003 to 2011. We use the dual-viewing capability of the AATSR instrument to accurately determine the contribution of aerosol to the reflection at the top of the atmosphere for observations over the bright surfaces of the cryosphere in the Arctic. The AOD is retrieved assuming that the surface reflectance observed by the satellite can be
10 well-parametrized by a bidirectional snow reflectance distribution function, BRDF. The spatial distribution of AODs shows that high values in spring (March, April, May) and lower AOD values in summer (June, July, August) are observed. The AEROSNOW AOD values are consistent with those from colocated AERONET measurements, with no systematic bias being found as a function of time. The AEROSNOW AOD in the high Arctic ($\geq 72^\circ\text{N}$) was validated by comparison with ground-based measurements at the PEARL, OPAL, Hornsund, and Thule stations. The AEROSNOW AOD value is less than 0.15 on
15 average and the linear regression of AEROSNOW and AERONET total AOD yields a slope of 0.98, a Pearson correlation coefficient of $R = 0.86$, and an RMSE = 0.01 at a monthly scale, both in spring and summer. The AEROSNOW observation of increased AOD values over the high Arctic cryosphere during spring is a clear confirmation that Arctic haze events were well captured by this dataset. In addition, the AEROSNOW AOD results provide a novel and unique total AOD data product for

the spring and summertime from 2003 to 2011, offering for the first time observational insight into the high Arctic cryospheric
20 region with significant spatial and temporal coverage.

1 Introduction

The Arctic has experienced a significant increase in near-surface air temperatures over the past three decades: the rate of
temperature increase being about two to three times larger than the global mean (Rantanen et al., 2022). This phenomenon is
known as Arctic Amplification (AA). The warming of the Arctic has increased the rate of melting of the Arctic cryosphere,
25 e.g. glaciers, sea ice, and snow-covered surfaces. Processes thought to influence AA include for example the following: surface
albedo feedback (Perovich and Polashenski, 2012), warm air intrusion (Boisvert et al., 2016), and oceanic heat transport
(Nummelin et al., 2017), cloud feedback (Kapsch et al., 2013; He et al., 2019; Middlemas et al., 2020), lapse rate feedback
(Pithan and Mauritsen, 2014), and biological and oceanic particle emission effects (Park et al., 2015; Campen et al., 2022).

Atmospheric aerosols are a collection of solid or liquid suspended particles that have both natural and anthropogenic sources.
30 It is well known that changes in the scattering and absorption of incoming solar radiation by aerosols have a direct impact on
climate change (Bond et al., 2013). Increases in aerosol result in more solar radiation being scattered back into space and the
atmosphere and surface are cooled. On the other hand, aerosols that absorb solar radiation warm the atmosphere and surface.
Aerosols also act as both cloud condensation nuclei (CCN) and ice nuclei particles (INP), affecting the microphysical and
radiative properties of clouds. In this way, aerosols also indirectly affect climate change (Twomey, 1977; Kaufman and Fraser,
35 1997; Hartmann et al., 2020). However, neither the contribution of aerosols to AA nor the effect of declining regional snow
and ice on aerosol during the AA period is well understood (Im et al., 2021).

In this study we use the Aerosol Optical Depth (AOD) as an optical measure of aerosol. It is valuable in the analysis of the
impact of aerosols on the Arctic climate and vice versa. The retrieval of AOD is complicated by the seasonal changes of solar
geometry, surface albedo, and meteorology (Mei et al., 2013a, 2020a; Stapf et al., 2020). The AOD is defined as the columnar
40 integration of the aerosol extinction coefficient (the sum of the absorption and scattering coefficient).

The Arctic is vast and the ground-based measurements of AOD are inevitably sparse. This has limited our understand-
ing of the direct and indirect impact of aerosols on AA, and vice versa. Recently there have been some campaigns, which
have investigated different processes of relevance to aerosol sources and sinks in the Arctic e.g. MOSAiC campaign (<https://mosaic-expedition.org>),
ACLOUD/PASCAL (Wendisch et al., 2023), PAMARCMIPs (Hoffmann et al., 2012; Nakoudi et al.,
45 2018; Ohata et al., 2021). In addition, there are other site-based long-term aerosol measurement studies (Herber et al., 2002;
Tomasi et al., 2007; Moschos et al., 2022; Schmale et al., 2022). However, these provide an inadequate spatiotemporal repre-
sentation of the Arctic region (Sand et al., 2017). The sparseness of AOD may explain, at least in part, the variations of AOD
simulations from different climate models (Sand et al., 2017). Without doubt, the lack of AOD measurements in the Arctic
limits our knowledge about radiative forcing and the Arctic warming in global and regional climate models (Goosse et al.,
50 2018).

Further, AOD has been retrieved from the measurements of reflectance at Top-Of-Atmosphere (TOA), made by passive satellite remote sensing instrumentation over the Arctic, but almost exclusively over snow- and ice-free areas i.e. land and ocean. A few recent studies have used such AOD products (e.g., (Glantz et al., 2014; Wu et al., 2016; Sand et al., 2017; Xian et al., 2021)) over open ocean and snow- and ice free surfaces, and make a valuable contribution to closing the data gap mentioned above. However, these AOD products are not suitable over the cryosphere due to an inadequate parameterization of the surface reflectance over residual snow- and ice-covered areas (Mei et al., 2020a) and Arctic cloud cover (Jafariserajehlou et al., 2019). In addition, typical illumination conditions, i.e. large solar zenith angles make the AOD retrieval used in the Arctic more challenging and lead potentially to a significant overestimation of AOD values (Mei et al., 2013a).

Several dedicated algorithms for passive satellite remote sensing over snow and ice have been developed. (Istomina et al., 2009, 2011) and later (Mei et al., 2013a, 2020b, a) have provided valuable pioneering research. However, these attempts have been mostly confined to the island of Spitsbergen in the Svalbard archipelago in northern Norway. Thus far, there have been no attempts to apply these algorithms systematically in the Arctic cryosphere to fill the data gap, identified above. Studies using active satellite remote sensing such as Sand et al. (2017) and Xian et al. (2021) are valuable, but the observational data are limited over the Arctic cryosphere.

Recently, Toth et al. (2018) and Xian et al. (2021) reported that the active satellite sensor, the Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP/CALIPSO) (Winker et al., 2004) has a significant fraction of aerosol profile data consisting of retrieval fill values (-9999s, or RFVs), due in part to the lidar's minimum detection limits. Indeed, in some areas in the Arctic, over 80% of CALIOP profiles consist solely of RFVs.

Consequently, the objective of this study is to retrieve the AOD over snow- and ice-covered regions of the Arctic. In this way, we extend the retrieval of aerosol loading over polar regions because past efforts, using the same AATSR source data, did not cover the high latitudes (Popp et al., 2016). To achieve this goal, we retrieve the total AOD using an approach first described by Istomina et al. (2009, 2011), which we have further developed and named AEROSNOW. We assessed the quality of AEROSNOW by using Aerosol Robotic Network (AERONET) measurements to validate the retrieved AOD. After retrieval and validation, we discuss the distribution of AOD over Arctic snow and ice in spring and summer, since ground-based or space-borne observational data on AOD covering the entire high Arctic cryosphere are limited. In this regard, the purpose of examining these distributions is to gain further confidence in this new data set and to test the distributions with respect to our expectations. For example, we examine whether the AOD retrieved by AEROSNOW is able to capture the increased pan-Arctic distribution of AOD in spring compared to summer (Willis et al., 2018), which would be a clear confirmation of whether or not Arctic haze events are well captured by this dataset.

We have generated the AEROSNOW AOD data set for the period from 2003 to 2011 (9 years). The algorithm uses the measurements, made by the Advanced Along-Track Scanning Radiometer (AATSR) data over the Arctic. A short description of the AATSR data and the corresponding retrieval is given in section 2. To determine the quality of the AEROSNOW data sets, we compare them with accurate ground-based AERONET measurements in the high Arctic. The description of the AERONET dataset is found in section 2.2. The AERONET and AEROSNOW values are then compared at selected high latitude AERONET stations over snow and ice-covered surfaces in section 3. Finally, we draw conclusions in section 4.

2 Data Sets and Data Processing

To investigate the distribution and variability of Arctic aerosols over snow and ice, we have used passive remote sensing during spring (March, April, April, May, (MAM)) and summer (June, July, August, (JJA)), which is the time when the Arctic is illuminated by solar radiation. The AEROSNOW algorithm is applied to the dual view Level 1B data product reflectance at the top of the atmosphere made by AATSR (Llewellyn-Jones et al., 2001). We have validated the AEROSNOW retrieved AOD by comparing it with the AOD measured by the ground-based sun-photometer measurements, AERONET (Holben et al., 1998).

2.1 Satellite Retrieval

2.1.1 AATSR Instrument

The AATSR flew, as part of the payload of the European Space Agency's (ESA) ENVISAT, which was launched on 28.02.2002 and failed on 08.04.2012. ENVISAT flew in a sun-synchronous orbit with an equatorial crossing local time of 10 o'clock. AATSR made measurements from May 2002 to April 2012. The spatial resolution of the AATSR observation data was 1 km at nadir. The swath width of AATSR was 512 km. AATSR had a dual viewing capability with a forward viewing angle of 55°. It made simultaneous measurements of the upwelling reflectances at wavelengths, from the visible to thermal infrared (0.55, 0.66, 0.87, 1.6, 3.7, 11, and 12 μm).

2.1.2 AEROSNOW Algorithm

The dual-viewing capability of the AATSR instrument was exploited to retrieve AOD over snow and ice using the AEROSNOW algorithm. AEROSNOW comprises a cloud identification routine, a cloud mask, and an algorithm to determine the AOD for cloud-free scenes. For the cloud mask, we adapted the implementation of the approach proposed in (Jafariserajehlou et al., 2019). The AATSR-SLSTR cloud identification algorithm (ASCIA) meets the requirements of the high-latitude AOD study (Jafariserajehlou et al., 2019) and uses a set of thresholds for radiation and time series measurements. Cloud-free scenes are assumed to be unchanged or only slightly changed for a given sampling period. We set this value to ± 30 min in this study (Jafariserajehlou et al., 2019), while cloudy or partly cloudy scenes exhibit much greater spatial and temporal variability. The ASCIA cloud detection algorithm achieved promising agreement of more than 95% and 83% within ± 2 and ± 1 okta, respectively, compared to ground-based synoptic surface observations (SYNOP) (WMO, 1995). In general, ASCIA shows better performance in detecting clouds in a ground scene observed at high latitudes than other algorithms applied to AATSR measurements. The ASCIA includes two main components used to detect the presence of clouds: i) a Pearson Correlation Coefficient (PCC) analysis at 1.6 μm and ii) the use of reflectance thresholds for a 3.7 μm channel.

The PCC analysis at a given viewing angle separates surface reflectance, which is stable over short periods of time, from cloud reflectance. Cloud reflectance is highly variable over a short period of time. To describe the developed computational procedure, x and y are assumed to be two random variables. Then the PCC can be written as a function of the covariance of x and y normalized by the square root of their variances (Rodgers and Nicewander, 1988; Benesty et al., 2009).

$$PCC = \frac{COV(x,y)}{\sigma_x \sigma_y} \quad (1)$$

Where $COV(x,y)$ is the covariance of the variables and σ is the squared deviation of the individual random variables (Rodgers and Nicewander, 1988; Benesty et al., 2009). The correlation coefficient parameter has values between -1 and +1 (Rodgers and Nicewander, 1988). The PCC values were generated in this study. The association between the two variables is stronger when the absolute value is closer to 1, while the PCC value is 0 when two variables are independent or, in other words, "uncorrelated" Benesty et al. (2009). As a result, PCC values calculated between multiple pairs of data for ground scenes of the same area at different times provide an indication of whether the scene is cloud-covered or cloud-free.

The reflectance thresholds for a $3.7\mu\text{m}$ channel were used in the second part of ASCIA. The reason for the wide application of this channel in cloud detection methods is the difference in single scattering albedo (SSA) at this band compared to shorter VIS and NIR wavelengths, which in turn is due to the significant sensitivity of SSA to the thermodynamic phase and particle size of clouds (Platnick and Fontenla, 2008). For example, scattering from liquid clouds with small droplets is relatively larger than absorption, and the ratio of NIR/VIS reflectance approaches 1. However, for large liquid droplets or ice particles, absorption increases and the ratio approaches zero (Platnick and Fontenla, 2008). In addition, cloud-free snow reflects relatively weakly compared to clouds in the $3.7\text{-}\mu\text{m}$ channel (Derrien et al., 1993; Platnick and Fontenla, 2008). Therefore, due to the different physical properties and radiance of snow/ice and clouds at $3.7\mu\text{m}$, the contrast is advantageous for cloud identification.

The reflectance of $3.7\mu\text{m}$ can be written as,

$$R_{3.7\mu\text{m}} = \frac{L_{3.7\mu\text{m}} - B_{3.7\mu\text{m}}T_{11\mu\text{m}}}{\mu_0 F_{3.7\mu\text{m}} - B_{3.7\mu\text{m}}T_{11\mu\text{m}}} \quad (2)$$

Where $R_{3.7\mu\text{m}}$ is the reflectance (i.e., the ratio of scattered radiance to incident solar radiance), L is the measured radiance at $3.7\mu\text{m}$, $B_{3.7\mu\text{m}}(T_{11\mu\text{m}})$ is the Planck function radiance (the contribution of thermal emission at $3.7\mu\text{m}$, $T_{11\mu\text{m}}$ measurements at $11\mu\text{m}$, $F_{3.7\mu\text{m}}$ is the solar constant at $3.7\mu\text{m}$, and 0 is the cosine of the solar zenith angle.

In the first step, a PCC analysis for a block of ground scenes ($25\text{km} \times 25\text{km}$) is used to identify cloudy and cloud-free blocks that are assumed to have low and high PCC values, respectively. The result of this step is a block-level binary flag. This serves as input to the second step of creating a ground scene-level binary flag ($1\text{km} \times 1\text{km}$ or $0.5\text{km} \times 0.5\text{km}$, depending on the spatial resolution of the instrument) to identify clouds, using knowledge of the reflectance of solar radiation in the $3.7\mu\text{m}$ channel. The combination of these two constraints is necessary because neither PCC analysis nor the reflectance of the $3.7\mu\text{m}$ channel alone is sufficient for accurate cloud identification (Jafariserajlou et al., 2019). For more information, the reader is referred to the schematic flow chart of the cloud identification algorithm shown in Fig. 4 of the article by Jafariserajlou et al. (2019).

For the selected cloud free scenes, the AOD is then retrieved. Instead of computational time-intensive online calculations a look up table (LUT) approach is used in the retrieval. The LUT contains AOD for values of the solar zenith angle θ , and relative azimuth angle ϕ . The method uses the ratio of the reflectance for nadir and forward observations (the dual-view), measured

at TOA. A forward radiative transfer model SCIATRAN (Roazanov, 2001; Roazanov et al., 2002, 2005) simulates the values of this ratio. An analytical solution for the BRDF of snow (Kokhanovsky and Breon, 2012), as well as tabulated values of transmissivity (from look-up tables) were used in an iterative procedure to obtain the AOD over Arctic snow and ice regions at 555 nm.

The algorithm takes advantage of the ability of the AATSR instrument to observe in two different viewing directions. It was described in Istomina et al. (2009, 2011) and Mei et al. (2012). Consequently, we now provide an overview of this algorithm. The reflectance of the surface can be approximated by two terms. One term describes the dependence of the reflectance on the wavelength and the other describes the dependence of reflectance on the viewing geometry. The surface reflectance ratio is mainly determined by the shape and magnitude of the surface BRDF (Vermote et al., 1997). This reduces the need for a highly accurate simulation of the wavelength-dependent surface reflectance, which is useful for bright surfaces such as snow- or ice-covered regions (Vermote et al., 1997). This can be well explained by the following equations:

$$\frac{\rho_{\text{sfc}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{sfc}}^n(\lambda, \mu_0, \mu, \phi)} = \frac{\rho_{\text{TOA}}^f(\lambda, \mu_0, \mu, \phi) - \rho_{\text{atm}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{TOA}}^n(\lambda, \mu_0, \mu, \phi) - \rho_{\text{atm}}^n(\lambda, \mu_0, \mu, \phi)} \cdot \frac{T^n(\lambda, \mu)}{T^f(\lambda, \mu)} \quad (3)$$

where $\rho_{\text{sfc}}(\lambda, \mu_0, \mu, \phi)$ is the reflectance from the surface, $\rho_{\text{TOA}}(\lambda, \mu_0, \mu, \phi)$ is the top of the atmospheric reflectance (TOA) observed by satellite, $\rho_{\text{atm}}(\lambda, \mu_0, \mu, \phi)$ is the atmospheric reflectance, $T(\lambda, \mu)$ is the total atmospheric transmittance from upward and downward directions, and f and n indicate AATSR forward and nadir observation angles, respectively.

Further, the Eq. 3 improved as follows,

$$\frac{\rho_{\text{sfc}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{sfc}}^n(\lambda, \mu_0, \mu, \phi)} = \frac{\Delta\rho^f(\lambda, \mu_0, \mu, \phi)}{\Delta\rho^n(\lambda, \mu_0, \mu, \phi)} \cdot \frac{\Delta\rho^n(\lambda, \mu_0, \mu, \phi) \cdot s + T^n(\lambda, \mu)}{\Delta\rho^f(\lambda, \mu_0, \mu, \phi) \cdot s + T^f(\lambda, \mu)} \quad (4)$$

$$\Delta\rho(\lambda, \mu_0, \mu, \phi) = \rho_{\text{TOA}}(\lambda, \mu_0, \mu, \phi) - \rho_{\text{atm}}(\lambda, \mu_0, \mu, \phi) \quad (5)$$

where, hemispheric atmospheric reflectance (s), which depends on the aerosol type as well as aerosol loading.

The decoupling of the contribution of aerosol from the surface signals a main issue for Eq. 4. Hence, we need to separate accurately the surface reflectance from the atmospheric contributions. Therefore, a suitable snow BRDF model is needed that depends on the viewing and illumination angle, wavelength, and snow properties such as the size and shape of grains, and characterizes both AATSR observation directions. The BRDF model is analytical and was compared with a series of multi-spectral and multidirectional measurements from the POLDER-3 (Polarization and Directionality of the Earth's Reflectances) instrument aboard the PARASOL satellite (Polarization and Anisotropy of Reflectances for Atmospheric Sciences coupled with Observations from a Lidar). We fixed the free parameters for the entire time series of AATSR, which involved a fixed snow grain size and snow impurity assumptions.

The BRDF model reproduces the directional variations in the measured reflectance with a root mean square (RMS) error that is typically 0.005 in the visible wavelength range (Kokhanovsky and Breon, 2012), assuming a fixed snow grain size and

snow contamination. This assumption is valid because the model is also able to reproduce the directional signature of snow, although its directional signature is very different from that of other types of surfaces such as vegetation or bare soil.

A snow BRDF model was selected as follows (Kokhanovsky and Breon, 2012):

$$180 \quad \rho(\mu, \mu_0, \phi) = \rho_0(\mu, \mu_0, \phi) A^{f(\mu, \mu_0, \phi)} \quad (6)$$

where

$$\begin{aligned} A &= \exp\left(\frac{-4s}{\sqrt{3}}\right), s = \sqrt{\frac{1-\omega}{1-g\omega'}} \\ f &= \frac{u(\mu)u(\mu_0)}{\rho_0(\mu, \mu_0, \phi)} \\ u(\mu) &= \frac{3}{7}(1+2\mu) \\ 185 \quad \rho_0(\mu, \mu_0, \phi) &= \frac{a+b(\mu+\mu_0)+c\mu\mu_0+p(\theta)}{4(\mu+\mu_0)} \end{aligned}$$

where $\rho_0(\mu, \mu_0, \phi)$ is the reflection function for non-absorbing snow layer, $\mu = \cos\theta$ and $\mu_0 = \cos\theta_0$, θ_0 and θ are solar zenith angle and satellite zenith angle, g is the asymmetry factor of snow particle, ω is the single scattering albedo, $a = 1.247$, $b = 1.186$, $c = 5.157$, ϕ is the azimuth angle, $p(\theta) = 11.1 \exp(-0.087\theta) + 1.1 \exp(-0.014\theta)$, respectively.

Some corrections are needed in order to take the snow structure into account as only pure snow-covered area is used for
190 the retrieval and in the real AATSR measurements. Mei et al. (2012) changed Eq. 4 and used the following Eq. 7 to mitigate atmospheric effects by introducing simulated $\rho_{\text{sfc},\text{sim}}(\lambda, \mu_0, \mu, \phi)$ and $\rho_{\text{TOA},\text{sim}}(\lambda, \mu_0, \mu, \phi)$ ratios of forward and nadir view:

$$\frac{\rho_{\text{sfc}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{sfc}}^n(\lambda, \mu_0, \mu, \phi)} = \frac{\rho_{\text{sfc},\text{sim}}^f(\lambda, \mu_0, \mu, \phi) \rho_{\text{TOA},\text{sim}}^n(\lambda, \mu_0, \mu, \phi, \tau) \rho_{\text{TOA}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{sfc},\text{sim}}^n(\lambda, \mu_0, \mu, \phi) \rho_{\text{TOA},\text{sim}}^f(\lambda, \mu_0, \mu, \phi, \tau) \rho_{\text{TOA}}^n(\lambda, \mu_0, \mu, \phi)} \quad (7)$$

Eq. 7 tries to mitigate the atmospheric effect of $\rho_{\text{TOA}}(\lambda, \mu_0, \mu, \phi)$ by simulated $\rho_{\text{sfc},\text{sim}}(\lambda, \mu_0, \mu, \phi)$ and $\rho_{\text{TOA},\text{sim}}(\lambda, \mu_0, \mu, \phi, \tau)$
195 ratio. Where $\rho_{\text{TOA},\text{sim}}(\lambda, \mu_0, \mu, \phi, \tau)$ is the simulated top of the atmospheric reflectance for a given AOD. The actual retrieval is working on Eq. 7 and Eq. 4, and is minimized with respect to the optical depth (tau) at 555nm as a cost function.

Another way to take this effect into account is proposed by Mei et al. (2012). The primary drive of the idea is that by using a correction term by the snow cover fraction (SCF), the ‘‘real snow’’ BRDF can be better estimated from the original BRDF model (Kokhanovsky et al., 2005).

The NDSI is defined as the following:

$$200 \quad \text{NDSI} = \frac{\rho_{0.55} - \rho_{1.6}}{\rho_{0.55} + \rho_{1.6}} \quad (8)$$

The SCF was then estimated using the empirical equation (Salomonson and Appel, 2004):

Aerosol component	Refractive index		Single Scattering Albedo	
	n	χ	Coarse mode	Accumulation mode
Water soluble	1.530	6.00E-03	0.75	0.92
Oceanic	1.381	4.26E-09	1.00	1.00
Dust	1.530	8.00E-03	0.71	0.89
Soot	1.750	4.40E-01	0.55	0.50

Table 1. Single scattering albedo (SSA), real ' n ' and imaginary ' χ ' part of the refractive index for coarse and accumulation mode of water-soluble, oceanic, dust and soot aerosol components at 550 nm (Istomina et al., 2011)

$$SCF = 1.21 \cdot NDSI + 0.06 \quad (9)$$

Then, the snow BRDF ratio can be rewritten as follows:

$$\frac{\rho_{\text{sfc}}^f(\lambda, \mu_0, \mu, \phi)}{\rho_{\text{sfc}}^n(\lambda, \mu_0, \mu, \phi)} = \frac{\rho_{\text{sfc, sim}}^f(\lambda, \mu_0, \mu, \phi) \cdot SCF^f}{\rho_{\text{sfc, sim}}^n(\lambda, \mu_0, \mu, \phi) \cdot SCF^n} \quad (10)$$

205 An important aerosol property is the aerosol phase function. In this work, two types of aerosols were used: one is a background aerosol and the other is Arctic haze. The phase functions for these two types are shown in Istomina et al. (2011). The basic aerosol properties used in the model, such as the single scattering albedo (SSA), the real part, and the imaginary part of the refractive index for the coarse and accumulation modes of the water-soluble, oceanic, dust, and soot aerosol components are given in Table. 1 adopted from Istomina et al. (2011). Further, in this work, we used the phase function for 550 nm measured ground-based by the Alfred Wegener Institute for Polar and Marine Research during the Arctic haze event on 23 March 210 2000 at Spitsbergen, Ny Ålesund, Svalbard, 78.923° N 11.923° E. Subsequently, the look-up table was calculated using the SCIATRAN radiative transfer package (Roazanov et al., 2014; Mei et al., 2023a).

2.2 AERONET Level 2 Aerosol Product

The AEROSOL ROBOTIC NETWORK, AERONET, is a federated network of ground-based global sun photometers measuring solar and sky irradiance at various wavelengths from the near ultraviolet to the near infrared with high accuracy (Holben et al., 2001; 215 Giles et al., 2019). AERONET sun photometers record AOD values every 15 minutes in typically seven spectral channels (nominally 340, 380, 440, 500, 670, 870, and 1020 nm) (Holben et al., 2001). The quality-assured AERONET version 3 level 2 data are used in this study (accessed at <http://aeronet.gsfc.nasa.gov>).

220 The AOD from AERONET stations in the high Arctic were used to assess the data quality of AOD estimated using AEROSNOW. The locations of the AERONET stations selected are PEARL (80.054N, 86.417W), OPAL (79.990°N, 85.939°W), Hornsund (77.001°N, 15.540°E) and Thule (76.516°N, 68.769°W) and shown in Fig. 1. Two sites are located over the Canadian

Figure 1. Location of PEARL, OPAL, Hornsund and Thule AERONET measurement stations considered in this study.

archipelago (CA), which typically has aerosol of natural origin (Breider et al., 2017) and one station Hornsund on Spitsbergen, which is known to be affected by polluted air masses from lower latitudes.

2.3 Data quality control

225 To compare the AOD of AERONET measured at 500 nm with those of AEROSNOW (measured at 555 nm), a conversion is required. The AOD at 500 nm is used to extrapolate the AOD at 555 nm by using 500-870 nm Angstrom Exponent. In addition, the AOD at 555 nm is considered as the total AOD to allow comparison with the AEROSNOW data. AERONET observations were averaged and compared to values measured within a 25-km radius and 30-minute time collocation of the AERONET stations for AEROSNOW. Monthly averages were calculated based on the spatio-temporal colocated data. Information about
 230 the collocated daily values derived is shown in the appendix (Fig. A1).

In post-processing AEROSNOW, we selected optimal conditions, i.e. by using a cutoff value for the solar zenith angle ($\geq 75^\circ$) and filtering out those scenes or pixels that had a Normalized-Difference Snow Index (NDSI) ≤ 0.97 . In this work, we adopted the recommendations in (Istomina (2011), Section 3.3.5) for a solar zenith angle (SZA) of 75 degrees based on sensitivity analysis using the SCIATRAN radiative transfer model (see also (Mei et al., 2023b)).

235 The NDSI is an index that refers to the presence of snow in a pixel and is a more accurate description of snow detection compared to fractional snow cover. Snow typically has a very high reflectance in the visible spectrum (VIS) and a very low reflectance in the shortwave infrared (SWIR). Snow coverage is determined by the NDSI ratio of the difference between the VIS and SWIR reflectance, and is defined in Eq. 8.

A pixel with NDSI > 0.0 is considered to have snow present, while a pixel with NDSI ≤ 0.0 represents a snow-free land
 240 surface (Riggs et al., 2017). In this study, NDSI was used in a rigorous post-processing of the datasets to filter out the mixed and snow-free regions. For the stations considered in this study, we found bimodal distributions of AOD, with the frequency of the second mode influenced by clouds and problematic surfaces. We filtered out 40% over problematic surfaces and residual clouds and 100% over central Greenland using rigid post-processing with NDSI. The AEROSNOW retrieval is based on Eq. 7 in the revised manuscript, which uses the ratio of the simulated nadir BRDF values for the nadir and forward views of the
 245 dual-viewing instrument AATSR. With this strategy, we mitigate the absolute errors in the BRDF but rather rely on the shape

of the BRDF as seen from both directions. For our study, a narrow interval of NDSI was required to limit the BRDF-induced error in retrieving the AOD, which is less than 30% using Istomina's approach (Istomina (2011), Section 3.3.3). Since we consider this error to be critical, we additionally introduced the Quality Flagging (QF) approach in our post-processing scheme by adopting independent additional support from MODIS Terra and Aqua cloud fraction (Ackerman et. al., 2007) apart from
250 ASCIA cloud detection algorithm, where we weighted the snow cover fraction even higher than the cloud fraction.

To ensure quality, we also noted that melt ponds and thin clouds not captured by rigid filtering deteriorate the retrieval quality of AEROSNOW. Recently Xian et al. (2021) introduced a post-processing scheme to remove erroneous AOD outliers. Instead of applying the rather qualitative quality flagging approach as proposed by the former, we applied a more quantitative one. We thoroughly examined the ratio of AEROSNOW to AERONET AOD greater than a factor of 1.6 by calculating a quality
255 flag (QF) parameter [$QF = (0.8 \times (\text{snow cover fraction}) + 0.2 \times (1 - \text{cloud fraction}))$] which penalizes the low levels of snow cover and (and to less extent) residual cloud fraction by using MODIS Terra and Aqua data products from NASA Worldview (<https://worldview.earthdata.nasa.gov/>) respectively. When using the AEROSNOW data beyond the AERONET stations, we applied this scheme to all data points of AEROSNOW. Empirical tests showed that an appropriate snow cover fraction is weighted higher than an appropriate clear sky fraction (1 - cloud fraction). This is expressed by the individual weighting
260 factors for snow cover fraction (0.8) and clear sky fraction (0.2). We found that a QF threshold value of 0.6 represents a compromise between data yield and data quality. Thus, in the final step, AOD values having a QF value of 0.6 or less were removed.

3 Result: Assessment of AEROSNOW AOD

3.1 Qualitative Analysis of AEROSNOW

265 Before we turn to quantitative validation of the AEROSNOW results, we discuss the spatio-temporal distribution of the AEROSNOW data here briefly in qualitative terms. The spatio-temporal frequency of observations over the Arctic from both ground and satellite is larger in summer (JJA) than in spring (MAM). Fig. 2 shows the monthly averaged AOD over snow and ice of the Arctic for the period 2003-2011, with significant differences in the spatial distribution of AOD. In this study, satellite retrievals are performed only when snow and ice are present (NDSI-threshold values, see section 2). The NDSI was
270 used to constrain the BRDF in terms of snow grain size and impurity (when snow accumulation is fresh) and clouds are absent. Accordingly, the best coverage is obtained over persistently homogeneous areas covered with (fresh) snow and ice. Greenland is an exception to the AOD retrieval. Possible reasons for this could be that the BRDF does not fit well because it does not adequately represent the snow grains and impurities of the Greenland glaciers and snow covered ice sheet and the elevated topography. Further, the clouds over Greenland are typically optically thin and low-hanging (Bennartz et al., 2013) and are
275 likely not all captured by the ASCIA cloud detection algorithm. Smoother patterns are observed in Fig. 2 over the Arctic sea ice compared to snow-covered land.

3.2 Statistical evaluation of AODs from AERONET and AEROSNOW

The satellite retrieved and ground based observations are compared. Uncertainties due to both space and time sampling differences are minimized. Fig. 3 shows the validation between AEROSNOW retrieved AOD over PEARL, OPAL, Hornsund and Thule, with AERONET AOD during this study period. Fig. A1 in the appendix depicts daily collocated values and statistics.

Much of the data analysis in this paper involves fitting a straight line to the AODs observed by both AERONET and AEROSNOW. Because the AOD observations by these two platforms are both subject to measurement errors (Sinyuk et al., 2012; Mei et al., 2013a), we have used a fitting procedure known as the reduced major axis (RMA) method, as described by Hirsch and Gilroy (1984); Ayers (2001).

RMA regression takes into account the uncertainties or errors of the two variables, while ordinary least squares (OLS) regression takes into account the uncertainties of one variable. Here, the best linear fit between the two variables is sought, which must be the same in X or in Y regardless of the variable, that is, aiming for a symmetric relationship. For this, different methods are possible, for example, by minimizing the perpendicular distance or the triangle, and we choose the RMA, that is, by minimizing the triangle. RMA has been used by other researchers in the analysis of air quality and atmospheric chemistry data see for example Keene et al. (1986); Arimoto et al. (1995); Freijer and Bloemen (2000); Ayers (2001); Wang et al. (2004)

By combining these four stations, the coefficient of correlation (R) is on average 0.86 and the root mean square error (RMSE) is 0.01. Validating each stations separately the R value is increasing to 0.90, 0.94, 0.81 and 0.87 over PEARL, OPAL, Hornsund and Thule respectively (Fig. 4). We consider R values of about 0.8 to be sufficient under the Arctic condition that these are exceptionally challenging retrievals.

3.3 Comparison of AODs from AERONET and AEROSNOW

In the next step, we analyze the collocated temporal evolution of the AEROSNOW results and compare with AERONET station data. The time-series of retrieved AEROSNOW AOD is shown together with AERONET data in Fig. 5. In general, the time-series for AERONET is well reproduced by AEROSNOW.

In general and as expected, we observe that PEARL, OPAL and Thule (extended Canadian archipelago, henceforth called CA-stations) exhibit similar temporal behavior. PEARL and OPAL AERONET sites are located around 11.5 km apart. OPAL is closer to the coast than PEARL station and are located at altitudes of 5.0 m and 615.0 m, respectively. Hornsund is in this context clearly different. This difference can be explained by using a chemical transport model by separating the total AOD to aerosol components (Breider et al., 2014; Swain et al., 2023).

The CA-stations show low average values AOD. This is associated with Arctic background scenarios. The seasonal variability over all these three stations are presented Fig. 6, which shows that both the AEROSNOW and AERONET results exhibit higher AOD during spring (MAM) and minimum during summer (JJA). A partially high estimation of AEROSNOW is observed over all the selected sites in August, which may be due to uncertainties in surface parameterization and aerosol types in this region.

On average, AEROSNOW appears to capture some haze events during spring and thereby has higher average values than in
 310 the summer season.

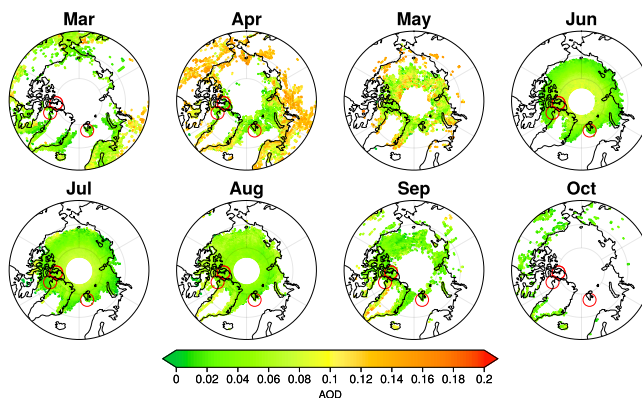

Figure 2. Pan-Arctic seasonal view of AEROSNOW retrieved AOD over snow and ice averaged from the year 2003 to 2011 for the months March to October, thus large parts of the period of insolation. Red circles indicate the location of AERONET stations.

Figure 3. Validation of monthly mean AEROSNOW retrieved AOD collocated with monthly mean AERONET observation AOD obtained over PEARL, OPAL, Hornsund, and Thule stations. The linear regression line are shown as the blue dashed line.

3.4 Spring and Summertime AOD over the Arctic Sea Ice

Similar to the analysis shown in Fig. 5, where we examined the time series of total AOD from AEROSNOW over AERONET
 stations, we now discuss qualitatively how AOD values change over time across the entire region of Arctic sea ice. The
 combination of seven AATSR channels was used to distinguish the spectral response of a clear, snow-covered landscape from
 315 that of clouds, land, and sea using the visible (Eq. 12, Eq. 13) and near-infrared (Eq. 11) nadir reflectances of the top of the

Figure 4. Validation of monthly mean AEROSNOW retrieved AOD collocated with monthly mean AERONET observation AOD obtained over PEARL, OPAL, Hornsund, and Thule stations. The linear regression lines are shown as blue dashed line.

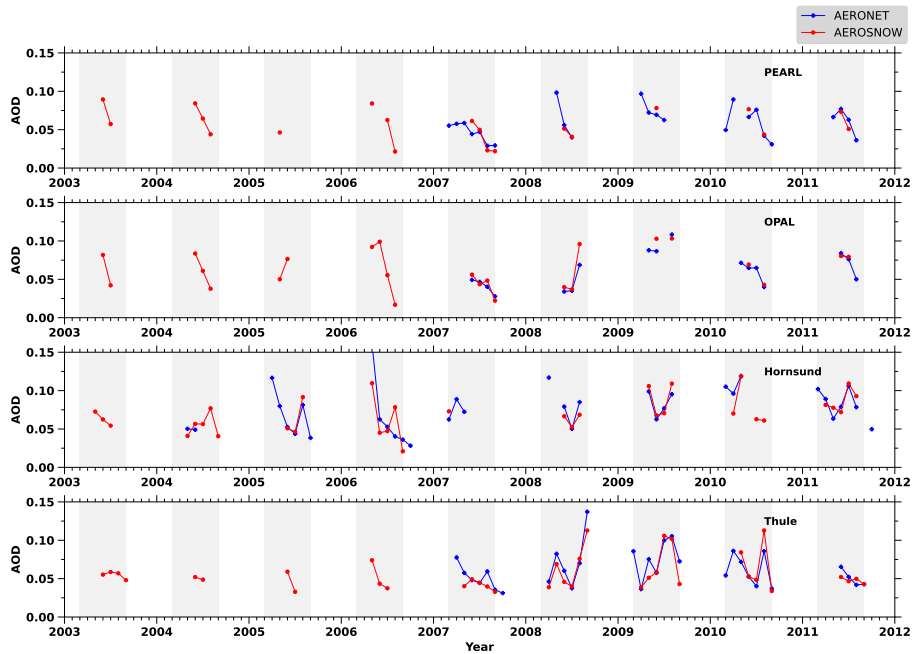

Figure 5. Monthly mean time-series of AERONET and AEROSNOW AOD at PEARL, OPAL, Hornsund, and Thule stations. The MAM, JJA periods are highlighted with light-grey shades.

Figure 6. Seasonal AOD variation over PEARL, OPAL, Hornsund and Thule with AEROSNOW and AERONET values average from 2003 to 2011. Blue and orange bar plots shows statistics for AERONET and AEROSNOW respectively.

Figure 7. Mean climatological MAM and JJA AEROSNOW derived AOD over Arctic Sea Ice averaged from the year 2003 to 2011. White area shows lack of data apart from the masked land area.

atmosphere. While the visible (VIS) and near-infrared (NIR) criteria. (Eq. 11, Eq. 12, 13) select scenes whose spectral behavior is similar to the snow spectrum (Istomina et al., 2011).

$$\frac{R_{TOA}(0.87\mu m) - R_{TOA}(1.6\mu m)}{R_{TOA}(0.87\mu m)} > 80\% \quad (11)$$

$$\frac{R_{TOA}(0.87\mu m) - R_{TOA}(0.66\mu m)}{R_{TOA}(0.87\mu m)} < 10\% \quad (12)$$

Figure 8. Monthly mean time-series of AEROSNOW AOD over Arctic sea-ice region. The MAM,JJA periods are highlighted with light-grey shades.

Figure 9. Seasonal AOD variation over Arctic sea-ice region values averaged from 2003 to 2011. Blue bars denote observed monthly mean AODs of AEROSNOW.

$$320 \quad \left| \frac{R_{TOA}(0.66\mu m) - R_{TOA}(0.55\mu m)}{R_{TOA}(0.66\mu m)} \right| < 10\% \quad (13)$$

Where R_{TOA} is the reflection at the top of the atmosphere.

The AEROSNOW AOD results over pan-Arctic sea ice shown in Fig. 7 and Fig. 8, exhibit maximum values in spring 2009 and minimum values in spring 2006. However, comparing the seasonally averaged climatology from 2003 to 2011, the AEROSNOW results indicate higher AOD in the spring, and smaller values in summer as shown in Fig. 7 and Fig. 9, which
325 was expected due to the Arctic haze events (Willis et al., 2018).

On the other hand, the AEROSNOW retrievals of AOD may be affected by cloud contamination because high levels of cloud cover are observed over the Arctic in summer with average values around 0.8 (Kato et al., 2006). Although we adopted reasonable cloud masking for the AOD retrievals, we cannot exclude entirely the possibility that residual cloud contamination prevails (Jafariserajehlou et al., 2019). Additionally, AEROSNOW captures the higher values of AOD over north Alaska and
330 Siberia during summer, a region which is often influenced by boreal forest fires during this period (Xian et al., 2021) (Fig. 7). During spring the higher values of AOD (0.1-0.12) are observed near Europe and the Asian continent and smaller values (0.07-0.08) towards CA.

Spring values are mostly dominated by long-range transport of anthropogenic aerosols from the lower latitudes of Europe, America, and Asia (Willis et al., 2018). The AEROSNOW estimates of AOD over central Arctic sea ice are reasonable and
335 thus a valuable source to fill the aerosol data deficit over the perennial sea ice region in the high Arctic.

4 Conclusions

This is the first time that AOD has been retrieved using satellite data over the entire Arctic snow and ice surface over a nine-year period and validated with ground based AERONET measurement. A satellite-based retrieval of AOD over Arctic snow and ice (AEROSNOW, (Istomina et al., 2009, 2011)) was conducted, which has been shown to fill the gap in data availability from
340 standard aerosol products such as e.g. MODIS. The AEROSNOW algorithm uses the dual-viewing capability of the AATSR instrument to minimize retrieval uncertainties (Istomina et al., 2009, 2011; Mei et al., 2013b). It showed good agreement with ground-based AERONET observations, with a correlation coefficient $R = 0.86$ and a low systematic bias.

The high anthropogenic aerosol loading (Arctic haze events) due to long-range transport (Willis et al., 2018) over Arctic snow and ice is captured by the AOD determined by AEROSNOW (see also (Swain et al., 2023)). Further, the monthly mean spatial
345 maps shown in Fig. 2 confirmed that the haze events are captured well. The time series and seasonality of the AEROSNOW AOD agree well with AERONET observations. Good agreement between the AEROSNOW and AERONET AOD is achieved over PEARL, OPAL, Hornsund, and Thule stations. The AEROSNOW retrieved AOD shows maximum values during spring (MAM) and minimum during summer (JJA), which is also in accordance with AERONET measurements, which shows a clear confirmation that Arctic haze events were well captured by the AEROSNOW retrieved AOD. Further improvement of the
350 AOD retrieval could be possible in terms of cloud masking, surface reflectivity properties, and the adoption of more appropriate aerosol types to be considered.

The promising AOD results obtained with AEROSNOW indicate that these can be used to evaluate and improve aerosol predictions for various chemical transport models, especially over the Arctic sea ice in spring and summer for the important period 2003-2011 (Swain et al., 2023), which is within the period of Arctic amplification.

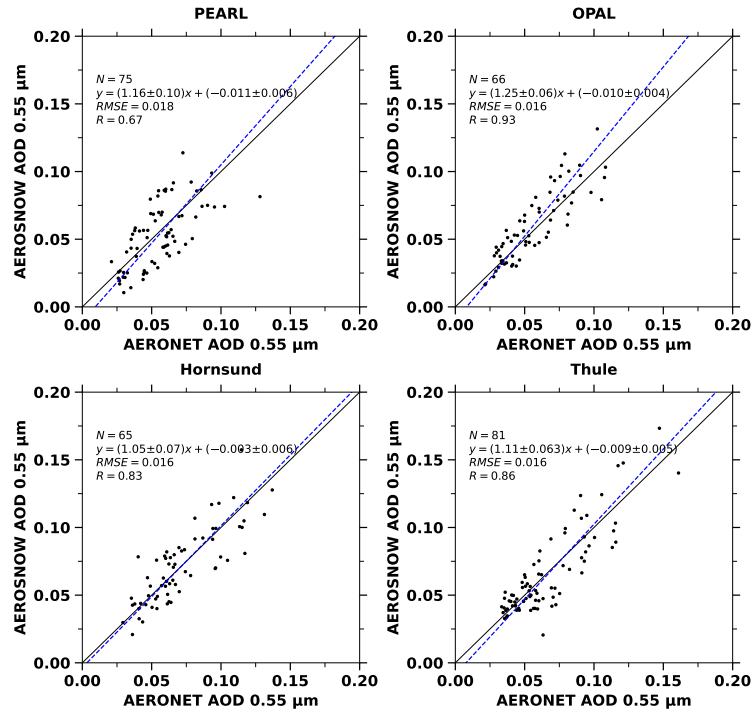

Figure A1. Validation of daily AEROSNOW retrieved AOD collocated with daily AERONET observation AOD obtained over PEARL, OPAL, Hornsund, and Thule stations. The linear regression lines are shown as blue dashed lines.

Code and data availability. The code and data supporting the conclusions of this manuscript are available upon request.

Author contributions. B.S., M.V. conceived the research. B.S. has processed the aerosol data, analyzed all records and wrote the manuscript. S.J. helped in algorithm development. M.V., A.D., L.L, Y.Z, S.J, S.S.G, A.H, C.R, and J.P.B. helped in shaping this manuscript. Funding acquisition by M.V. and J.P.B. All authors contributed to the interpretation of the results and the final drafting of the paper.
