8 **Abstract.** The High Latitude sNow Detection and Estimation aLgorithm for ATMS (HANDEL-ATMS) is a new
9 machine learning (ML)-based snowfall retrieval algorithm for Advanced Technology Microwave Sounder
10 (ATMS) observations that is developed specifically to detect and quantify high-latitude snowfall events that often
11 form in cold, dry environments and produce light snowfall rates. ATMS and the future European MetOp-SG
12 Microwave Sounder offer good high-latitude coverage and sufficient microwave channel diversity (23 to 190
13 GHz) that allows both surface radiometric properties to be dynamically characterized and the non-linear and
14 sometimes subtle passive microwave response to falling snow to be detected. HANDEL-ATMS is based on a
15 combined active-passive microwave observational dataset in the training phase, where each ATMS multichannel
16 observation is associated with coincident (in time and space) CloudSat Cloud Profiling Radar (CPR) vertical snow
17 profiles and surface snowfall rates. The main novelty of the approach is the radiometric characterization of the
18 background surface (including snow-covered land and sea ice) at the time of the overpass to derive multi-channel
19 surface emissivities and clear-sky contribution to be used in the snowfall retrieval process. The snowfall retrieval
20 is based on four different artificial neural networks for snow water path (SWP) and surface snowfall rate (SSR)
21 detection and estimate. HANDEL-ATMS shows very good detection capabilities - POD = 0.83, FAR = 0.18, and
22 HSS = 0.68 for the SSR detection module. Estimation error statistics show a good agreement with CPR snowfall
23 products for $SSR > 10^{-2} \text{ mm h}^{-1}$ (RMSE = 0.08 mm h^{-1} , bias = $0,02 \text{ mm h}^{-1}$). The analysis of the results for an
24 independent CPR dataset and of selected snowfall events evidence the unique capability of HANDEL-ATMS to
25 detect and estimate SWP and SSR also in presence of extreme cold and dry environmental conditions typical of
26 high latitudes.

27 **1 Introduction**

28 Snowfall retrieval is one important topic in the atmospheric science field. On a global scale, snowfall represents
29 only 5 % of the total global precipitation but it is predominant above 60 - 70 ° N/S (Levizzani *et al*, 2011). In
30 recent years, several studies have highlighted the strong influence of global warming on snowfall distribution and
31 regimes, especially at high latitudes (Liu *et al*, 2009, Liu *et al*, 2012, Bintanja & Selten, 2014, Vihma *et al*, 2015).
32 However, global snowfall quantification is a challenging topic in weather sciences. Ground-based instruments
33 such as raingauges or snowgauges provide only punctual measurements which can not fully capture the spatial
34 variability of precipitation phenomena (Kidd *et al*, 2017); moreover, the variability of snowflake shape and density
35 strongly influences particle fall speed and trajectory and therefore reduces the gauge-based measurement accuracy
36 of falling snow, especially compared to rain measurements (Skofronick-Jackson *et al*, 2015). Weather radars can
37 provide areal measurements of precipitation - the rate estimation is based on the conversion of the measured
38 backscattered radiation to precipitating hydrometeors content - but such operation presents some technical
39 limitations (Kidd & Huffman, 2011). Finally, most of the regions where snowfall is predominant - such as
40 Greenland, Siberia, Canada, and Antarctica - are uninhabited or otherwise sparsely populated areas where weather
41 observation networks are very scarce or totally absent. Therefore, the development of satellite-based methods for
42 snowfall retrieval is necessary for global monitoring of snowfall. Passive Microwave (PMW) sensors onboard
43 polar orbiting satellites can be exploited for snowfall detection purposes because the microwave (MW) signal is
44 directly responsive to the spatial distribution and microphysics properties of precipitation-sized hydrometeors in
45 the clouds; at the same time, the use of PMW sensors guarantees a high spatial coverage and high temporal
46 resolution (Kidd & Huffman, 2011).

47 PMW snowfall detection and quantification are typically based on the ability to interpret the snowfall scattering
48 signature in the high-frequency channels ($> 90 \text{ GHz}$), which respond more effectively to ice microphysics and are

49 less prone to surface effects than low-frequency channels, and to distinguish it from the clear-sky (surface and
50 atmosphere) contribution (e.g., *Panegrossi et al, 2017*). However, several factors make the PMW snowfall signal
51 ambiguous and the relationship between multichannel measurements and surface snowfall intensity highly non-
52 linear, especially in extremely cold/dry environmental conditions (*Panegrossi et al, 2022*). The snowfall scattering
53 signal is relatively weak and is highly dependent on the complex microphysical properties of snowflakes (*Kim et*
54 *al, 2008, Kulie et al, 2010, Kongoli et al, 2015*), it is often masked by supercooled liquid water emission signal
55 (*Wang et al, 2013, Battaglia & Delanoë, 2013, Panegrossi et al, 2017, Rysman et al, 2018, Battaglia &*
56 *Panegrossi, 2020, Panegrossi et al, 2022*), and can be contaminated by the extremely variable background surface
57 emissivity (*Liu and Seo, 2013, Takkiri et al, 2019, Rahimi et al, 2017*), especially in cold and dry conditions
58 typical of the high latitude regions (*Camplani et al, 2021*). In this context, the availability of the latest generation
59 MW radiometers - such as the conically-scanning radiometer GPM Microwave Imager (GMI) and the cross-track
60 scanning radiometer Advanced Technology Microwave Sensor (ATMS) - whose channels cover a wide range of
61 frequencies - offers new possibilities for global snowfall monitoring. The multi-channel PMW observations can
62 be used for both a dynamic radiometric characterization of the background surface - using the low-frequency
63 channels (< 90 GHz) - and for the detection and the estimation of the snowfall using the high-frequency channels
64 (> 90 GHz) (*Panegrossi et al, 2022*).

65 The PMW capability to characterize physically and radiometrically the background surface varies from sea to
66 land, especially for the identification of cold/frozen surfaces. For what concerns the ocean, sea ice detection using
67 PMW observations has been a well-documented topic in the remote sensing science field since the 70s. This is
68 due to the strong contrast between sea ice (≈ 0.9) and open water (≈ 0.5) emissivity values at the MW low-
69 frequency range (~ 19 GHz) (*Comiso, 1983*). Other studies highlighted the ability to discriminate between different
70 types of ice using a set of low-frequency window channels, because the differences between the emissivities of
71 the different types of sea ice increase with increasing frequency; in particular, at higher frequencies (30-50 GHz)
72 the contrast between the emissivity of “new” ice and “old” ice increases, with a decrease of the emissivity at
73 higher frequencies for “older” sea ice (*Comiso, 1983, Ulaby & Long, 2014*). Moreover, it has been observed that
74 the simultaneous presence of open water and sea ice causes a decrease in the low-frequency channel emissivity;
75 the observed emissivity can be considered as a linear combination of the emissivity spectra of sea ice and open
76 water (*Ulaby & Long, 2014*). For what concerns continental areas, the detection of snow-covered land surfaces
77 using MW measurements results to be more difficult. In dry conditions, a snowpack acts as a volume scatterer;
78 the scattering effect is dependent on the grain size and shape and the depth of the snowpack (*Clifford, 2010*).
79 However, the presence of liquid water can mask the scattering signature (*Mätzler & Hüppi, 1989*). At the same
80 time, large areas of Greenland and Antarctica, while covered by dry snowpacks throughout the year, do not show
81 a significant difference between the two ATMS low-frequency channels. Finally, some snow-free areas, such as
82 rocky mountains and cold deserts, present a scattering signature very similar to that of the snowpack (see
83 *Grody & Basist, 1996*). Therefore, the detection of snow-covered areas is very complex. A set of several tests, each of
84 which identifies snowpacks characterized by different physical and radiometric characteristics, may be used.

85 This paper describes the development of a machine learning-based algorithm for snowfall retrieval (the High
86 Latitude sNowfall Detection and Estimation aLgorithm for ATMS, HANDEL-ATMS), exploiting ATMS
87 radiometer multi-channel measurements and using the CloudSat Cloud Profiling Radar (CPR) snowfall products
88 as reference. The algorithm has been developed focusing on the typical conditions of high-latitude regions - low
89 humidity, low temperature, presence of snowpack on land or sea ice over ocean, and light snowfall intensity.

90 The main novelty of the approach is the exploitation of the ATMS wide range of channels (from 22 GHz to 183
91 GHz) to obtain the dynamic radiometric characterization of the background surface at the time of the overpass.
92 The derived surface emissivities are used to infer the clear-sky contribution to the measured brightness
93 temperatures (TBs) in the high-frequency channels in the snowfall retrieval process. This approach is similar to
94 the work of *Zhao and Weng, 2002*, for AMSU observations limited to non-scattering surfaces (i.e., ocean and
95 vegetated land), however the application to surfaces with a very complex and time-varying emissivity (such as
96 snow cover and sea ice) required a far-away more advanced algorithm taking advantage of machine learning
97 techniques. Moreover, the algorithm also exploits an observational dataset composed of ATMS multichannel
98 observations and coincident (time and space) CloudSat CPR vertical snow profiles and surface snowfall rates
99 (hereafter the ATMS-CPR coincident dataset).

100 Several snowfall retrieval algorithms for cross-track scanning radiometers have evolved in the last 20 years
101 starting from the Advanced Microwave Sounder Unit-B (AMSU-B) (Zhao and Weng, 2002, Kongoli et al, 2003,
102 Skofronick-Jackson et al, 2004, Noh et al, 2009, Liu and Seo 2013), and Microwave Humidity Sounder (MHS)
103 (see Liu & Seo, 2013, Edel et al, 2020), and evolving to ATMS (Kongoli et al, 2015, Meng et al, 2017, Kongoli
104 et al, 2018, You et al, 2022, Sanò et al, 2022). Some of them are based on radiative transfer simulations of observed
105 snowfall events (Kongoli et al, 2003, Skofronick-Jackson et al, 2004, Kim et al, 2008), or on in-situ data (Kongoli
106 et al, 2015, Meng et al, 2017, Kongoli et al, 2018), others on CPR observations (Edel et al, 2020, You et al, 2022,
107 Sanò et al, 2022), or a combination of them (Noh et al, 2009, Liu & Seo, 2013). In the last five years, there has
108 been an increasing use of machine learning (ML) approaches trained on CPR-based coincidence datasets. These
109 approaches have proven to be very effective for snowfall retrieval. On one side, ML techniques are suitable to
110 handle the complex, non-linear PMW multichannel response to snowfall (Rysman et al, 2018, Edel et al, 2020,
111 Sanò et al, 2022). On the other hand, the use of CPR-based datasets overcomes some of the limitations deriving
112 from the use of cloud-radiation model simulations, which are particularly challenging for snowfall events.
113 However, some limitations of the radar product used as a reference and issues related to the spatial and temporal
114 matching between the CPR and the PMW radiometer measurements introduce some uncertainty. Moreover, the
115 2-C-Snow-Profile (2CSP) product is based on assumptions on snow microphysics, uses optimal estimation to
116 retrieve snow parameters, uses a simplified radar reflectivity equation, and is affected by CloudSat CPR
117 limitations as outlined in Battaglia & Panegrossi, 2020.

118 For what concerns ATMS, the ML-based Snow retrieval ALgorithm fOr gpM-Cross Track (SLALOM-CT)
119 (Sanò et al, 2022) has been developed within the EUMETSAT Satellite APplication Facility for Hydrology (H
120 SAF) in preparation for the launch of the EPS-SG Microwave Sounder (MWS). Similarly to HANDEL-ATMS, it
121 is trained on an ATMS-CPR coincidence dataset. SLALOM-CT is the evolution for cross-track scanning
122 radiometers of the Snow retrieval ALgorithm fOr GMI (SLALOM) (Rysman et al, 2018, Rysman et al, 2019)
123 which was the first ML algorithm for snowfall detection and retrieval for GMI trained and tested on GMI-CPR
124 coincident observations made available in the NASA GPM-CloudSat coincidence dataset (Turk et al, 2021a). One
125 of the novelties in the SLALOM (SLALOM-CT) approach is the use of the GMI (ATMS) low-frequency channels
126 to better constrain the snowfall retrieval to the characteristics of the surface at the time of the overpass (Turk et
127 al, 2021b). SLALOM-CT is based on a modular scheme, i.e., four separate modules are used for snowfall
128 detection, supercooled water layer detection, snow water path (SWP), and surface snowfall rate (SSR) estimate.
129 The predictor set is composed of the ATMS TBs and some environmental variables (2 meters Temperature - T_{2m} ,
130 Total Precipitable Water - TPW, and principal components derived from temperature and humidity profiles).
131 However, none of the algorithms mentioned here were tailored specifically to the extreme conditions typical of
132 high latitudes. The present work has the aim to develop an algorithm for snowfall detection and estimation by
133 exploiting the large frequency range typical of the last generation radiometers and to obtain a dynamic radiometric
134 characterization of the background surface at the time of the satellite overpass in order to highlight the complex
135 relationship between upwelling radiation and snowfall signature, which makes the detection very difficult in the
136 typical conditions of the high latitudes.

137 This article is organized as follows: Section 2 provides background information on ATMS and CPR, on the
138 methodology used to build the coincidence dataset, and on the machine learning approaches used to develop the
139 algorithm. In Section 3 the algorithm structure is described. In Section 4 the overall performance scores are
140 reported and analyzed; a case study is analyzed and a comparison with SLALOM-CT is reported. Section 5 is
141 dedicated to the summary of the main results and to the conclusions.

142 **2. Instruments and methods**

143 **2.1 Advanced Technology Microwave Sounder (ATMS)**

144 ATMS is a total power cross-track scanning radiometer within 52.7° off the nadir direction. It has a total of 22
145 channels with the first 16 channels primarily used for temperature sounding from the surface to about 1 hPa (45
146 km) and the remaining channels used for water vapor sounding in the troposphere from the surface to about 200
147 hPa (10 km), and for cloud properties and precipitation retrieval. There are two receiving antennas: one serving
148 channels 1–15 below 60 GHz, and the other for channels above 60 GHz. The beamwidth changes with frequency
149 and is 5.2° for channels 1–2 (23.8–31.4 GHz), 2.2° for channels 3–16 (50.3–57.29 and 88.2 GHz), and 1.1° for
150 channels 17–22 (165.5–183.3 GHz). The corresponding nadir resolutions are 74.78, 31.64, and 15.82 km,
151 respectively. The outmost field of view (FOV) sizes are $323.1 \text{ km} \times 141.8 \text{ km}$ (cross-track \times along-track), 136.7

152 km \times 60.0 km, and 68.4 km \times 30.0 km, respectively (Weng *et al*, 2012). ATMS is currently carried by three near-
153 polar orbiting satellites, Suomi National Polar-orbiting Partnership (SNPP), NOAA-20, and NOAA-21 providing
154 global coverage including polar regions. Each satellite revisiting time is equal to 12 hours at the equator, but drops
155 to 100 minutes over the polar regions, ensuring a very high temporal resolution for the research area of interest in
156 this work. Moreover, the operational nature of the mission guarantees observations for the next decades. It is
157 worth noticing that the polarization of ATMS channels is not defined as vertical or horizontal, but as “Quasi-
158 Vertical” or “Quasi-Horizontal”. The “Quasi” prefix is used to indicate that ATMS (and any other cross-track
159 scanner) measures vertical or horizontal polarization only when looking at nadir and a mixture of V and H
160 polarization for off-nadir scan angles.

161 **2.2 Cloud Profiling Radar (CPR)**

162 The CPR is a 94 GHz nadir-looking radar onboard CloudSat. CloudSat was launched on April 28, 2006; the W-
163 band (94 GHz) Cloud Profiling Radar (CPR) operations began on June 2, 2006. CPR has been acquiring the first-
164 ever continuous global time series of vertical cloud structures and vertical profiles of cloud liquid and ice water
165 content with a 485-m vertical resolution and a 1.4-km antenna 3-dB footprint. The reference CloudSat snowfall
166 product is the 2C-Snow-Profile (2CSP) product (Version 5 is used in this work). It provides estimates of snowfall
167 characteristics for each observed profile. In particular, it provides an estimate of the Snow Water Path (SWP), i.e.,
168 the total snow water content integrated over the atmospheric column, and of the Surface Snowfall Rate (SSR)
169 (Stephens *et al*, 2008). SWP is estimated also when there is no snowfall at the ground level, therefore, the presence
170 of SWP is not always linked to the SSR, especially in warmer near-surface conditions (Wood & L’Ecuyer, 2018).
171 2CSP has several limitations, such as the contamination of the signal in the lowest 1000 - 1500 m of the profile
172 due to ground-clutter, the underestimation of the heavy snowfall, due to attenuation of the radar signal in these
173 conditions, and the limited temporal sampling (although it is higher in the polar regions), and the day-only
174 operation mode since 2011, which limits its use during the winter seasons (Milani and Wood, 2021, Panegrossi
175 *et al*, 2022). However, 2CSP has been demonstrated to be more accurate than GPM Dual-frequency Precipitation
176 Radar (DPR) snowfall products (Casella *et al*, 2017) and in good agreement with estimates obtained by ground-
177 based radars (e.g., Mroz *et al*, 2021), although it is affected by underestimation for medium-heavy snowfall events.
178 Moreover, the polar orbit and the W-band high sensitivity make CPR suitable for snowfall monitoring at higher
179 latitudes (as demonstrated in several studies, e.g., Kulie *et al*, 2016, Milani *et al*, 2018) typically characterized by
180 light/moderate intensity (Beranghi *et al*, 2016). These features appear to be an advantage compared to the GPM-
181 Core Observatory (GPM-CO), which provides observations only between 67 ° N and 67 ° S, and to the K_u- and
182 K_a-band DPR has low sensitivity and is not suitable to effectively detect light snowfall events (Casella *et al*,
183 2017).

184 **2.3 ATMS-CPR Coincidence Dataset**

185 The present study is based on a coincidence dataset between CPR and ATMS observations between January 2014
186 and August 2016. The same dataset has been used for the development of SLALOM-CT (Sanò *et al*, 2022). Each
187 coincidence comes from observations from CloudSat CPR and ATMS within a maximum 15-minute time
188 window. In the period considered within the dataset, only the SNPP satellite was in orbit, so the dataset is
189 composed only of observations obtained from ATMS onboard this satellite. Moreover, the elements in the dataset
190 have been selected by removing all corrupted data and by applying an additional filter based on the minimum
191 distance between CPR and ATMS instantaneous field of view (IFOV) center (22 km). The zonal distribution of
192 the coincidences is due to the orbital geometry of CloudSat and SNPP, which are both sun-synchronous with a
193 relatively small difference in the satellite height (i.e., about 689 km and 833 km for CloudSat and SNPP
194 respectively). Therefore, the coincidence dataset is built from longer orbit fragments (often semi-orbits) and by a
195 very large number of elements near the poles. There is an asymmetry in the CPR sampling between the Northern
196 and the Southern hemispheres that can be observed in the dataset due to the CPR daytime-only mode operation
197 since 2011, which influences mostly the acquisitions in the Southern Polar region (Milani & Wood, 2021).

198 The database has been built considering the horizontal resolution of the high-frequency channels of ATMS. The
199 CPR snowfall product used as reference is the 2CSP (V5) product. Some model-derived variables, specifically
200 the Total Precipitable Water (TPW), the 2-meters Temperature (T_{2m}), the Skin Temperature, the Freezing Level
201 Height, and the temperature and humidity profiles, have been added to the dataset to be used as ancillary
202 parameters. Both 2D and 3D environmental variables have been obtained from the European Center Medium
203 Weather Forecast (ECMWF). In particular, they are obtained from the CPR ECMWF-AUX product where the set

204 of ancillary ECMWF atmospheric state variable data is associated with each CloudSat CPR bin (the product is
205 described by *Partain, 2022*). Moreover, a cloud-cover fraction index, which indicates the fraction of CPR
206 observations where cloud is observed on the total CPR observations within each ATMS pixel, is added to the
207 dataset.

208 Information about the presence of supercooled water is added to the coincidence dataset to be used towards the
209 correct interpretation of the snowfall signal in presence of supercooled water layers. The supercooled water
210 information has been extracted from the DARDAR product (*DARDAR, Delanoë & Hogan, 2010*). DARDAR,
211 which stands for raDAR+LiDAR, combines CPR radar and Cloud-Aerosol Lidar with Orthogonal Polarization
212 (CALIOP) lidar observations, onboard Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations
213 (CALIPSO) satellite, and estimates both the cloud water phase and the ice water content and ice particle effective
214 radius (*Battaglia & Delanoë, 2013, Ceccaldi et al, 2013*). In particular, the coincidence dataset includes an index
215 indicating the presence of supercooled cloud liquid water within each ATMS pixel, calculated as the fraction of
216 DARDAR observations where supercooled water within and on the top of the cloud is observed to the total
217 DARDAR observations within each pixel.

218 The association of ATMS TBs and CPR products has been done by averaging the CPR snow products with a
219 Gaussian function approximating the ATMS high-frequency antenna pattern (varying with the scan angle). It is
220 worth noting, however, that the ATMS IFOV is under-sampled by the narrow swath of the CPR (see *Sanò et al,*
221 *2022* for details). Moreover, it is worth noting that CPR 2CSP limitations for snowfall detection and estimation
222 (see Section 2.2) might affect the ATMS-based snowfall estimates.

223 In this work, the dataset has been filtered based on humidity (TPW < 10 mm), temperature ($T_{2m} < 280$ K), and
224 elevation conditions (the working limits of the PESCA algorithm, see *Camplani et al, 2021*) leading to a good
225 representation of the higher latitudes with 80 % of the dataset elements located above 60°N/S. The dataset is made
226 of $2,14 \cdot 10^6$ elements, including $1,07 \cdot 10^6$ elements with falling snow (2CSP SWP > 0 kg m⁻²) and $9,99 \cdot 10^5$ with
227 snowfall at the surface (2CSP SSR > 0 mm h⁻¹). The training and test phases have been conducted by splitting
228 randomly the dataset, with 1/3 of the elements in the training and 2/3 of the elements in the test dataset.

229 **2.4 Machine Learning Approaches**

230 The algorithm is based on different machine-learning (ML) techniques. Moreover, clustering techniques have
231 been used to characterize the background surface from a radiometric point of view. In particular, an unsupervised
232 clustering technique has been used to identify emissivity clusters with small internal variability, and a supervised
233 clustering technique has been used to identify an emissivity spectrum based on other parameters.

234 **2.4.1 Artificial Neural Networks**

235 The HANDEL-ATMS snowfall detection and estimation modules have been developed using feedforward
236 multilayer neural network architectures, i.e., a neural network architecture where the neurons are arranged in
237 layers. This architecture, which is defined by the number of layers, the number of neurons for each layer, and the
238 transfer function of each neuron, has to be designed beforehand. The weights of connection links and the bias
239 values for each layer are estimated with a training process, based on the Levenberg–Marquardt algorithm (*Sanò*
240 *et al, 2015*). The specific network architectures and the training and optimization procedure of HANDEL-ATMS
241 algorithm are described in detail in section 3.2.

242 **2.4.2 Self Organizing Maps**

243 The unsupervised clustering method used for the background surface classification is the Self Organizing Map
244 (SOM) method (*Faussett, 2006, Kohonen, 2012*). The characteristic of this method is that classes that are close to
245 each other from a topological point of view can be considered similar also from a physical and radiometric point
246 of view (*Munchak et al, 2020*). SOMs have been used in previous studies for the classification of the background
247 surface by creating clusters based on emissivity values (*Prigent et al, 2001, Cordisco et al, 2006, Prigent et al,*
248 *2008, Munchak et al, 2020*).

249 **2.4.3 Linear Discriminant Analysis**

250 Several supervised clustering methods have been tested in this study, such as the linear discriminant analysis, the
251 quadratic discriminant analysis, the classification tree, and the nearest neighbor method. The final choice came
252 down to linear discriminant analysis (LDA, see *Hastie et al, 2009*) because this method guarantees satisfactory
253 accuracy in the results with a difference between the performances of the training and the test phase which is not
254 too significant, and a computational effort which is not too high.

255 3 Algorithm description

256 The configuration of HANDEL-ATMS is summarized in the Flowchart in Figure 1. The process begins with the
257 classification of the background surface using the PMW Empirical cold Surface Classification Algorithm
258 (PESCA, see *Camplani et al, 2021*); then, the surface emissivity spectra are derived through a refinement process
259 based on LDA and these are used to estimate clear-sky simulated TB (TB_{sim}) using the ECMWF-AUX
260 atmospheric temperature and water vapor profiles. Then, the differences between the clear-sky simulated TB and
261 the ATMS observed TB (TB_{obs}) are evaluated ($\Delta TB_{obs-sim} = TB_{obs} - TB_{sim}$). Four ANNs are then applied to a
262 predictor set consisting of ATMS TB_{obs} , $\Delta TB_{obs-sim}$, a surface classification flag, and other ancillary parameters
263 (elevation and ATMS viewing angle for the final version). Finally, the pixels classified with the presence of
264 snowfall by the detection module, are used in the estimation modules while for no-snowfall flagged pixels the
265 snowfall rate value is set to 0 mm h^{-1} . In the following sections, the main blocks of the algorithm are described in
266 detail.

267 3.1 Surface Classification and Emissivity Spectra Estimation

268 3.1.1 PESCA Design and Performances

269 The dynamic classification and radiometric characterization of the background surface at the time of the satellite
270 overpass is based on PESCA exploiting ATMS low-frequency channels (*Camplani et al, 2021*). The algorithm
271 discriminates between frozen and unfrozen surfaces (sea ice and open water, snow-covered land and snow-free
272 land), and identifies 10 surface classes (4 over ocean, 5 over land, 1 for coast). The algorithm has been tuned
273 against the NOAA AutoSnow product (*Romanov, 2019*), which gives daily maps of sea ice and snow cover. For
274 each ATMS observation, a flag reporting the AutoSnow class percentage (sea ice, open water, snow-covered land,
275 snow-free land) has been calculated; then, a threshold has been applied to discriminate between sea ice and open
276 water pixels (sea ice AutoSnow class $> 10 \%$) and between snow-covered and snow-free land pixels (snow-
277 covered land AutoSnow class $> 50 \%$). ATMS pixels have been classified into land, ocean, and coast pixels using
278 a land-sea mask.

279 The land module discriminates between snow-free land and snow-covered land and identifies four different snow
280 cover classes (Perennial, Winter Polar, Thin, and Deep Dry). It is based on a decision tree that makes use of a
281 limited number of inputs: the ratio between TB_{23QV} and TB_{31QV} (**ratio**), the difference between TB_{23QV} and TB_{88QV}
282 or Scattering Index (**SI**), 23 GHz pseudo-emissivity (**pem₂₃**) (i.e., the ratio between the 23 GHz observed TB and
283 the near-surface temperature value). The module has been described by *Camplani et al, 2021*.

284 For what concerns the ocean module, a simple relationship to distinguish between sea ice and open water
285 observations has been identified. In Figure 2 a Cartesian plane where the x-axis represents 23 GHz observed TBs
286 and the y-axis represents the T_{2m} is shown. In the figure, each point represents a pseudo-emissivity value, and the
287 color describes the mean AutoSnow sea ice percentage within each bin (see Figure 2, left panel). It is possible to
288 observe that open water (0 % of sea ice, blue) and sea ice (100 % of sea ice, red) are characterized by very different
289 pseudo-emissivities. There is a transition area between open water and sea ice pseudo-emissivity values for IFOVs
290 where both open water and sea ice are present. The simple relationship for sea ice identification is reported in the
291 left panel as a green line where the condition for sea ice identification is defined by Equation 1.

$$292 TB_{23QV} > T_{2m} - 96 K$$

293 (1)

294 Downstream of the sea ice/open water identification, information about sea ice characteristics is obtained from
295 the analysis of the two low-frequency pseudo-emissivity values (pem_{23} and pem_{31}) (defined as the ratio between
296 the observed TB and the near-surface temperature value) which can be considered a good approximation of sea-
297 ice emissivity for low-frequency channels especially in cold and dry conditions. In Figure 3 (top panel) it is
298 possible to observe that there are sea ice-classified observations characterized by the contemporary presence of
299 open water and sea ice above the bisector of the plane and in correspondence with low emissivity values. In the
300 center panel, where the color represents sea ice occurrences, it is evident the presence of one cluster, in
301 correspondence with high pseudo-emissivity, with two “tails” above and below the bisector. This behavior has
302 been used to identify 3 different sea ice classes (New Sea Ice, Broken Sea Ice, and Multilayer Sea Ice) using a
303 Nearest Neighbor Method based on a set of reference points that define the areas of interest for each sea ice class.
304 In Figure 3 (bottom panel) a classification representation is reported, where the markers represent the reference
305 points. The labels of the classes have been chosen by analyzing their physical properties and by comparing the

306 estimated emissivity spectra with those reported in previous studies (*Hewison & English, 1999, Munchak et al,*
307 *2020*).

308 PESCA's upper working limits for T_{2m} and TPW have been established to 280 K and 10 mm, respectively (see
309 *Camplani et al, 2021* for details). Moreover, the land module does not work in the high elevation areas outside
310 the polar regions (surface elevation > 2500 m for latitude < 67 ° N/S) because the ATMS low spatial resolution
311 does not allow for depicting the small-scale snow-cover variability that characterizes the orographic regions. An
312 analysis carried out using the ATMS-CPR coincidence dataset highlights that the presence of cloud cover does
313 not influence the overall PESCA performances (not shown). Within these well-defined limits, PESCA manages
314 to optimally discriminate between sea ice, open water, snow-free land, and snow-covered land. The statistical
315 scores of PESCA identification of sea ice and snow cover (using AutoSnow as reference truth) are summarized
316 in Table 1. In particular, the Probability of Detection (POD), the False Alarm Ratio (FAR), and the Heidke Skill
317 Score (HSS) are reported. POD, FAR, and HSS are defined by equations 2, 3, and 4.

$$318 \quad POD = \frac{h}{h+m}$$

319 (2)

$$320 \quad FAR = \frac{f}{f+h}$$

321 (3)

$$322 \quad HSS = \frac{2(h*cn - f*m)}{(h+m)*(m+cn) + (h+f)*(f+cn)}$$

323 (4)

324 where h represents the hits, f represents the false alarms, m represents the misses and cn represents the correct
325 negatives. PESCA manages to optimally detect the presence of a frozen background (sea ice over the ocean, snow
326 covered land over the continental part) at the time of the satellite overpass. It is important to underline that the
327 variability of the HSS compared to POD and FAR is due to the different number of correct negatives. An analysis
328 of the physical characteristics of the PESCA classes has been conducted by considering the mean T_{2m} , and the
329 geographical and seasonal distribution associated with each class. For what concerns the land classes, please refer
330 to *Camplani et al, 2021*. For what concerns sea ice, the New Sea Ice class, which is detected during the winter at
331 high latitudes and for low temperatures, represents the sea ice that forms during the winter. The Broken Sea Ice
332 class, which is predominant in the lower latitudes and whose occurrence increases during the Spring season,
333 represents the co-presence of sea ice and water. The Multilayer Sea Ice class, which is detected only at the high
334 latitudes, for very low temperatures, and constantly throughout the year, represents the ice pack typical of those
335 regions and extreme cold conditions.

336 In Table 2 the number of PESCA class occurrences, the percentage of snowfall observations, and the most
337 significant environmental characteristics in the ATMS-CPR coincident dataset are reported. It can be observed
338 that Land and Ocean classes are characterized by the warmest/moistest conditions and by the most intense
339 snowfall events (on average), while Perennial and Winter Polar Snow classes and New and Multilayer Sea Ice
340 classes are characterized by the coldest/driest environmental conditions and by the lightest snowfall events (on
341 average). Thin Snow and Broken Sea Ice classes show intermediate environmental conditions and snowfall
342 intensity values. It is also interesting to highlight that a mismatch between the percentage of SWP and SSR
343 observations is observed mostly over the Ocean class and, less frequently over other classes (Land, Thin Snow,
344 and Coast), where warmer and moister environmental conditions are found.

345 **3.1.2 PESCA Emissivity Spectra Estimation**

346 The emissivity spectra of each class have been estimated by applying the PESCA algorithm to the cloud-free (0%
347 CPR cloud mask fraction) ATMS observations in the ATMS-CPR dataset satisfying PESCA working limits. The
348 ATMS clear-sky TBs measured for each PESCA surface class have been used as input to an inverse radiative
349 transfer model (RTM) based on plane-parallel approximation (*Ulaby & Long, 2014*) and the *Rosenkrantz, 1998*
350 gas absorption model. The emissivity spectra have been estimated by calculating the mean and the standard
351 deviation of the emissivity values for each class (excluding the values lower than the 10th percentile and higher
352 than the 90th percentile). The emissivity spectra dependence on the ATMS viewing angle for polarized surfaces
353 has been neglected because an analysis of such dependence in the ATMS-CPR coincidence dataset has shown
354 that it is not significant (emissivity difference smaller than 0.05 for angles up to 52.7 °). This is due to the fact
355 that cross-track scanning radiometers measure a signal (off-nadir) that derives from a mixture between the two
356 polarizations (e.g., quasi-vertical, QV, and quasi-horizontal, QH). As a consequence, although the emissivities of

357 polarized surfaces, such as open water surfaces, are strongly influenced by the viewing angle, the emissivity
358 variation is compensated by the effect of the mixture of the two polarizations (*Felde & Pickle, 1995, Prigent et*
359 *al, 2000, Mathew et al, 2008, Prigent et al, 2017*).

360 The estimated spectra are shown in Figure 4 and Figure 5 for ocean and land classes respectively (the coast has
361 also been considered as a separate class; however, its spectrum is not shown in Figures 4-5). It is possible to
362 observe that the classes are well-characterized from a radiometric point of view, showing distinct behavior of the
363 emissivity spectra (e.g., the mean values). However, all the classes present significant standard deviations at high
364 frequency, and some classes - such as the snow classes and the Broken Sea Ice class - present a high value of
365 standard deviation also at low frequency.

366 The clear-sky RTM simulations based on the mean emissivity values estimated for each class have been compared
367 to the coincident observed clear-sky TBs - but the RMSE between simulated and observed clear-sky TBs appeared
368 to be too high to implement a robust signal analysis (>10 K). For this reason, a refinement process for the
369 emissivity spectra estimation based on machine learning techniques has been developed downstream of the
370 PESCA classification.

371 The refinement process has been based on a combination of an unsupervised classification technique (SOM) and
372 a supervised technique (LDA). The unsupervised classification identifies clusters characterized by the minimum
373 inner variability from a radiometric point of view. The supervised technique, instead, has the goal to identify the
374 previously obtained clusters, and the associated emissivity spectra, by using only input variables that are not
375 affected by the presence of clouds. The final emissivity spectra are estimated as the mean emissivity for each
376 frequency within each cluster identified by the supervised technique. Therefore, as first step, the emissivity
377 spectra have been clusterized in order to minimize the emissivity variability in each cluster by arranging the
378 retrieved emissivity values for six ATMS channels (23.8 GHz, 31.4 GHz, 50.3 GHz, 88.2 GHz, 165.5 GHz, and
379 183.31 ± 7 GHz) in a one-dimensional SOM architecture. Then, an LDA model has been trained using the
380 previously obtained clusters as reference and using the PESCA input parameters (**pem₂₃**, **pem₃₁**, **ratio**, and **SI**),
381 some environmental parameters (**TPW**, **T_{2m}**, surface pressure - **P_{surf}**), and ancillary variables (latitude - **lat**, Julian
382 day - **jd**, altitude - **DEM**, the maximum solar height during the day - **H_{sun}**) as input. The use of the LDA is
383 necessary to associate an emissivity spectrum to all the observations that are classified by PESCA, independently
384 of the presence of clouds. It is worth noticing that the whole predictor set of the LDA has resulted to be redundant;
385 therefore, a subset of the predictors has been selected for each class. The accuracy of the LDA classification is
386 given by the ratio between the number of hits (observations where LDA identifies the associated SOM class) and
387 the total number of observations; it can be considered as an indicator of the effectiveness of the LDA model in
388 rebuilding the SOM results.

389 The evaluation of the refinement process is based on the comparison between the simulated clear-sky TBs and the
390 observed clear-sky TBs. For each PESCA surface class, the number of clusters that simultaneously lowers the
391 errors (RMSE) between the simulated and observed clear-sky TBs at high frequency (without lowering the
392 classification accuracy too much) is chosen.

393 In Table 3 the number of clusters, the predictors selected, the accuracy, RMSE and percentage normalized root
394 mean squared error (NRMSE%) (*Gareth et al, 2013*) estimated on the test dataset, are reported for the 165.5 GHz
395 channel. NRMSE% is defined by Equation 5.

$$396 \quad NRMSE\% = \left(\frac{RMSE}{\sigma} * 100 \right)$$

397 (5)

398 where σ represents the standard deviation of the measured clear-sky TBs dataset in each PESCA class. It can be
399 considered an indicator of the effectiveness of the refinement process.

400 For some classes, such as the Ocean class, the refinement process leads to low RMSE values (< 4 K). For other
401 classes, such as Deep Dry Snow and Broken Sea Ice, RMSE remains > 5 K even with a high number of clusters,
402 although there is a significant reduction compared to the initial variance in each class (NRMSE% < 50). This is
403 due to the variability of snow-covered background within each class; in the worst scenario, the limited number of
404 predictors is insufficient to infer the emissivity spectrum at high frequency. Overall, the refinement process allows
405 to obtain a general improvement of the accuracy of the dynamic emissivity estimation for the PESCA classes;
406 however, for some classes, the high-frequency channel uncertainty remains significant. The emissivity spectra
407 obtained by PESCA refinement are used as inputs of the RTM to obtain clear-sky simulated TBs (TB_{sim}) to be

408 compared to the actual observations (TB_{obs}). The comparison between clear-sky simulated TBs with observed TBs
409 allows to highlight and interpret the MW signal in presence of snowfall.
410 In Figure 6, the snowfall signal is represented as a function of the SWP for the 165.5 GHz channel and different
411 PESCA classes. The red line and shaded areas represent the mean values and standard deviations of the difference
412 between observed TBs and clear-sky simulated TBs ($\Delta TB_{obs-sim} = TB_{obs} - TB_{sim}$) for SWP bins calculated for
413 observations where $2CSP\ SWP > 0\ kg\ m^{-2}$. The blue lines represent the uncertainty due to surface emissivity
414 variability for each PESCA class. They are centered on the estimated bias for each class (close to 0 K) and the
415 dashed lines correspond to the standard deviation of $\Delta TB_{obs-sim}$ in clear sky conditions. A clear scattering signal
416 ($\Delta TB_{obs-sim} < 0$) is observed over all the classes considered for intense snowfall events ($SWP > 1\ kg\ m^{-2}$). For
417 lower SWP values, the signal is more ambiguous and changes with the background surface. While over Land there
418 is a clear scattering signal for $SWP > 0.1\ kg\ m^{-2}$, over the Perennial Snow class a scattering signal can be observed
419 only for $SWP > 0.5\ kg\ m^{-2}$. For $SWP < 0.1\ kg\ m^{-2}$, the mean $\Delta TB_{obs-sim}$ for snowfall observations is less than its
420 standard deviation in clear sky. This is due mainly to the emissivity variability for each surface class and to the
421 error introduced by the use of model-derived temperature and water vapor profiles in the RT simulations.
422 However, while for the Land class the mean $\Delta TB_{obs-sim} < 0\ K$ can be explained as a predominant scattering effect
423 for all SWP values, for the Perennial Snow class the mean $\Delta TB_{obs-sim} > 0\ K$ can be interpreted as a predominant
424 emission signal with respect to the radiatively cold background (see Figure 5). The Thin Snow class shows an
425 intermediate behavior: for $SWP < 0.1\ kg\ m^{-2}$ the red shaded area within the RMSE limits (blue lines) of the RT
426 simulations denotes the difficulty in interpreting the signal, while a clear scattering signal can be observed for
427 $SWP > 0.3\ kg\ m^{-2}$. For what concerns ocean and new sea ice classes, a clear scattering signal is visible only for
428 high SWP values ($> 1\ kg\ m^{-2}$) while for low SWP values a significant emission signal is observed. The emission
429 effect observed over ocean and sea ice is likely generated by supercooled cloud liquid water. The ubiquitous
430 presence of supercooled water layers in snowing clouds (Wang *et al*, 2013, Battaglia & Panegrossi, 2020),
431 especially over oceans (Battaglia & Delanoë, 2013), generates an emission effect that is particularly significant
432 over radiatively cold surfaces (such as Perennial Snow, Ocean and New Sea Ice at high frequency, see Figure 4),
433 and can mask or overcome the weak scattering signal generated by falling snow especially in light snowfall events.
434 It is also important to underline that the DARDAR product identifies mostly supercooled water layers at the cloud
435 top (Rysman *et al*, 2018, Panegrossi *et al*, 2017), while it has been shown that the impact of supercooled water
436 layers embedded in the clouds can be very significant on the measured TBs at MW high-frequency window
437 channels (Battaglia & Panegrossi, 2020, Panegrossi *et al*, 2022).

438 3.2 ANN Design for Snowfall Retrieval

439 The snowfall detection and estimation modules have been based on ANNs. Four ANNs have been developed: two
440 for the detection of SWP and SSR and two for the SWP and SSR estimate. The performances of more than 50
441 architectures have been tested, by varying the number of layers, the number of neurons for each layer, and the
442 activation functions. The final architecture, for all modules, is composed of four layers: an input layer with a
443 neuron number equal to the predictor number, a hyperbolic tangent function as the activation function, a first
444 hidden layer (60 neurons), and a hyperbolic tangent function, a second hidden layer (30 neurons), with a sigmoid
445 function (for more information about the Neural Network characteristics, see Sanò *et al*, 2015). At the same time,
446 several predictor sets have been tested combining in different ways ATMS TB_{obs} , $\Delta TB_{obs-sim}$, PESCA surface
447 class, ATMS angle of view, ancillary information (surface elevation from a Digital Elevation Model), and model-
448 derived environmental variables (T_{2m} , TPW, and the Freezing Level Height). In Table 4 the statistical scores of
449 the algorithm performance for the SSR detection module obtained for different predictor sets are reported. It is
450 possible to see that the best performance is obtained when the predictor set is composed of ATMS TB_{obs} and
451 $\Delta TB_{obs-sim}$, (besides the PESCA surface flag, the pixel surface elevation, and the cosine of the viewing angle). In
452 particular, it is notable the improvement of the detection capabilities with respect to a predictor set composed of
453 ATMS TB_{obs} and environmental parameters, which is used in other approaches such as that of SLALOM-CT. On
454 the other hand, the simultaneous use of both the $\Delta TB_{obs-sim}$ and the environmental parameters show scores almost
455 equal to that obtained by using only $\Delta TB_{obs-sim}$. This indicates that the computation of the multi-channel clear-sky
456 TBs at the time of the overpass through the estimation of the dynamic surface class emissivity spectra and its
457 deviation from the measured TBs plays a fundamental role in snowfall retrieval, in particular in cold/dry
458 environmental conditions. It provides essential information to the ANN to be able to exploit the subtle snowfall-
459 related signal in ATMS measurements. This is the most innovative aspect of HANDEL-ATMS.

460 Based on these results, the final set of predictors for HANDEL-ATMS is composed of 16 ATMS channels TB_{obs}
 461 (1-9, 16-22, channels 10-15 have not been considered because their weighting function peaks above the
 462 tropopause), and the corresponding $\Delta TB_{obs-sim}$, the PESCA classification flag, the pixel elevation (obtained from
 463 a DEM) and the cosine of the viewing angle.

464 4. Results

465 4.1 HANDEL-ATMS Performances

466 In Table 5 the statistical scores of HANDEL-ATMS detection module performances are reported in terms of POD,
 467 FAR, and HSS. These statistical scores - and the plot reported in the next figures - have been calculated for the
 468 test dataset.

469 In Figure 7 and Figure 8 the dependence of HANDEL-ATMS snowfall detection statistical scores on TPW and
 470 T_{2m} is reported. In both figures, it is possible to observe that the SWP detection capabilities improve (with an
 471 increase of POD and HSS and a decrease of FAR) with increasing humidity and temperature. This is due to the
 472 combined effect of a stronger scattering signal associated with more intense snowfall events - linked to moister
 473 and warmer environmental conditions, as can be observed in Figure 12 and Table 2 - and to the lower
 474 transmissivity of the atmosphere which masks the background surface signal, reducing its impact and the
 475 uncertainties linked to its variability. On the other hand, colder and drier conditions are usually linked to
 476 background surface types characterized by high radiometric variability such as Perennial Snow and Winter Polar
 477 Snow classes, which cause uncertainty in emissivity estimation. It is possible to observe that in Figure 7 SSR
 478 detection capabilities show a maximum HSS value for TPW between 3 mm and 5 mm, and then there is a slight
 479 decrease due to the decrease of POD. A similar situation can be observed in Figure 8, where HSS reaches a
 480 maximum between 250 K and 275 K, and it is lower than for SWP. This is due to the fact that PMW measurements
 481 respond mostly to the snow in the atmospheric column and in moister/warmer conditions the presence of snow in
 482 the atmosphere is not always linked to surface snowfall. In both cases, it is worth noting that also considering very
 483 dry ($TPW \approx 2$ mm) or very cold ($T_{2m} \approx 240$ K) conditions, HANDEL-ATMS shows good detection capabilities,
 484 in spite of the uncertainties linked to the modeling of the background surface and the weakness of the signal in
 485 such conditions. In Figure 9 the dependence of HANDEL-ATMS snowfall detection statistical scores on SWP
 486 and SSR values retrieved by CPR 2CSP is reported. Only POD is reported because the statistics are calculated for
 487 snowfall observations only ($2CSP \text{ SWP/SSR} > 0 \text{ kg m}^{-2}/\text{mm h}^{-1}$). It is possible to observe that also considering
 488 very low SWP and SSR values ($SWP \approx 0.001 \text{ kg m}^{-2}$, $SSR \approx 0.001 \text{ mm h}^{-1}$), HANDEL-ATMS manages to detect
 489 around 60 % of the snowfall events.

490 The detection capabilities are influenced both by the typical environmental conditions of each PESCA class and
 491 by the uncertainties linked to the emissivity estimation. In Figure 10 the statistical scores of the algorithm
 492 performance by considering each PESCA class for both the SWP and the SSR detection module are reported. It
 493 can be observed that, also considering specifically the classes associated with extremely dry and cold
 494 environmental conditions such as Perennial Snow or Winter Polar Snow (see *Camplani et al, 2021* and Table 2),
 495 where the detection is more problematic due to low snowfall intensity (see Table 2) and to the uncertainties in the
 496 emissivity retrieval (see Table 3), HANDEL-ATMS has good detection capabilities (POD and FAR values greater
 497 than 0.7 and less than 0.25, respectively, for both SWP and SSR). On the other hand, for surface classes
 498 characterized by the highest emission estimation uncertainties, such as Deep Dry Snow, the statistical scores are
 499 coherent with the general scores and better than those obtained in presence of extremely dry/cold environmental
 500 conditions. So, it is possible to conclude that the extremely cold/dry environmental conditions have more influence
 501 on the detection than the uncertainties on clear sky emissivity estimation. Generally, these results provide evidence
 502 that HANDEL-ATMS can be used to analyze snowfall occurrence in the polar regions.

503 The error statistics of the two estimation modules are reported in Table 6 in terms of bias, RMSE and the
 504 coefficient of determination R^2 , which is defined by Equation 6.

$$R^2 = 1 - \frac{RMSE^2}{std^2}$$

505 (6)

506 It is worth noticing that the biases are negligible for both modules while RMSE values are comparable to the light
 507 events recorded in the dataset. Moreover, as expected, RMSE and R^2 values are respectively higher and lower for
 508 the SSR module than for the SWP module. In Figure 11 the density scatterplots between the SWP and SSR values
 509 retrieved by HANDEL-ATMS and 2CSP corresponding values are reported. For both modules, an overestimation
 510

511 can be observed for very light snowfall ($SWP < 10^{-2} \text{ kg m}^{-2}$ and $SSR < 10^{-2} \text{ mm h}^{-1}$), while there is a very good
512 agreement for higher SWP and SSR values. In order to relate these results to the environmental conditions, Figure
513 12 shows the dependence of HANDEL-ATMS snowfall estimation error statistics, as well as SWP and SSR, on
514 TPW. The curves represent, for each 1-mm TPW bin, the mean 2CSP SWP or SSR computed, the RMSE, and the
515 relative bias (the ratio between the bias and the SWP/SSR mean value for each bin). As expected, TPW and
516 snowfall intensity are strongly correlated. An increase in the absolute RMSE can be observed as TPW increases,
517 and it is larger than the SWP/SSR mean value for $TPW < 8 \text{ mm}$. A similar behavior can be observed by analyzing
518 the dependence of HANDEL-ATMS snowfall estimation error statistics on T_{2m} (not shown). A very moderate
519 overestimation is observed for $TPW < 8 \text{ mm}$ and for lower SWP and SSR values ($< 0.1 \text{ mm h}^{-1}$), with relative
520 bias around 5%, (up to 8% only for extremely low TPW values and very low number of observations, see Figure
521 7), while underestimation (relative bias up to -5%) is observed for higher TPW values and higher SWP and SSR
522 values. Generally, light snowfall events are linked to the very cold/dry environmental conditions typical of high-
523 latitude regions. So, the algorithm manages to estimate also the very light SWP and SSR typical of high latitudes
524 but tends to slightly overestimate snowfall intensity in such conditions.

525 From the analysis of Figure 7-12, it can be concluded that HANDEL-ATMS has good detection capabilities (also
526 for extremely light snowfall), but it shows some limitations in correctly estimating its intensity, with slight
527 overestimation of the very light snowfall typical of high latitudes.

528 **4.2 A Case Study: Greenland-2016/04/24**

529 The case study reported corresponds to the observation of a moderately light snowfall event over the central part
530 of Greenland that occurred on 24 April 2016. ATMS overpass is between 14:51:23 UTC. and 14:57:47 UTC.,
531 while the CPR overpass is between 15:05:25 UTC. and 15:11:45 UTC., with a time difference of 14 minutes and
532 2 seconds. This event presents several characteristics typical of high latitudes, such as light snowfall rate, dry and
533 cold atmospheric conditions, and presence of a frozen background surface, a typical case of interest for the
534 application of HANDEL-ATMS.

535 In Figure 13 PESCA classification is reported. The entire territory of Greenland, except for a narrow area on the
536 southwestern coast, is identified as a snow-covered surface; the PESCA identifies the Perennial Snow class in the
537 central part of Greenland and along the CloudSat track, and the Polar Winter Snow class near the northern
538 shoreline. CloudSat overpasses the central part of the island, and the CPR track is along the central part of the
539 ATMS swath.

540 In Figure 14 a synopsis of the event along the CPR track is reported showing T_{2m} and TPW, the 2CSP SWP and
541 SSR values, and the cross-section of CPR reflectivity, with the DARDAR supercooled water information
542 superimposed (in magenta). Moreover, the PESCA surface classification and the TBs of the main ATMS high-
543 frequency channels along the CloudSat track are also shown. The event is characterized by dry conditions (TPW
544 $< 5 \text{ mm}$) and T_{2m} below 273 K, except over the coast. CPR observes a cloud system associated with the snowfall
545 event between 68° N and 76° N ; DARDAR detects the presence of a supercooled water layer at the cloud top
546 between 68° N and 72° N and indicates the presence of supercooled droplets embedded in the deeper cloud
547 associated with the more intense snowfall. According to the 2CSP product, a light shallow snowfall system is
548 found in the inner part of the island while deeper, more intense snowfall, with a peak of intensity between 72° N
549 and 76° N , is found near the shoreline. For what concerns the associated ATMS observations, an increase of the
550 88 GHz and 165 GHz TBs is observed in correspondence with the supercooled water layer, while only a slight
551 decrease of 165.5 and $183.31 \pm 7 \text{ GHz}$ TBs can be observed in coincidence with the snowfall intensity peak.

552 In Figure 15 the maps of the TB_{obs} at 165.5 GHz (top panel) and the $\Delta TB_{obs-sim}$ at 165.5 GHz (bottom panel) are
553 reported. In the top panel, it is possible to observe that, despite the snowfall event, there is not a clear TB scattering
554 signal in the area where 2CSP detects snowfall ($70^\circ \text{ N} - 76^\circ \text{ N}$, $40^\circ \text{ W} - 70^\circ \text{ W}$), instead a slight increase in the
555 TBs can be observed in the area where DARDAR detects the supercooled water layer at the cloud top. The map
556 of $\Delta TB_{obs-sim}$ shows an emission signal ($\Delta TB_{obs-sim} > 0$) over the central part of the ATMS swath due to the
557 combined effect of the emission by the supercooled liquid water layers at the cloud top, as evidenced by
558 DARDAR, (evidently exceeding the scattering signal of the weak and shallow snowfall), over a radiatively cold
559 surface background. Only near the shoreline, the observed TBs are slightly lower than the clear-sky simulated
560 TBs ($\Delta TB_{obs-sim} < 0$) due to the stronger scattering signal of the deeper snowfall system. In Figure 16 the results
561 of the HANDEL-ATMS four modules are reported. It is worth noting that both detection modules find snowfall
562 in the central region of Greenland and near the northern coast. The estimated snowfall intensity for this event is

563 generally low ($SWP < 0.1 \text{ kg m}^{-2}$ and $SSR < 0.1 \text{ mm h}^{-1}$) except over the western coast, where SWP reaches 0.5
564 kg m^{-2} and SSR reaches 1 mm h^{-1} . It is worth noticing that HANDEL-ATMS detects snowfall also where there
565 is an emission signal ($\Delta TB_{\text{obs-sim}} > 0$) and that discontinuities in snowfall retrievals are not observed in
566 correspondence with surface class changes.

567 Finally, a comparison between HANDEL-ATMS and 2CSP is reported in Figure 17. There is a substantial
568 agreement on the snowfall detection of the two products. HANDEL-ATMS tends to overestimate very light SWP
569 and SSR in presence of the shallow system (2CSP $SWP < 0.05 \text{ kg m}^{-2}$ and $SSR < 0.1 \text{ mm h}^{-1}$, between 68° N and
570 72° N), consistently with what is shown in Figure 10, while there is a good agreement between 72° N and 76°
571 N , where snowfall intensity increases.

572 The analysis of this case study demonstrates that the algorithm can interpret the ambiguity of the
573 emission/scattering signal often associated with snowfall events at high latitudes (as described in Section 4.1) and
574 efficiently detect, and, to a less extent, quantify snowfall even in extreme cold and dry conditions.

575 **4.3 Comparison with SLALOM-CT**

576 SLALOM-CT has been introduced in Section 1. It presents some similarities with HANDEL-ATMS: it is based
577 on an ANN approach and uses the CPR 2CSP product as reference. On the other hand, substantial differences
578 have to be highlighted: SLALOM-CT was designed to operate on a global scale, while HANDEL-ATMS has been
579 developed specifically for the environmental conditions typical of high latitudes. Moreover, the predictor sets are
580 different: in addition to TB observations, SLALOM-CT relies on several model-derived environmental
581 parameters, while HANDEL-ATMS relies on differences between simulated clear-sky TBs, based on the dynamic
582 estimation of the background surface emissivity (i.e., at the time of the satellite overpass), and observed TBs
583 ($\Delta TB_{\text{obs-sim}}$), as described in Section 3.

584 In Table 7 a comparison between the statistical scores of the detection performances of the two algorithms is
585 reported for different environmental conditions. The comparison has been carried out considering the same
586 elements of the ATMS-CPR coincidence dataset. It can be observed that the differences between the two algorithm
587 performances increase as the environmental conditions become more extreme (i.e., lower T_{2m} and TPW), with
588 consistently better snowfall detection capabilities of HANDEL-ATMS than SLALOM-CT. Considering the
589 working limits of HANDEL-ATMS, POD increases by 2 % and FAR decreases by 8 %, while for very cold/dry
590 conditions ($T_{2m} < 250 \text{ K}$, $TPW < 5 \text{ mm}$), POD increases by 7 % and FAR decreases by 16 %; for extremely
591 dry/cold conditions ($T_{2m} < 240 \text{ K}$, $TPW < 3 \text{ mm}$), typical of the inner part of Greenland and Antarctica, POD
592 increases by 18 % and FAR decreases by 16 %.

593 **5 Conclusions and Future Perspectives**

594 In this paper, a new snowfall retrieval algorithm, the High lAtitude sNow Detection and Estimation aLgorithm
595 for ATMS (HANDEL-ATMS), is described. The algorithm is based on machine learning techniques trained with
596 CPR 2CSP snowfall product and it is designed specifically for the cold and dry environmental conditions typical
597 of high-latitude regions. The driving and innovative principle in the algorithm development is the exploitation of
598 the full range of ATMS channel frequencies to characterize the background surface radiative properties at the time
599 of the overpass to be able to better isolate and interpret the snowfall-related contribution to the measured multi-
600 channel upwelling radiation. A similar approach has been used by *Zhao & Weng, 2002*; however, their application
601 was limited to non-scattering surfaces and was based on empirical relationships. This approach is proven to be
602 effective for snowfall detection and quantification at high latitudes, particularly in presence of a frozen (snow-
603 covered land or sea ice) background surface, also compared to other state-of-the-art machine learning-based
604 methods.

605 HANDEL-ATMS can detect snowfall at high latitudes in good agreement with CPR. The estimation modules tend
606 to slightly overestimate the intensity of light snowfall events ($SWP < 10^{-2} \text{ kg m}^{-2}$), with mean relative bias $< 5\%$
607 for $SSR < 0.1 \text{ mm h}^{-1}$, but it shows good accuracy for more intense snowfall events ($SWP > 10^{-2} \text{ kg m}^{-2}$, $SWP <$
608 1 kg m^{-2}). It is worth noting, however, that the uncertainty associated with the surface emissivity estimation in
609 some conditions affects the capabilities of HANDEL-ATMS to correctly interpret the snowfall signature. Such
610 uncertainty propagates in the RTM simulation of clear-sky TBs used as input in the algorithm. Despite these
611 limitations, it is worth noticing that the development of an algorithm capable of retrieving snowfall at high
612 latitudes with good accuracy is an important development in the climate science field. The possibility to exploit
613 the high temporal sampling of the near-polar operational satellites carrying ATMS radiometers allows to achieve
614 full coverage of the polar regions. Moreover, the future European MetOp Second Generation (MetOp-SG)

615 mission, with the launch of the Sat-A Microwave Sounder (MWS), with characteristics very similar to ATMS,
616 will soon provide additional coverage to improve global snowfall monitoring. HANDEL-ATMS methodology
617 will be adapted to be able to exploit MWS measurements in the future. The capability to estimate snowfall at high
618 temporal resolution is ancillary to the development of a snowfall monitoring system for the high latitudes and to
619 the analysis of the snowfall climatology in these areas, with possible applications in climate change studies in the
620 polar regions.

621 Future research will address some open issues. The estimation of the surface emissivity and the simulated clear-
622 sky multi-channel TBs needs to be further improved, either by considering other predictor sets or by using a
623 different technique for the emissivity spectra definition including a more advanced RTM. Another important
624 aspect is the quantification of the error linked to the background surface emissivity estimation on the snowfall
625 detection capabilities. This would be also useful for the development of modules for mountainous areas, which
626 have not been considered in the current version of the algorithm. Moreover, the effect on the algorithm snowfall
627 detection capabilities of the uncertainties linked to the model-derived environmental variables (e.g., temperature
628 and water vapor profile), which are used in the clear-sky TB simulations, should be investigated. The use of the
629 ATMS water vapor (183 GHz band) and temperature (50 GHz band) sounding channels to characterize the
630 atmospheric conditions at the time of the overpass in order to complement or avoid the use of model-derived data
631 is another subject of future research. Moreover, the development of a separate supercooled liquid water detection
632 module will be also evaluated, similarly to what is done in other PMW snowfall detection and estimation
633 algorithms (Rysman *et al*, 2018, Sanò *et al*, 2022). Such information can be exploited to improve snowfall
634 detection and estimation capabilities since the emission by the cloud droplets in dry conditions tends to mask the
635 snowfall scattering signal (Panegrossi *et al*, 2017, Panegrossi *et al*, 2022), and adds larger uncertainties in the
636 CPR snowfall products used as reference (Battaglia & Panegrossi, 2021). Moreover, recent studies have
637 highlighted that TBs correlate more strongly with lagged surface precipitation (with a time lag of 30-60 min for
638 snowfall) than the simultaneous precipitation rate (You *et al*, 2019). Therefore, an analysis based on a coincident
639 dataset characterized by different time lags will be conducted. The results of this analysis will be compared with
640 HANDEL-ATMS performances in order to identify a way to exploit this information towards the improvement
641 of SSR detection and estimation. Finally, since the algorithm has been developed only for specific environmental
642 conditions typical mostly of high latitudes an integration with other approaches, such as that of the SLALOM-
643 CT, designed for global estimation of snowfall, could be considered in the future to improve global snowfall
644 monitoring based on ATMS and on future cross-track scanning radiometers.

645

646 **Data Availability**

647 ATMS data are provided by the NOAA CLASS facility www.avl.class.noaa.gov/ (last access 4 April 2023), CPR
648 data are distributed by the CloudSat data processing center <https://www.cloudsat.cira.colostate.edu/> (last access
649 4 April 2023), DARDAR data are available from the ICARE FTP server of the University of Lille ([ftp.icare.univ-](ftp.icare.univ-lille1.fr)
650 [lille1.fr](ftp.icare.univ-lille1.fr), last access 4 April 2023) and ECMWF operational forecasts are distributed by ECMWF through the
651 MARS facility via the ECGATE cluster. AutoSnow data are provided by the NOAA Satellite and Information
652 Service https://satepsanone.nesdis.noaa.gov/northern_hemisphere_multisensor.html (last access 4 April 2023).
