12

13 **Abstract.** This paper explores the possibility of using multi-source precipitation estimates for
14 climatological applications. A data processing algorithm (RainGRS Clim) has been developed to work
15 on precipitation accumulations such as daily or monthly totals, which are significantly longer than
16 operational accumulations (generally between 5 min and 1 h). The algorithm makes the most of
17 additional opportunities, such as the possibility to complement with delayed data, access to high-quality
18 data that are not operationally available, and the greater efficiency of the algorithms for data quality
19 control and merging on longer accumulations. Verification of the developed algorithms was carried out
20 on monthly accumulations through comparison with precipitation from manual rain gauges. As a result,
21 monthly accumulations estimated by RainGRS Clim were found to be significantly more reliable than
22 accumulations generated operationally. This improvement is particularly noticeable for the winter
23 months, when precipitation estimation is much more difficult due to less reliable radar estimates.

24

25 **1. Introduction**

26

27 The estimation of precipitation on the ground surface with high spatial resolution is one of the
28 most important issues in meteorology, but at the same time one of the most complex because of the very
29 high spatial and temporal variability of precipitation, especially in the case of intense events associated
30 with convective phenomena. This makes its precise quantitative estimation very difficult and subject to
31 many errors. None of the available techniques, i.e. rain gauge measurements, meteorological radar
32 measurements or satellite estimates based on measurements in different electromagnetic radiation bands,
33 provide satisfactory precision. Consequently, different methods are being developed to combine
34 precipitation data obtained by these techniques, with the aim of exploiting the advantages of each
35 technique while minimising its weaknesses (Ochoa-Rodriguez et al., 2019; Jurczyk et al., 2020b;
36 Wetchayont et al., 2023).

37 The generation of such multi-source precipitation estimates is currently the standard procedure
38 used for quantitative precipitation estimation (QPE). In operational (i.e. real-time) applications, the most
39 common time step for estimating the precipitation field is the 1-hour step, as it often follows the demand
40 from hydrological rainfall-runoff models (Sokol et al., 2021). However, sub-hourly resolutions, such as
41 10-minute resolution, are also increasingly used. Such data are becoming essential, in particular as input
42 for nowcasting precipitation forecast models, for precipitation-runoff models forecasting flash floods,
43 which are triggered by intense but short-lived and rapidly fluctuating precipitation (e.g., Chan et al.,
44 2016; Neuper and Ehret, 2019), or for performing analyses of the occurrence of precipitation extremes
45 (e.g., Bonaccorso et al., 2020; Lengfeld et al., 2020; Marra et al., 2022).

46 However, there is also growing demand among climatologists and agrometeorologists, for
47 example, for longer precipitation totals – of the order of days, months or years, or even entire multi-year
48 periods – that still maintain high spatial resolution. This demand can in fact already be met, as radar
49 observations of precipitation, providing the highest spatial resolution of all measurement techniques,

50 have been performed routinely for several decades. So, long series of radar as well as multi-source
51 precipitation estimates are already available. Weather radar networks have covered a large part of the
52 more densely populated areas of the globe, so that increasingly radar data, when supplemented with
53 other observations, are also applied in climatological studies to provide extensive information on the
54 multi-year variability of the precipitation field with very high spatial resolution not available with other
55 measurement techniques (Fabry et al., 2017; Saltikoff et al., 2019a). They are also used to study the
56 climatology of intense convective phenomena, as the high spatial resolution is particularly important in
57 this case (Hamidi et al., 2017; Burcea et al., 2019; Voormansik et al., 2021; Hänsler and Weiler, 2022;
58 Piscitelli et al., 2022).

59 Consequently, there is a need to produce reliable estimates of precipitation accumulation over
60 longer time periods (daily, monthly, yearly, or even longer) with data from databases containing
61 operationally generated multi-source precipitation at higher temporal resolutions, e.g. as 10-min
62 precipitation accumulations. It turns out that simply adding up, for example, 10-min estimates does not
63 give satisfactory results, because any quality control algorithms for precipitation observations become
64 much more effective for longer accumulations of at least 1 hour (Morbidelli et al., 2018; Villalobos-
65 Herrera et al., 2022). In particular, any algorithms for the adjustment of radar to rain gauge data often
66 work too randomly when shorter accumulations are used, and the cross-checking of different types of
67 precipitation data is then also subject to much higher uncertainty.

68 Generating accumulations for longer time intervals therefore provides the possibility of carrying
69 out so-called reanalyses, i.e. re-generating the corresponding precipitation accumulation. This brings the
70 following potential benefits: (i) data sets can be supplemented with data that were missing from the
71 operational estimation, e.g. due to delays in their arrival at the system, (ii) in addition, data from such
72 measurement techniques that are available too late for operational applications, or measured with a
73 longer calculation step (e.g. daily, such as from manual rain gauges) can be used (Imhoff et al, 2021),
74 (iii) algorithms for performing quality control on radar precipitation data and then combining them with
75 data from other sources generally work much more effectively on longer accumulations (Wagner et al.,
76 2012; Park et al., 2019).

77 Various initiatives are being undertaken to estimate precipitation data for climatological purposes
78 with the high spatial resolution obtained from radar observations, including on a trans-national scale.
79 One of the major initiatives in this area is the EURADCLIM (EUropean RADar CLIMatology) dataset,
80 which is based on radar data obtained from the Operational Program on the Exchange of Weather Radar
81 Information (OPERA) – a EUMETNET (EUropean METeorological NETwork) initiative (Saltikoff et
82 al., 2019b), and rain gauge data obtained from the European Climate Assessment & Dataset (ECA&D)
83 project. Both of these networks are pan-European and cover the area of most of Europe. In the
84 EURADCLIM programme, radar quality control adapted to longer precipitation accumulation intervals,
85 such as 1-h and daily intervals, is performed (Overeem et al., 2023). Quality control is also performed
86 on longer rain gauge accumulations within ECA&D (Klok and Klein Tank, 2009).

87 The concept of generating long-term precipitation estimation presented in this paper is based on
 88 using algorithms for quality control of the input data and combining them into multi-source estimates,
 89 which are applied operationally to 10-min data. However, new quality control methods and new data
 90 sources were also included – something that was not possible during the operational generation of
 91 precipitation estimates.

92 Section 2 describes all input data, those available operationally as well as those used for
 93 reanalyses. Section 3 presents the algorithm for combining precipitation data into a multi-source
 94 precipitation field, used both operationally and for reanalyses, and Section 4 proposes a scheme for
 95 generating long-term estimates. Section 5 shows and discusses the results of the verification of the
 96 reanalyses of monthly totals in different seasons compared to operationally generated estimates, while
 97 Section 6 shows an example of the system performance. Finally, Section 7 provides conclusions.

98

99 **2. Precipitation data**

100

101 *2.1. Precipitation measurement data available for the area of Poland*

102

103 Table 1 summarises the general characteristics of the precipitation data available for the area of
 104 Poland: from in situ and remote sensing measurements, available both in real-time and after a shorter or
 105 longer processing time, which can take up to two months (this is the case for quality control of the data
 106 from manual rain gauges).

107

108 Table 1. In situ precipitation measurement networks available for Poland.

109

Observation technique	Temporal resolution	Network density / spatial resolution	Delay
Telemetric rain gauge network	10 min	1 gauge per 625 km ² (about 500 gauges)	6 min (then data from more than 90% of the gauges are usually available)
Manual rain gauge network	24 hrs	1 gauge per 434 km ² (about 720 gauges)	About 2 months (due to the transfer of the data and manual quality control)
Ground weather radar network	10 min	About 1 km	6 min (because the lowest scan is generated at the beginning)
Geostationary meteorological satellites (Meteosat and NWC-SAF software)	5 min (in rapid scan system)	About 5-6 km	1-5 min (due to scan strategy)

110

111 This study uses precipitation data generated by the Institute of Meteorology and Water
112 Management – National Research Institute (IMGW), which performs the function of the national
113 meteorological and hydrological service in Poland (Szturc et al., 2018). All these data are quality
114 controlled by dedicated applications or systems.

115
116 *2.2. Rain gauge data*

117

118
119

120 **Figure 1.** Rain gauge networks of IMGW, from left: telemetric and manual rain gauge networks.

121

122 10-min precipitation accumulations are provided operationally at IMGW by a network of
123 telemetric rain gauges, most of which are tipping-bucket gauges – considered one of the less accurate
124 of the various types of rain gauge (Hoffmann et al., 2016; Segovia-Cardozo et al., 2021) in addition to
125 being subject to significant failure rates. For quality control of telemetric rain gauge data, the
126 RainGaugeQC system is used at IMGW to perform error detection and corrections on 10-min data in
127 real-time (Ośródk et al., 2022).

128 One of the most important additional benefits of carrying out reanalyses, relative to the generation
129 of a real-time precipitation field, is the possibility to exploit the much more accurate measurements
130 performed by manual rain gauges mostly once a day. The network of such rain gauges (Hellmann type)
131 installed at IMGW is relatively dense, and even denser than the network of telemetric rain gauges (Fig.
132 1 and Table 1). These are the most accurate of the in situ point measurements, but they are available
133 with a very long delay of almost two months, mainly due to the human-made data quality control. In
134 addition, measurements from manual rain gauges are subjected to quality control in the IMGW historical
135 database, using standard algorithms based on procedures recommended by the WMO (WMO-No. 305,
136 1993, Chapter 6).

137

138 *2.3. Weather radar data*

139

140 The radar data used to generate the precipitation field estimates come from the Polish POLRAD
141 weather radar network, operated by the IMGW. It consists of eight Doppler radars manufactured by
142 Leonardo Germany (Fig. 2). They are currently being replaced by new models with dual-polarised radar
143 beams, and two new radars are being installed. Three-dimensional raw data, so-called volumes (raw
144 data), and two-dimensional products are generated by the Rainbow 5 system every 10 min (a shift to 5-
145 min measurement frequency is currently underway), with 0.5-km spatial resolution and a range of 250
146 km. For further details on the POLRAD network, see Ośródk and Szturc (2022).

147

148

149

150 **Figure 2.** Computational domain of Poland (900 km x 800 km) with 250-km radar coverage of the weather radar
151 network in Poland in 2022.

152

153 The RADVOL-QC system (Ośródk et al., 2014; Ośródk and Szturc, 2022) is used to quality
154 control of radar data of the POLRAD network, which corrects the source 3D radar data and generates
155 dynamic maps of the data quality index. Merging data from individual radars into radar composite maps
156 is done by applying algorithms that take account of the spatial distribution of the quality index in the
157 radar data, which is assessed dynamically for each time step (Jurczyk et al., 2020a).

158

159 *2.4. Precipitation from meteorological satellites*

160

161 Satellite precipitation is generated by an algorithm developed at IMGW based on products
162 provided by the EUMETSAT NWC-SAF programme (Tapiador et al., 2019). The algorithm working
163 within RainGRS system is based on several NWC-SAF products, depicting the spatial distribution of
164 clouds and the intensity of precipitation, including convective precipitation. A detailed description of
165 the algorithm was presented by Jurczyk et al. (2020b).

166 Quality control of satellite precipitation is also carried out by the RainGRS system, taking into
167 account primarily which NWC-SAF products are available at a given time. The quality of satellite
168 precipitation, which is quantified by the quality index, is significantly lower at night-time, when visible
169 range-based products analysing the physical properties of hydrometeors are not available.

170

171 **3. RainGRS system**

172

173 *3.1. Merging of precipitation data into a multi-source precipitation field*

174

175 At IMGW, multi-source estimation of the precipitation field is carried out operationally by the
176 RainGRS system. A detailed description of this system, which combines rain gauge, radar and satellite
177 precipitation data summarised in Table 1, was presented by Jurczyk et al. (2020b). This combination
178 algorithm takes into account the quality information of the individual input data, attributed to them when
179 performing their quality control.

180 In operational work, the 10-min computational step of generating estimates of the precipitation
181 field is enforced by the resolution of the radar data, which is the source of the most important high-
182 resolution information on the spatial distribution of the precipitation field. When the radars of the
183 POLRAD network are replaced (process in ongoing from 2022 to 2023), all included radars will operate
184 with a 5-min time step. This will enable the temporal resolution of the multi-source precipitation
185 estimates generated by RainGRS to be increased as well.

186 The algorithm for combining rainfall data from different sources is based on a conditional
187 merging that attempts to enhance the strengths of the individual inputs and reduce the impact of their
188 weaknesses. It is commonly assumed that radar data is the best representation of the spatial distribution
189 of the precipitation field, while a network of rain gauges effectively reduces the bias of this estimation.
190 Satellite rainfall, in contrast, plays a mainly complementary role in the absence of other data.

191 First, the rain gauge values are interpolated at radar pixel resolution, employing the Ordinary
192 Kriging method to obtain an unbiased estimate of precipitation. The radar values at rain gauge locations
193 and the same method of interpolation are used to get the interpolated radar field. Subsequently, the
194 deviation between the measured and interpolated radar value ($R - R_{int}$) is computed and added to the rain
195 gauge interpolated value at each pixel of the domain, according to the following formula:

196

$$R_G = G_{int} + (R - R_{int}) \quad (1)$$

197 where R_{int} is the radar precipitation interpolated from data at rain gauge locations. A satellite field S_G is
 198 obtained from an analogical formula.

199 It can be noted that the accuracy of the computed estimate depends on the distance to the nearest
 200 available rain gauge, and the radar precipitation field is preferable in the case of a long distance.
 201 Therefore, the resulting precipitation field R_G is recombined with the radar precipitation field, applying
 202 the weighted scheme, which includes the quality of individual precipitation fields to obtain a combined
 203 GR field:

$$204 \quad GR = \frac{R_G \cdot QI_G + R \cdot QI_R \cdot (1 - QI_G)}{QI_G + QI_R \cdot (1 - QI_G)} \quad (2)$$

205 where QI_G and QI_R are the quality indices for gauge and radar, respectively. The quality index, QI , is
 206 the dimensionless quantity ranging from 0 (for the poorest quality) to 1 (for the best data).

207 A combined gauge-satellite field GS is obtained analogically to the above procedure, where the
 208 satellite data S and relevant quality field QI_S are taken.

209 The final quantitative precipitation estimate (GRS) is a combination of gauge-radar and gauge-
 210 satellite fields computed by means of the following weighted formula:

$$211 \quad GRS = \frac{GR \cdot QI_d + GS \cdot (1 - QI_d) \cdot QI_S}{QI_d + QI_S \cdot (1 - QI_d)} \quad (3)$$

212 where the QI_d is a field of radar data quality as a function of the distance d to the nearest radar site.

213

214 *3.2. Generation of daily accumulations*

215

216 The basic 10-min precipitation accumulations are aggregated into different time intervals (e.g. 1-
 217 hour, several hours, daily, or longer accumulations) depending on current needs. Due to gaps in data
 218 that occur in operational work, sometimes these accumulations may not be complete. In order to ensure
 219 the completeness of the accumulations, the gaps are complemented by temporal interpolation of the data
 220 from time steps directly before and after the gap. Such averaging from neighbouring measurements is
 221 carried out if this interval is not too long, and in the opposite case data are set to have no data value. For
 222 example, when generating hourly accumulation, at most two consecutive 10-minute measurements are
 223 allowed to be missing, but no more than three terms may be missing in one hour.

224

225 **4. Generation of daily and monthly precipitation reanalyses (RainGRS Clim)**

226

227 *4.1. Climatological reanalyses versus operational estimates*

228

229 Reanalysis of the precipitation fields is carried out on daily accumulations. This provides the
 230 following benefits in terms of the reliability of the generated estimates:

- 231 1. *Complementation with data that was missing operationally due to its late arrival in the system.*
232 For reanalyses, a time regime is not as strict as in an operational work, so data that arrived too
233 late can be included. In the operational RainGRS, more than 90% of the rain gauge data
234 generally arrives within six minutes, so the remaining data can be involved in reanalyses.
235 When it comes to radar data, delays mainly affect data from foreign radars.
- 236 2. *The use of measurement techniques that are available too late to be used operationally, or that*
237 *take measurements with a time step longer than 10 minutes as standard.* In the proposed
238 algorithm for performing reanalyses, in addition to using daily precipitation accumulations
239 provided by those measurement techniques from which data are operationally available, data
240 from manual rain gauges can also be used. These measurements are taken only once a day and
241 are available after about two months – for this reason they are not used in the operational
242 version of RainGRS, but due to their high reliability these data are very important, even
243 crucial.
- 244 3. *Greater effectiveness of quality control and data merging algorithms when applied to*
245 *accumulations longer than 10 minutes, e.g. daily.* Longer precipitation accumulations are more
246 consistent, as they are much less affected by temporal inconsistencies between different
247 measurement techniques (this is especially the case with radar measurements, which in
248 practice are instantaneous), and are moreover less sensitive to errors of a random nature, which
249 become more averaged over a longer time interval. Thus, the algorithms for both quality
250 control and multi-source combination perform more effectively.

251 At IMGW, combined daily accumulations have been generated since 2021 by the algorithm
252 described in this paper. The resulting daily precipitation estimates can already be directly used to
253 generate longer precipitation accumulations, e.g. monthly, seasonal, annual or even multi-year. In view
254 of the above possibilities, which create new areas of application for multi-source precipitation fields,
255 e.g. in climatology, the version of RainGRS that generates reanalyses of daily precipitation accumulation
256 is referred to as the climatology version RainGRS Clim.

257

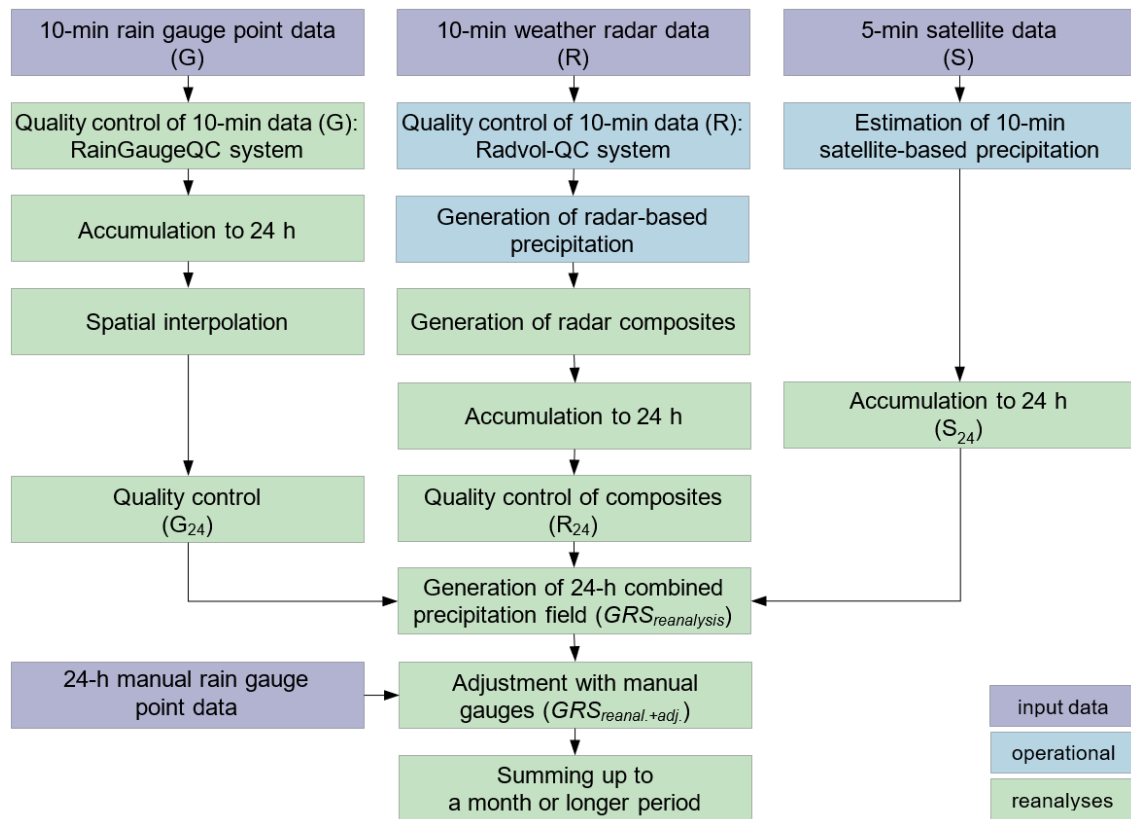

258 *4.2. Algorithm for the estimation of climatological multi-source precipitation fields*

259

260 The algorithm presented in this section for calculating quality-controlled daily and monthly
261 rainfall totals follows the following scheme (Fig. 3):

- 262 1. Daily totals are calculated from 10-min rain gauge data. In order to ensure the completeness
263 of the 10-min data, missing rain gauge data is completed with spatially interpolated values
264 from the data that are available. The Ordinary Kriging method is used to interpolate the data.
- 265 2. The daily point accumulations from the rain gauges are spatially interpolated to obtain
266 precipitation fields.

- 267 3. A human expert check of the daily rain gauge fields is carried out, during which erroneous
268 values from individual rain gauges are removed. This check on the daily values enables the
269 detection of errors that were not detected on the 10-min accumulations with automatic QC
270 algorithms. The daily accumulations from the rain gauges are then spatially interpolated again
271 (as in point 2).
- 272 4. Daily accumulations of radar and satellite precipitation fields are calculated, also
273 supplemented with late data.
- 274 5. The daily radar precipitation fields are corrected by removing disturbances occurring at the
275 locations of some radars, as this correction only works effectively on longer accumulations.
- 276 6. Estimates of daily accumulations $GRS_{reanalysis}$ are calculated by the RainGRS system using
277 the algorithm described in Section 3.1, which uses daily accumulations of individual
278 precipitation fields as input data. This approach minimises errors associated with temporal
279 inconsistencies in the data (Villalobos-Herrera et al., 2022).
- 280 7. An adjustment of daily accumulations calculated by the RainGRS to observations from manual
281 rain gauges, which are considered the most reliable point estimate of rainfall, is performed.
282 The adjustment factor is determined separately for each manual rain gauge location and then
283 spatially interpolated using the inverse distance weighting method to distribute it spatially
284 (Wang et al., 2020). This adjustment results in daily accumulations $GRS_{reanal.+adj.}$ of multi-
285 source rainfall fields after reanalysis and adjustment.
- 286 8. The long-term accumulations of the combined precipitation fields (e.g., monthly) can be
287 calculated from the daily accumulations prepared in the above manner.

Figure 3. The algorithm for determining quality-controlled daily, monthly, and other precipitation accumulations.

Fig. 4 shows an example of daily rainfall accumulations obtained operationally and after reanalysis. The differences between the two fields are generally not large, but locally they can be quite significant – a fragment from the computational domain is selected to highlight them. Larger differences between them are apparent in cases where some rain gauge data have been removed as a result of manual QC (during which they were found to be clearly erroneous) and which was not recognised by operational control. It is likely that in the 10-min accumulations the measurement errors were not so noticeable as to consider these values to be completely erroneous. The removal of each such value also affects the values in a certain vicinity of the rain gauge’s location due to changes in the field of interpolated gauges, relevant QI field and consequently in the RainGRS field. In addition, some of the differences between the two fields are due to the varying performance of the data combination algorithm (Sect. 3.1) on daily accumulations when compared to 10-min ones.

305

306

307 **Figure 4.** Fields of daily precipitation accumulations, before and after reanalysis: (a) $GRS_{real-time}$ and (b)
 308 $GRS_{reanalysis}$. Fragment of Poland's computational domain (325 km x 425 km), 11 December 2022.

309

310 5. Verification

311

312 5.1. Methodology of the verification

313

314 In order to verify any precipitation field estimate, a precipitation field reference that can be
 315 considered as a “ground truth” is needed. Lysimeters are regarded as one of the most accurate point
 316 precipitation measurement techniques, but Hellmann-type manual rain gauges have similar reliability
 317 (Hoffmann et al., 2016). IMGW does not have at its disposal a network of lysimeters, however, it does
 318 have a relatively dense network of manual Hellmann type rain gauges, therefore these were considered
 319 to provide the most accurate technique of point measurement of precipitation available in IMGW. Thus,
 320 the results obtained in the present study were verified on them.

321

322 However, it should be borne in mind that the data from the manual rain gauges are not
 323 independent, as they have previously been used for adjustment of the RainGRS Clim data. Thus, the
 324 basic quantity verified in this Section is not the final precipitation estimates produced after adjustment
 325 to the manual rain gauge data, but the estimates after quality control and reanalysis, i.e., $GRS_{reanalysis}$.
 326 However, the verification of the final reanalyses $GRS_{reanal.+adj.}$ also provides interesting information,
 327 though one should be careful especially with criteria directly related to the estimated values, such as
 BIAS or RMSE, rather than, for example, their correlation with the reference field.

328 The period from January 2021 to December 2022 was analysed. For each of these 24 months, the
 329 statistics of the monthly precipitation estimates BIAS, RRSE, RMSE, and CC were calculated, taking
 330 the accumulations from the manual rain gauges as reference:

331

332 – statistical bias:

$$333 \quad \text{BIAS} = \frac{1}{n} \sum_{i=1}^n (F_i - O_i) \quad (4)$$

334 – root mean square error:

$$335 \quad \text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (F_i - O_i)^2} \quad (5)$$

336 – root relative square error:

$$337 \quad \text{RRSE} = \frac{\sqrt{\sum_{i=1}^n (F_i - O_i)^2}}{\sqrt{\sum_{i=1}^n (O_i - \bar{O})^2}} \quad (6)$$

338 – Pearson correlation coefficient:

$$339 \quad \text{CC} = \frac{\sum_{i=1}^n (F_i - \bar{F})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^n (O_i - \bar{O})^2 \sum_{i=1}^n (F_i - \bar{F})^2}} \quad (7)$$

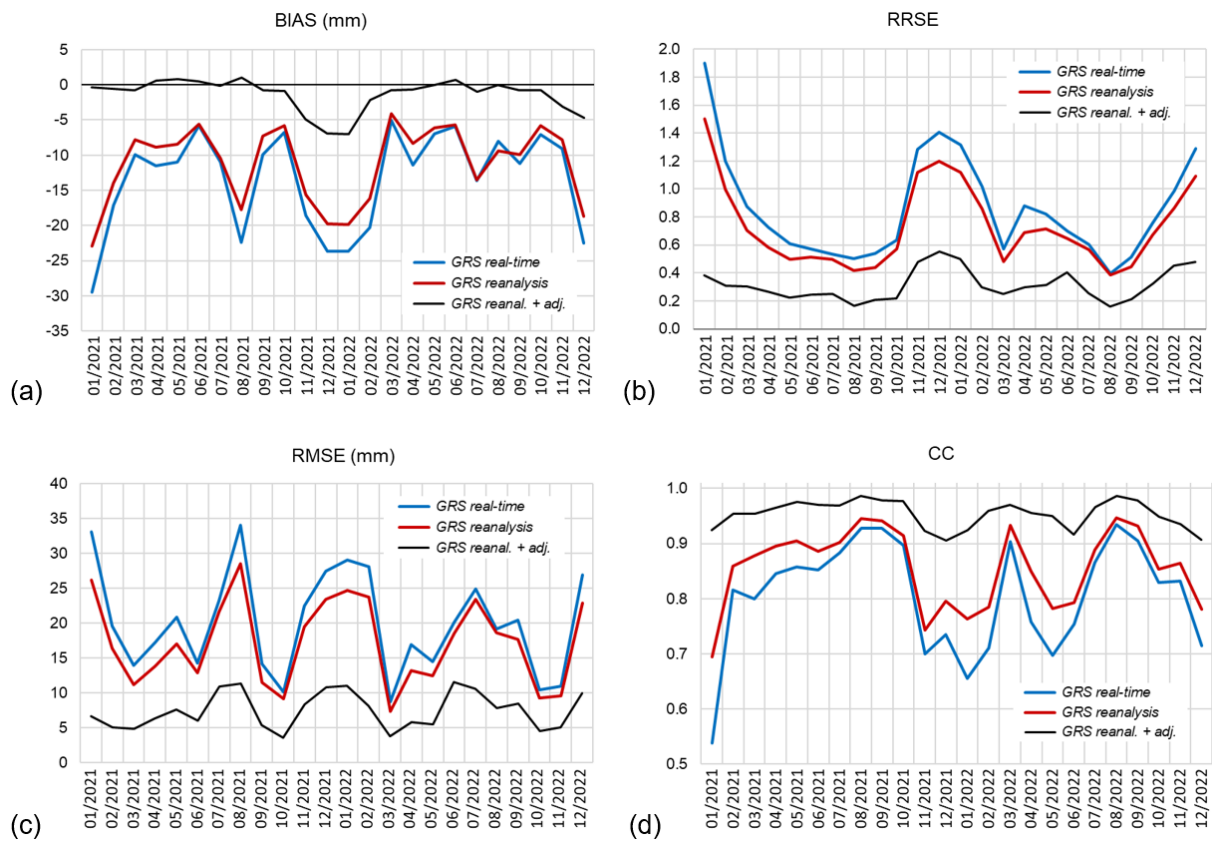

340

341 where F_i is the assessed value, O_i is the reference value (from manual rain gauges), i is the pixel number,
 342 n is the number of pixels, a \bar{F} and \bar{O} are the mean values of F_i and O_i .

343

344 *5.2. Monthly statistics*

345

346
 347
 348 **Figure 5.** Values of monthly characteristics: (a) BIAS, (b) RRSE, (c) RMSE, (d) CC, for precipitation estimates
 349 $GRS_{real-time}$, $GRS_{reanalysis}$, and $GRS_{reanal.+adj.}$ for consecutive months, using point data from manual rain
 350 gauges as reference. Data for 2021 and 2022.

351
 352 Figure 5 shows how the values of the four statistics BIAS, RRSE, RMSE, and CC, change in the
 353 following months, i.e. depending on the seasonal precipitation characteristics.

354 The most evident phenomenon visible in the BIAS graph is large underestimation of monthly
 355 precipitation accumulations, especially in winter months (December – February) that can reach up to 20
 356 mm (Fig. 5a), which in Poland means several dozen percent of monthly accumulations. This is a result
 357 of the fact that the precipitation measurements from both rain gauges and radars are underestimated in
 358 IMGW due to the use of specific types of measuring devices, as mentioned in Sections 2.2 and 2.3.
 359 Additionally, in winter the reason for these errors is the difficulty in radar measurements that occurs
 360 during snowfall from lower clouds than in other seasons and causes most of this precipitation to become
 361 invisible to radar as a result of overshooting the precipitation by the radar beam.

362 Reanalysis and quality control on daily accumulations leads to a reduction of BIAS by a few mm
 363 per month, mainly in the winter months. This is mostly due to the clearly better performance of the
 364 algorithm for the combination of rain gauge and radar data, which copes better with low precipitation
 365 on longer accumulations. After adjustment to observations from manual rain gauges it is possible to deal
 366 with the problem of underestimation of the precipitation field – the BIAS is then practically eliminated,

367 and is visible only to a small extent, mainly in winter. But even then, it is reduced several times, to
368 approximately -7 mm per month (Fig. 5a). In warmer seasons the observed BIAS values are relatively
369 smaller, though August 2021 is a clear outlier. Such large errors in this month, visible not only in BIAS
370 but also in RMSE, are due to the fact that this month was characterised by extremely high precipitation:
371 the monthly total for a large part of southern Poland was over 300 mm, while in this region the multi-
372 year average precipitation in August is about 100 mm. High precipitation accumulations are
373 automatically associated with an increase in the values of statistics of an absolute nature, so that they
374 are not visible in the values of relative statistics such as RRSE and CC.

375 The RRSE annual cycle (Fig. 5b) also shows the largest estimation errors in winter. The error is
376 rather high in winter, at about 1.3 – 1.4 for $GRS_{real-time}$, and the reanalysis improved the reliability of
377 the precipitation estimate, resulting in a decrease of the RRSE to a value of about 1.1 – 1.2. For the other
378 months, the error is lower, at about 0.5 for $GRS_{real-time}$, and the reanalysis improved the reliability of
379 the estimate to a lesser extent, as the RRSE decreased by about 0.1.

380 High values of RMSE (Fig. 5c) are observed in winter, when they reach 27-29 mm for
381 $GRS_{real-time}$, but unlike RRSE, they also occur in the summer months, which is related to the frequent
382 occurrence of intense convective precipitation during this season. They do not induce a similar increase
383 in RRSE values, because this statistic is relative as the result of dividing the RMSE by the standard
384 deviation from the reference value (Eq. 6). Reanalysis reduces RMSE values in winter by about 5 mm
385 per month, slightly less in the other seasons, and adjustment to manual rain gauges reduces them to
386 values of about 5-10 mm per month independently of the season.

387 The correlation coefficient CC (Fig. 5d) is more sensitive to the existence of relationship between
388 evaluated and reference data than the other statistics, which are based on the comparison of estimated
389 and reference values. The CC values also indicate the lowest reliability of the precipitation estimates in
390 winter, when the coefficient equals about 0.65 and improves to about 0.75 after reanalysis. The reason
391 for these low values can also be explained by the low variability of the precipitation accumulations over
392 this period, which results in a low correlation with the manual rain gauge measurements. In other
393 seasons, especially in the summer months, the CC values are much higher, as they reach approximately
394 0.8 – 0.9 for both operational and reanalysed estimates. The adjustment to the manual rain gauges
395 increases the correlations to approximately 0.9 – 0.95.

396 In March 2022, there was a noticeable deviation from the typical annual pattern described above
397 for the CC coefficient. This was due to the exceptionally dry period that occurred at that time in the
398 whole country, particularly in northern Poland. Typically, monthly precipitation accumulation for
399 March is around 30-40 mm in Poland, but in 2022 it was significantly lower, and in the northern part of
400 the country it was often even zero. In this case, the correlation coefficient usually increases, so that in
401 this particular month, the correlation value for $GRS_{real-time}$ was as high as 0.90, rising to 0.93 after
402 reanalysis. Another unexpected value of the CC coefficient was observed in May 2022, when the
403 correlation is around 0.7, which was improved by reanalysis and adjustment, after which the CC

404 increased to around 0.95. The reason for this effect was probably a Legionowo radar replacement at that
 405 time, because this radar covers a large part of the domain where other radars do not reach.

406 In general, the reliability of monthly estimates of precipitation field accumulation is clearly
 407 dependent on the season. Two evident phenomena can be observed here: in winter (November –
 408 February), high values of BIAS, RRSE, and RMSE are noticeable at the same time as low values of CC,
 409 as indicated in the above analysis. In summer (July – August), the situation is different, as convective,
 410 thunderstorm precipitation is often observed during this time, so the intensity of precipitation is higher,
 411 and monthly accumulations are much higher, which is also reflected in the RMSE values, while the
 412 correlation (CC) with the reference data is then significantly higher.

413 Table 2 summarises statistics for two selected months from 2022: January for winter and August
 414 for summer. The table shows the values of quality metrics for the three multi-source precipitation fields:
 415 operationally generated ($GRS_{real-time}$), after reanalysis ($GRS_{reanalysis}$), and after adjustment of this
 416 reanalysed precipitation field ($GRS_{reanal.+adj.}$), with manual rain gauge observations as a reference. All
 417 statistics are worse for winter than for summer, however, reanalysis as well as adjustment worked much
 418 more effectively in winter. Precipitation reanalysis, involving merging individual rainfall fields on daily
 419 (instead of 10-min) accumulations, along with the associated more effective data quality control, results
 420 in a clear improvement in all quality statistics in winter (January 2022), e.g. RMSE by almost 4.5 mm
 421 and CC by 0.1. In summer (August 2022), however, this impact is much smaller, and amounts to less
 422 than 0.6 mm and 0.02, respectively, but BIAS slightly increased. The further improvement, which results
 423 from adjustment to data from manual rain gauges, is much more evident – in winter it is more than 13.5
 424 mm in RMSE and 0.16 in CC, and in summer more than 11.8 mm and 0.04, respectively.

425
 426 Table 2. Values of quality metrics for merged daily precipitation fields: before reanalysis ($GRS_{real-time}$), after
 427 reanalysis ($GRS_{reanalysis}$), and after reanalysis and adjustment ($GRS_{reanal.+adj.}$), using point data from manual
 428 rain gauges as reference. Months: (a) January 2022, (b) August 2022.

429
 430 (a) January 2022

Metric	BIAS (mm)	RMSE (mm)	RRSE (--)	CC (--)
$GRS_{real-time}$	-23.72	29.04	1.32	0.66
$GRS_{reanalysis}$	-19.83	24.63	1.12	0.76
$GRS_{reanal.+adj.}$	-7.06	11.06	0.50	0.92

431
 432 (b) August 2022

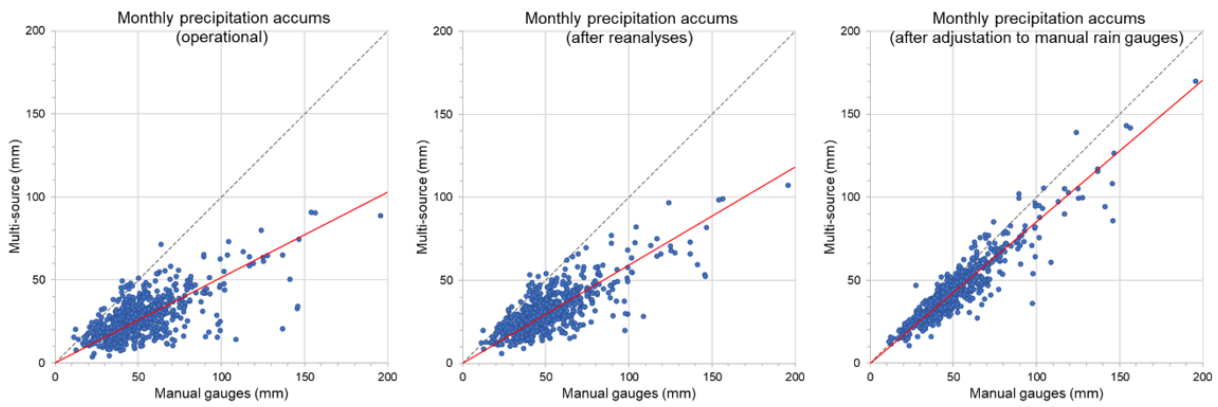

Metric	BIAS (mm)	RMSE (mm)	RRSE (--)	CC (--)
$GRS_{real-time}$	-8.04	19.18	0.40	0.93
$GRS_{reanalysis}$	-9.35	18.60	0.38	0.95

$GRS_{reanal.+adj.}$	-0.03	7.77	0.16	0.99
----------------------	-------	------	------	------

441

Concluding, for all the statistics used here, the improvement in the quality of monthly accumulation of estimated precipitation fields $GRS_{reanalysis}$ i $GRS_{reanal.+adj.}$ relative to operational fields $GRS_{real-time}$ is clearly visible. The differences between the statistics of $GRS_{reanal.+adj.}$ and $GRS_{real-time}$ are much larger. This is mainly due to the fact that, in the absence of any other possibility, the verification was carried out using data from manual rain gauges as a reference, and here they are dependent data, as they are used during the generation of the final $GRS_{reanal.+adj.}$ (see point 7 in the data processing scheme in Section 4.2).

Figure 6. Plots of the dependence of monthly precipitation estimate values, from left: $GRS_{real-time}$, $GRS_{reanalysis}$ and $GRS_{reanal.+adj.}$ on values measured with manual rain gauges, along with trend lines. Months: (a) January 2022, (b) August 2022.

448 Fig. 6 shows graphs of the relationship between the estimated fields of monthly accumulated
449 RainGRS precipitation calculated operationally (generated in real-time), after reanalysis and after
450 adjustment of this reanalysed precipitation field, and monthly accumulations observed by manual rain

451 gauges, for the same two months for which the values of statistics are summarised in Table 2. The graphs
 452 show precipitation values at locations of manual rain gauges. The correlation for the $GRS_{reanalysis}$
 453 estimate compared to $GRS_{real-time}$ improved, although only slightly. This conformity, measured by the
 454 distance between the trend line (red) and the one-to-one line (dashed), clearly improved in winter, but
 455 declined slightly in summer. The conformity with manual rain gauges for the $GRS_{reanal.+adj.}$ estimate
 456 is clearly greater than that for the $GRS_{reanalysis}$, but it should be borne in mind that the data from manual
 457 rain gauges are not fully independent. Nevertheless, this comparison gives some information about the
 458 effectiveness of the final step in generating precipitation field estimates with the RainGRS Clim system.
 459

460 6. Example of a climatological estimate of monthly precipitation accumulation

461

462

463

464 **Figure 7.** Fields of monthly precipitation accumulations: (a) $GRS_{real-time}$, (b) $GRS_{reanalysis}$, and (c)
 465 $GRS_{reanal.+adj.}$. Domain of Poland, April 2021.

466

467 In Fig. 7 we can see an example of estimates of monthly precipitation accumulations for the
 468 domain of Poland, 900 km x 800 km (see Fig. 2). From the left there are estimates: operational, after the
 469 reanalysis, and after reanalysis and adjustment to manual rain gauges data. In general, values of the
 470 estimated precipitation increased after the reanalysis as a result of the more effective performance of the
 471 merging algorithm on longer accumulations. After the adjustment to manual rain gauges, the further,
 472 much higher increase of the precipitation values is because radar-based precipitation estimates are
 473 underestimated in the case of Polish weather radars. Moreover, it should be taken into account that rain
 474 gauges also underestimate rainfall, because they are mostly tipping bucket devices (Segovia-Cardozo et
 475 al., 2021).

476

477 The area of underestimated precipitation in the centre of Poland marked with “1” in Fig. 7 is the
 478 place where the distance to the closest radar site is longest – more than 200 km, where the radar beam
 479 passes over part of the precipitation (overshoots). Moreover, the telemetric rain gauge network is rather
 sparse here. Adjustment to manual rain gauges has made it possible to correct this underestimation.

480

481 The area denoted “2” in Fig. 7 indicates the region where there are no radars, even from
 neighbouring countries. Reanalysis partially improves it by complementing the lack of data with

482 satellite-based precipitation, but not wholly effectively due to the higher uncertainty of the satellite
483 estimates.

484

485 **7. Conclusions**

486

487 The following general conclusions can be drawn about the proposed methodology for the
488 generation of long-term precipitation estimates by the RainGRS Clim system:

489 1. Based on an analysis of available precipitation data, it was assumed that the most reliable
490 precipitation measurement technique is a network of manual rain gauges. In particular, it was
491 assumed that these measurements are unbiased. Since their daily accumulations are available
492 with a long delay due to their transfer and manual quality control, they cannot be used in real
493 time, but they can be used effectively to perform adjustment of reanalyses (see Sections 5.2
494 and 5.3).

495 2. The second major limitation of manual rain gauges is that they only provide point observations.
496 However, the relatively high density of this measurement network in Poland (Fig. 1) makes
497 them very useful in the adjustment of other precipitation field estimates.

498 3. With daily accumulations, which, due to the time step of manual rain gauge measurements,
499 are the basic accumulations in the algorithm for generating climatological precipitation
500 estimates described in Section 4.2, it becomes possible to perform much more effective quality
501 control, particularly in terms of removing various types of artifacts in weather radar data.

502 4. Algorithms for merging rain gauge, weather radar, and satellite data perform much more
503 effectively for daily totals than for 10-min totals. This is mainly due to the fact that longer
504 accumulations of precipitation are more consistent, as in this case time inconsistencies
505 between different measurement techniques play a much smaller role. In addition, with longer
506 accumulations, errors of a random nature are more averaged out (see Section 4.1).

507 5. The results presented in the paper show that after reanalysis, estimates of precipitation field
508 are of higher reliability than operationally generated estimates. Adjustment of the data after
509 reanalysis to data from manual rain gauges resulted in a further, much higher quality
510 improvement (Sections 5.2 and 5.3). However, it should be kept in mind that the final estimates
511 are obtained using data from manual rain gauges, so the results of the verification performed
512 on these data, which in this case are partially dependent, should be treated with caution.

513 6. Having estimates of precipitation accumulated over longer time intervals in RainGRS Clim,
514 such as monthly intervals, creates the possibility of applying them to climatological analyses.
515 They provide valuable information, especially when high spatial resolution of precipitation
516 data is important.

517

518 *Code availability.* The data processing codes are protected through the economic property rights to the software
519 and are not available for distribution. The codes used for processing follow the methodologies and equations
520 described herein.

521

522 *Data availability.* The data used in this paper are available upon request.

523

524 *Author contributions.* AJ, KO, JS, and MP designed algorithms of the RainGRS Clim system. MP, KO, and AK
525 developed the software code and performed the simulations. JS, KO, AJ, AK, and MP prepared the paper. JS made
